- Metabolic syndrome (increased body mass index ± type 2 diabetes/hypertension)
- Autoimmune disease history
- Alcohol history
- Inflammatory bowel disease
- Family history of liver disease, autoimmune disease or the metabolic syndrome

*Symptoms may be absent and abnormal liver function tests detected incidentally.

22.17 Congenital non-haemolytic hyperbilirubinaemia

Syndrome	Inheritance	Abnormality	Clinical features	Treatment
Unconjugated hyperbilirubinaemia				
Gilbert's	Can be autosomal recessive or dominant	↓Glucuronyl transferase ↓Bilirubin uptake	Mild jaundice, especially with fasting	None necessary
Crigler–Najjar:				
Type I	Autosomal recessive	Absent glucuronyl transferase	Rapid death in neonate (kernicterus)	
Type II	Autosomal recessive	↓↓Glucuronyl transferase	Presents in neonate	Phenobarbital, phototherapy or liver transplant
Conjugated hyperbilirubinaemia				
Dubin–Johnson	Autosomal recessive	↓Canalicular excretion of organic anions, including bilirubin Pigmentation of liver biopsy tissue	Mild jaundice	None necessary
Rotor's	Autosomal recessive	↓Bilirubin uptake ↓Intrahepatic binding	Mild jaundice	None necessary

Hepatocellular jaundice can be due to acute or chronic injury (see Fig. 22.11), and clinical features of acute or chronic liver disease may be detected clinically (see Box 22.7).

Characteristically, jaundice due to parenchymal liver disease is associated with increases in transaminases (AST, ALT), but increases in other LFTs, including cholestatic enzymes (GGT, ALP), may occur and suggest specific aetiologies (see below). Acute jaundice in the presence of an ALT of >1000 U/L is highly suggestive of an infectious cause (e.g. hepatitis A or B), drugs (e.g. paracetamol) or hepatic ischaemia. Imaging is essential, in particular to identify features suggestive of cirrhosis, define the patency of the hepatic vasculature and obtain evidence of portal hypertension. Liver biopsy has an important role in defining the aetiology of hepatocellular jaundice and the extent of liver injury.

Obstructive (cholestatic) jaundice

Cholestatic jaundice may be caused by:

- failure of hepatocytes to initiate bile flow
- obstruction of the bile ducts or portal tracts
- obstruction of bile flow in the extrahepatic bile ducts between the porta hepatis and the papilla of Vater.

In the absence of treatment, cholestatic jaundice tends to become progressively more severe because conjugated bilirubin is unable to enter the bile canaliculi and passes back into the blood, and also because there is a failure of clearance of unconjugated bilirubin arriving at the liver cells. The causes of cholestatic jaundice are listed in Box 22.15. Cholestasis may result from defects at more than one of these levels. Those confined to the extrahepatic bile ducts may be amenable to surgical or endoscopic correction.

Clinical features (Box 22.18) comprise those due to cholestasis itself, those due to secondary infection (cholangitis) and those of the underlying condition (Box 22.19). Obstruction of the bile duct drainage due to blockage of the extrahepatic biliary tree is characteristically associated with pale stools and dark urine. Pruritus may be a dominant feature and can be accompanied by skin excoriations. Peripheral stigmata of chronic liver disease are absent. If the gallbladder is palpable, the jaundice is unlikely to be caused by biliary obstruction due to gallstones, probably because a chronically inflamed, stone-containing gallbladder cannot readily dilate. This is Courvoisier's Law, and suggests

i 22.18 Clinical features and complications of cholestatic jaundice

Cholestasis

Early features

- Jaundice
- Dark urine
- Pale stools
- Pruritus

Late features

- Malabsorption (vitamins A, D, E and K): weight loss, steatorrhoea, osteomalacia, bleeding tendency
- Xanthelasma and xanthomas

Cholangitis

- Fever
- Rigors
- Pain (if gallstones present)

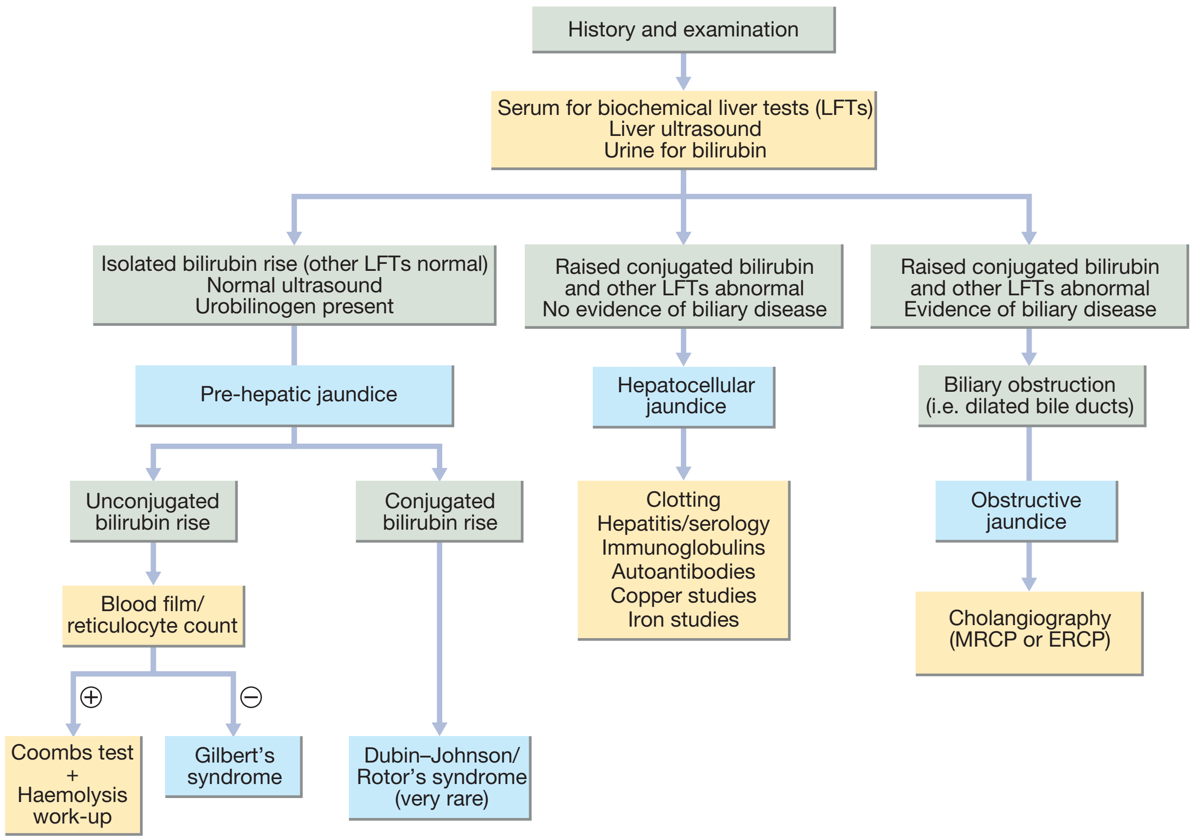

Fig. 22.15 Investigation of jaundice. (ERCP = endoscopic retrograde cholangiopancreatography; LFTs = liver function tests; MRCP = magnetic resonance cholangiopancreatography)

22.19 Clinical features suggesting an underlying cause of cholestatic jaundice*

Clinical feature	Causes
Jaundice	
Static or increasing	Carcinoma Primary biliary cholangitis Primary sclerosing cholangitis
Fluctuating	Choledocholithiasis Stricture Pancreatitis Choledochal cyst Primary sclerosing cholangitis
Abdominal pain	Choledocholithiasis Pancreatitis Choledochal cyst
Cholangitis	Stone Stricture Choledochal cyst
Abdominal scar	Stone Stricture
Irregular hepatomegaly	Hepatic carcinoma
Palpable gallbladder	Carcinoma below cystic duct (usually pancreas)
Abdominal mass	Carcinoma Pancreatitis (cyst) Choledochal cyst
Occult blood in stools	Ampullary tumour

*Each of these diseases can give rise to almost any of the clinical features shown but the box indicates the most likely cause of the clinical features listed.

that jaundice is due to a malignant biliary obstruction (e.g. pancreatic cancer). Cholangitis is characterised by 'Charcot's triad' of jaundice, right upper quadrant pain and fever. Cholestatic jaundice is characterised by a relatively greater elevation of ALP and GGT than the aminotransferases.

Ultrasound is indicated to determine whether there is evidence of mechanical obstruction and dilatation of the biliary tree (Fig. 22.15). EUS provides an additional investigation modality for investigation of lower common bile duct obstruction.

Management of cholestatic jaundice depends on the underlying cause and is discussed in the relevant sections below.

Hepatomegaly

Hepatomegaly may occur as the result of a general enlargement of the liver or because of primary or secondary liver tumour (Box 22.20). The most common liver tumour in Western countries is liver metastasis, whereas primary liver cancer complicating chronic viral hepatitis is more common in the Far East. Unlike carcinoma metastases, those from neuro-endocrine tumours typically cause massive hepatomegaly but without significant weight loss. Cirrhosis can be associated with either hepatomegaly or reduced liver size in advanced disease. Although all causes of cirrhosis can involve hepatomegaly, it is much more common in alcoholic liver disease and haemochromatosis. Hepatomegaly may resolve in patients with alcoholic cirrhosis when they stop drinking.

22.20 Causes of change in liver size

Large liver (hepatomegaly)

- Liver metastases
- Multiple or large hepatic cysts
- Cirrhosis (early): non-alcoholic fatty liver disease, alcohol, haemochromatosis
- Hepatic vein outflow obstruction
- Infiltration: amyloid

Small liver

- Cirrhosis (late)

Ascites

Ascites is present when there is accumulation of free fluid in the peritoneal cavity. Small amounts of ascites are asymptomatic, but with larger accumulations of fluid (>1 L) there is abdominal distension, fullness in the flanks, shifting dullness on percussion and, when the ascites is marked, a fluid thrill/fluid wave. Other features include eversion of the umbilicus, herniae, abdominal striae, divarication of the recti and scrotal oedema. Dilated superficial abdominal veins may be seen if the ascites is due to portal hypertension.

Pathophysiology

Ascites has numerous causes, the most common of which are malignant disease, cirrhosis and heart failure. Many primary disorders of the peritoneum and visceral organs can also cause ascites, and these need to be considered even in a patient with chronic liver disease (Box 22.21). Splanchnic vasodilatation is thought to be the main factor leading to ascites in cirrhosis. This is mediated by vasodilators (mainly nitric oxide) that are released when portal hypertension causes shunting of blood into the systemic circulation. Systemic arterial pressure falls due to pronounced splanchnic vasodilatation as cirrhosis advances. This leads to activation of the renin–angiotensin system with secondary aldosteronism, increased sympathetic nervous activity, increased atrial natriuretic hormone secretion and altered activity

22.21 Causes of ascites

Low SAAG (exudative)	High SAAG (transudative)
Common causes	
Malignant disease: Hepatic Peritoneal	Cardiac failure Hepatic cirrhosis
Other causes	
Acute pancreatitis Lymphatic obstruction Infection: Tuberculosis Nephrotic syndrome	Hypoproteinaemia: Protein-losing enteropathy Malnutrition Hepatic venous occlusion: Budd–Chiari syndrome Sinusoidal obstruction syndrome (Veno-occlusive disease)
Rare causes	
Hypothyroidism	Meigs' syndrome* Constrictive pericarditis

*Meigs' syndrome is the association of a right pleural effusion with or without ascites and a benign ovarian tumour. The ascites resolves on removal of the tumour.
(SAAG = serum ascites albumin gradient; see text)

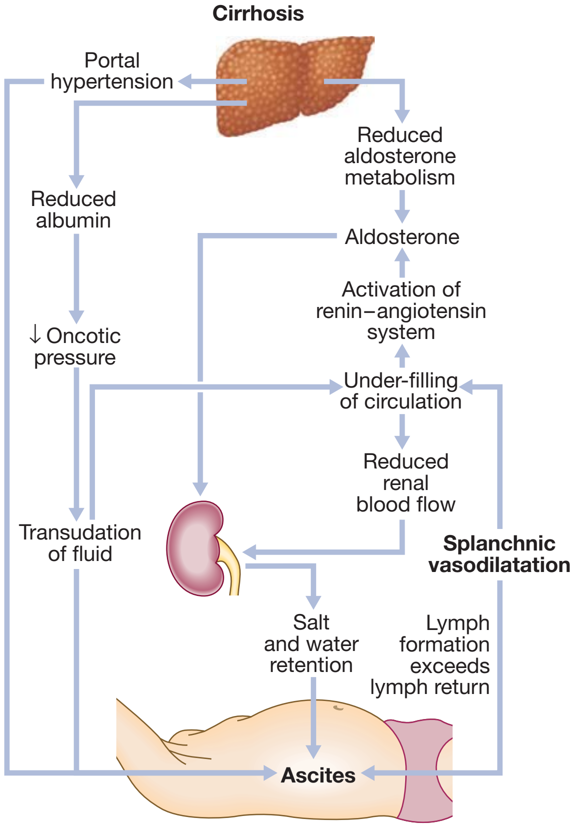

Fig. 22.16 Pathogenesis of ascites.

of the kallikrein–kinin system (Fig. 22.16). These systems tend to normalise arterial pressure but produce salt and water retention. In this setting, the combination of splanchnic arterial vasodilatation and portal hypertension alters intestinal capillary permeability, promoting accumulation of fluid within the peritoneum.

Investigations

Ultrasonography is the best means of detecting ascites, particularly in the obese and those with small volumes of fluid. Paracentesis (if necessary under ultrasonic guidance) can be used to obtain ascitic fluid for analysis. The appearance of ascitic fluid may point to the underlying cause (Box 22.22). Pleural effusions are found in about 10% of patients, usually on the right side (hepatic hydrothorax); most are small and identified only on chest X-ray, but occasionally a massive hydrothorax occurs. Pleural effusions, particularly those on the left side, should not be assumed to be due to the ascites.

Measurement of the protein concentration and the serum–ascites albumin gradient (SAAG) can be a useful tool to distinguish ascites of different aetiologies. Cirrhotic patients typically develop ascites with a low protein concentration ('transudate'; protein concentration <25 g/L (2.5 g/dL)) and relatively few cells. In up to 30% of patients, however, the total protein concentration is >30 g/L (3.0 g/dL). In these cases, it is useful to calculate the SAAG by subtracting the concentration of the ascites fluid albumin from the serum albumin. A gradient of >11 g/L (1.1 g/dL) is 96% predictive that ascites is due to portal hypertension. Venous outflow obstruction due to cardiac failure or hepatic venous outflow obstruction can also cause a transudative ascites, as

22.22 Ascitic fluid: appearance and analysis

Cause/appearance

- Cirrhosis: clear, straw-coloured or light green
- Malignant disease: bloody
- Infection: cloudy
- Biliary communication: heavy bile staining
- Lymphatic obstruction: milky-white (chylous)

Useful investigations

- Total albumin (plus serum albumin) and protein*
- Amylase
- Neutrophil count
- Cytology
- Microscopy and culture

*To calculate the serum–ascites albumin gradient (SAAG).

indicated by an albumin gradient of >11 g/L (1.1 g/dL) but, unlike in cirrhosis, the total protein content is usually >25 g/L (2.5 g/dL).

High protein ascites ('exudate'; protein concentration >25 g/L (2.5 g/dL) or a SAAG of <11 g/L (1.1 g/dL) raises the possibility of infection (especially tuberculosis), malignancy, pancreatic ascites or, rarely, hypothyroidism. Ascites amylase activity of >1000 U/L identifies pancreatic ascites, whereas low ascites glucose concentrations suggest malignant disease or tuberculosis. Cytological examination may reveal malignant cells (one-third of cirrhotic patients with a bloody tap have a hepatocellular carcinoma). Polymorphonuclear leucocyte counts of >250 × 10^6/L strongly suggest infection (spontaneous bacterial peritonitis; see below). Laparoscopy can be valuable in detecting peritoneal disease.

The presence of triglyceride at a level >1.1 g/L (110 mg/dL) is diagnostic of chylous ascites and suggests anatomical or functional abnormality of lymphatic drainage from the abdomen. The ascites in this context has a characteristic milky-white appearance.

Management

Successful treatment relieves discomfort but does not prolong life; if over-vigorous, it can produce serious disorders of fluid and electrolyte balance, and precipitate hepatic encephalopathy (p. 864). Treatment of transudative ascites is based on restricting sodium and water intake, promoting urine output with diuretics and, if necessary, removing ascites directly by paracentesis. Exudative ascites due to malignancy is treated with paracentesis but fluid replacement is generally not required. During management of ascites, the patient should be weighed regularly. Diuretics should be titrated to remove no more than 1 L of fluid daily, so body weight should not fall by more than 1 kg daily to avoid excessive fluid depletion.

Sodium and water restriction

Restriction of dietary sodium intake is essential to achieve negative sodium balance and a few patients can be managed satisfactorily by this alone. Restriction of sodium intake to 100 mmol/24 hrs ('no added salt diet') is usually adequate. Drugs containing relatively large amounts of sodium, and those promoting sodium retention, such as non-steroidal anti-inflammatory drugs (NSAIDs), must be avoided (Box 22.23). Restriction of water intake to 1.0–1.5 L/24 hrs is necessary only if the plasma sodium falls below 125 mmol/L.

22.23 Some drugs containing relatively large amounts of sodium or causing sodium retention

High sodium content	
• Alginates • Antacids • Antibiotics • Phenytoin	• Effervescent preparations (e.g. aspirin, calcium, paracetamol) • Sodium valproate
Sodium retention	
• Carbenoxolone • Glucocorticoids • Metoclopramide	• Non-steroidal anti-inflammatory drugs • Oestrogens

Diuretics

Most patients require diuretics in addition to sodium restriction. Spironolactone (100–400 mg/day) is the first-line drug because it is a powerful aldosterone antagonist; it can, however, cause painful gynaecomastia and hyperkalaemia, in which case amiloride (5–10 mg/day) can be substituted. Some patients also require loop diuretics, such as furosemide, but these can lead to fluid and electrolyte imbalance and renal dysfunction. Diuresis may be improved if patients are rested in bed, perhaps because renal blood flow increases in the horizontal position. Patients who do not respond to doses of 400 mg spironolactone and 160 mg furosemide, or who are unable to tolerate these doses due to hyponatraemia or renal impairment, are considered to have refractory or diuretic-resistant ascites and should be treated by other measures.

Paracentesis

First-line treatment of refractory ascites is large-volume paracentesis. Paracentesis to dryness is safe, provided the circulation is supported with an intravenous colloid such as human albumin (6–8 g per litre of ascites removed, usually as 100 mL of 20% or 25% human albumin solution (HAS) for every 1.5–2 L of ascites drained) or another plasma expander. Paracentesis can be used as an initial therapy or when other treatments fail.

Transjugular intrahepatic portosystemic stent shunt

A transjugular intrahepatic portosystemic stent shunt (TIPSS; p. 870) can relieve resistant ascites but does not prolong life; it may be an option where the only alternative is frequent, large-volume paracentesis. TIPSS can be used in patients awaiting liver transplantation or in those with reasonable liver function, but can aggravate encephalopathy in those with poor function.

Complications

Renal failure

Renal failure can occur in patients with ascites. It can be pre-renal and due to vasodilatation from sepsis and/or diuretic therapy, or due to hepatorenal syndrome.

Hepatorenal syndrome

This occurs in 10% of patients with advanced cirrhosis complicated by ascites. There are two clinical types; both are mediated by renal vasoconstriction due to under-filling of the arterial circulation.

Type 1 hepatorenal syndrome This is characterised by progressive oliguria, a rapid rise of the serum creatinine and a very poor prognosis (without treatment, median survival is less than 1 month). There is usually no proteinuria, a urine sodium excretion of less than 10 mmol/24 hrs and a urine/plasma osmolarity ratio of more than 1.5. Other non-functional causes of renal failure must be excluded before the diagnosis is made. Treatment consists of albumin infusions in combination with terlipressin (or octreotide and midodrine where terlipressin is not approved for use) and is effective in about two-thirds of patients. Haemodialysis should not be used routinely because it does not improve the outcome. Patients who survive should be considered for liver transplantation, which, along with TIPSS, is an effective treatment in appropriate patients.

Type 2 hepatorenal syndrome This usually occurs in patients with refractory ascites, is characterised by a moderate and stable increase in serum creatinine, and has a better prognosis.

Spontaneous bacterial peritonitis

Spontaneous bacterial peritonitis (SBP) may present with abdominal pain, rebound tenderness, absent bowel sounds and fever in a patient with obvious features of cirrhosis and ascites. Abdominal signs are mild or absent in about one-third of patients, and in these individuals hepatic encephalopathy and fever are the main features. Diagnostic paracentesis may show cloudy fluid, and an ascites neutrophil count of $>250\times10^6$/L almost invariably indicates infection. The source of infection cannot usually be determined, but most organisms isolated are of enteric origin and *Escherichia coli* is the most frequently found. Ascitic culture in blood culture bottles gives the highest yield of organisms. SBP needs to be differentiated from other intra-abdominal emergencies, and the finding of multiple organisms on culture should arouse suspicion of a perforated viscus.

Treatment should be started immediately with broad-spectrum antibiotics, such as cefotaxime or piperacillin/tazobactam). Recurrence of SBP is common but may be reduced with prophylactic quinolones, such as norfloxacin or ciprofloxacin. Prophylactic antibiotics reduce the incidence of SBP and improve survival in cirrhotic patients with gastrointestinal bleeding. In patients with a previous episode of SBP and continued ascites, norfloxacin (400 mg/day) prevents recurrence.

Prognosis

Only 10–20% of patients survive for 5 years from the first appearance of ascites due to cirrhosis. The outlook is not universally poor, however, and is best in those with well-maintained liver function and a good response to therapy. The prognosis is also better when a treatable cause for the underlying cirrhosis is present or when a precipitating cause for ascites, such as excess salt intake, is found. The mortality at 1 year is 50% following the first episode of bacterial peritonitis.

Hepatic encephalopathy

Hepatic encephalopathy is a neuropsychiatric syndrome caused by liver disease. As it progresses, delirium is followed by coma. Simple delirium needs to be differentiated from delirium tremens and Wernicke's encephalopathy, and coma from subdural haematoma, which can occur in alcoholics after a fall (Box 22.24). Features include changes of intellect, personality, emotions and consciousness, with or without neurological signs. The degree of encephalopathy can be graded from 1 to 4, depending on these features, and this is useful in assessing response to therapy (see Box 22.9). When an episode develops acutely, a precipitating factor may be found (Box 22.25). The earliest features are very

mild and easily overlooked, but as the condition becomes more severe, apathy, inability to concentrate, delirium, disorientation, drowsiness, slurring of speech and eventually coma develop. Convulsions sometimes occur. Examination usually shows a flapping tremor (asterixis), inability to perform simple mental arithmetic tasks or to draw objects such as a star (constructional apraxia; p. 847), and, as the condition progresses, hyper-reflexia and bilateral extensor plantar responses. Hepatic encephalopathy rarely causes focal neurological signs; if these are present, other causes must be sought. Fetor hepaticus, a sweet musty odour to the breath, is usually present but is more a sign of liver failure and portosystemic shunting than of hepatic encephalopathy. Rarely, chronic hepatic encephalopathy (hepatocerebral degeneration) gives rise to variable combinations of cerebellar dysfunction, Parkinsonian syndromes, spastic paraplegia and dementia.

Pathophysiology

Hepatic encephalopathy is thought to be due to a disturbance of brain function provoked by circulating neurotoxins that are normally metabolised by the liver. Accordingly, most affected patients have evidence of liver failure and portosystemic shunting of blood, but the balance between these varies from individual to individual. Some degree of liver failure is a key factor, as portosystemic shunting of blood alone hardly ever causes encephalopathy. The 'neurotoxins' causing encephalopathy are unknown but are thought to be mainly nitrogenous substances produced in the gut, at least in part by bacterial action. These substances are normally metabolised by the healthy liver and excluded from the systemic circulation. Ammonia has traditionally been considered an important factor. Recent interest has focused on γ-aminobutyric acid (GABA) as a mediator, along with octopamine, amino acids, mercaptans and fatty acids that can act as neurotransmitters. The brain in cirrhosis may also be sensitised to other factors, such as drugs that can precipitate hepatic encephalopathy (Box 22.25). Disruption of the function of the blood–brain barrier is a feature of acute hepatic failure and may lead to cerebral oedema.

22.24 Differential diagnosis of hepatic encephalopathy

- Intracranial bleed (subdural/extradural haematoma, p. 1133)
- Drug or alcohol intoxication (pp. 1194 and 1195)
- Delirium tremens/alcohol withdrawal (p. 1194)
- Wernicke's encephalopathy (p. 1195)
- Primary psychiatric disorders (p. 1191)
- Hypoglycaemia (p. 738)
- Neurological Wilson's disease (p. 1115)
- Post-ictal state

22.25 Factors precipitating hepatic encephalopathy

- Drugs (especially sedatives, antidepressants)
- Dehydration (including diuretics, paracentesis)
- Portosystemic shunting
- Infection
- Hypokalaemia
- Constipation
- ↑Protein load (including gastrointestinal bleeding)

Investigations

The diagnosis can usually be made clinically; when doubt exists, an electroencephalogram shows diffuse slowing of the normal alpha waves with eventual development of delta waves. The arterial ammonia is usually increased in patients with hepatic encephalopathy. Increased concentrations can, however, occur in the absence of clinical encephalopathy, rendering this investigation of little diagnostic value.

Management

The principles are to treat or remove precipitating causes (Box 22.25) and to suppress the production of neurotoxins by bacteria in the bowel. Dietary protein restriction is rarely needed and is no longer recommended as first-line treatment because it is unpalatable and can lead to a worsening nutritional state in already malnourished patients. Lactulose (15–30 mL 3 times daily) is increased gradually until the bowels are moving twice daily. It produces an osmotic laxative effect, reduces the pH of the colonic content, thereby limiting colonic ammonia absorption, and promotes the incorporation of nitrogen into bacteria. Rifaximin (400 mg 3 times daily) is a well-tolerated, non-absorbed antibiotic that acts by reducing the bacterial content of the bowel and has been shown to be effective. It can be used in addition, or as an alternative, to lactulose if diarrhoea becomes troublesome. Chronic or refractory encephalopathy is one of the main indications for liver transplantation.

Variceal bleeding

Acute upper gastrointestinal haemorrhage from gastro-oesophageal varices (Fig. 22.17) is common in chronic liver disease. Investigation

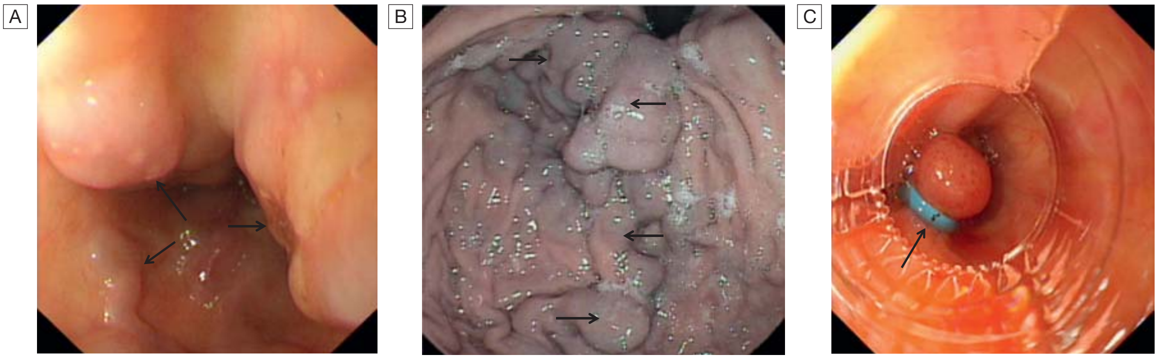

Fig. 22.17 Varices: endoscopic views. A Oesophageal varices (arrows) at the lower end of the oesophagus. B Gastric varices (arrows). C Appearance of oesophageal varices following application of strangulating bands (band ligation, arrow).

and management are discussed on page 780 and the specific management of variceal bleeding on page 869.

Cirrhosis

Cirrhosis is characterised by diffuse hepatic fibrosis and nodule formation. It can occur at any age, has significant morbidity and is an important cause of premature death. It is the most common cause of portal hypertension and its complications. Worldwide, the most common causes are chronic viral hepatitis, prolonged excessive alcohol consumption and NAFLD but any condition leading to persistent or recurrent hepatocyte death may lead to cirrhosis. The causes of cirrhosis are listed in Box 22.26.

Cirrhosis may also occur in prolonged biliary damage or obstruction, as is found in primary biliary cholangitis (PBC), primary sclerosing cholangitis (PSC) and post-surgical biliary strictures. Persistent blockage of venous return from the liver, such as is found in sinusoidal obstruction syndrome (SOS; veno-occlusive disease) and Budd–Chiari syndrome, can also result in cirrhosis.

Pathophysiology

Following liver injury, stellate cells in the space of Disse (see Fig. 22.3, p. 849) are activated by cytokines produced by Kupffer cells and hepatocytes. This transforms the stellate cell into a myofibroblast-like cell, capable of producing collagen, pro-inflammatory cytokines and other mediators that promote hepatocyte damage and tissue fibrosis (see Fig. 22.4, p. 849).

Cirrhosis is a histological diagnosis (Fig. 22.18). It evolves over years as progressive fibrosis and widespread hepatocyte loss lead to distortion of the normal liver architecture that disrupts the hepatic vasculature, causing portosystemic shunts. These changes usually affect the whole liver but in biliary cirrhosis (e.g. PBC) they can be patchy. Cirrhosis can be classified histologically into:

- *Micronodular cirrhosis*, characterised by small nodules about 1 mm in diameter and typically seen in alcoholic cirrhosis.
- *Macronodular cirrhosis*, characterised by larger nodules of various sizes. Areas of previous collapse of the liver architecture are evidenced by large fibrous scars.

Clinical features

The clinical presentation is highly variable. Some patients are asymptomatic and the diagnosis is made incidentally at ultrasound or at surgery. Others present with isolated hepatomegaly, splenomegaly, signs of portal hypertension (p. 868) or hepatic insufficiency. When symptoms are present, they are often non-specific and include weakness, fatigue, muscle cramps, weight loss, anorexia, nausea, vomiting and upper abdominal discomfort (Box 22.27). Cirrhosis will occasionally present because of shortness of breath due to a large right pleural effusion, or with hepatopulmonary syndrome (p. 898).

Hepatomegaly is common when the cirrhosis is due to alcoholic liver disease or haemochromatosis. Progressive hepatocyte destruction and fibrosis gradually reduce liver size as the disease progresses in other causes of cirrhosis. A reduction in liver size is especially common if the cause is viral hepatitis or autoimmune liver disease. The liver is often hard, irregular and non-tender. Jaundice is mild when it first appears and is due primarily to a failure to excrete bilirubin. Palmar erythema

i 22.26 Causes of cirrhosis

- Alcohol
- Chronic viral hepatitis (B or C)
- Non-alcoholic fatty liver disease
- Immune:
  - Primary sclerosing cholangitis
  - Autoimmune liver disease
- Biliary:
  - Primary biliary cholangitis
  - Secondary biliary cirrhosis
  - Cystic fibrosis
- Genetic:
  - Haemochromatosis
  - Wilson's disease
  - α_1-antitrypsin deficiency
- Cryptogenic (unknown – 15%)
- Chronic venous outflow obstruction
- Any chronic liver disease

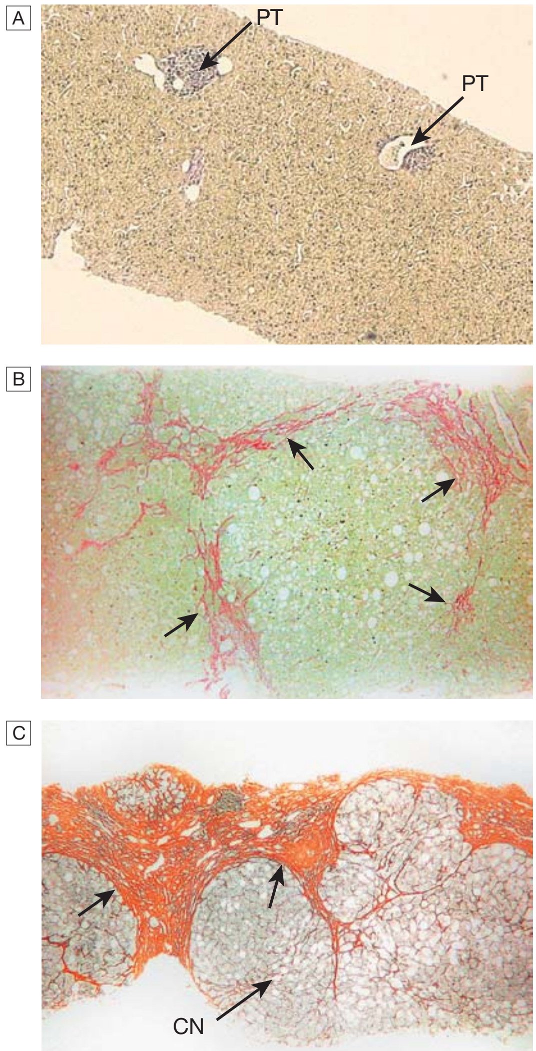

Fig. 22.18 Histological features in normal liver, hepatic fibrosis and cirrhosis. **A** Normal liver. Columns of hepatocytes 1–2 cells thick radiate from the portal tracts (PT) to the central veins. The portal tract contains a normal intralobular bile duct branch of the hepatic artery and portal venous radical. **B** Bridging fibrosis (stained pink, arrows) spreading out around the hepatic vein and single liver cells (pericellular) and linking adjacent portal tracts and hepatic veins. **C** A cirrhotic liver. The liver architecture is disrupted. The normal arrangement of portal tracts and hepatic veins is now lost and nodules of proliferating hepatocytes are broken up by strands of pink-/orange-staining fibrous tissue (arrows) forming cirrhotic nodules (CN).

22.27 Clinical features of hepatic cirrhosis

- Hepatomegaly (although liver may also be small)
- Jaundice
- Ascites
- Circulatory changes: spider telangiectasia, palmar erythema, cyanosis
- Endocrine changes: loss of libido, hair loss
  - Men: gynaecomastia, testicular atrophy, impotence
  - Women: breast atrophy, irregular menses, amenorrhoea
- Haemorrhagic tendency: bruises, purpura, epistaxis
- Portal hypertension: splenomegaly, collateral vessels, variceal bleeding
- Hepatic (portosystemic) encephalopathy
- Other features: pigmentation, digital clubbing, Dupuytren's contracture

22.28 Features of chronic liver failure

- Worsening synthetic liver function:
  - Prolonged prothrombin time
  - Low albumin
- Jaundice
- Portal hypertension
- Variceal bleeding
- Hepatic encephalopathy
- Ascites:
  - Spontaneous bacterial peritonitis
  - Hepatorenal failure

22.29 Child–Pugh classification of prognosis in cirrhosis

Score	1	2	3
Encephalopathy	None	Mild	Marked
Bilirubin (µmol/L (*mg/dL*))*			
Primary biliary cholangitis/sclerosing cholangitis	<68 (*4*)	68–170 (*4–10*)	>170 (*10*)
Other causes of cirrhosis	<34 (*2*)	34–50 (*2–3*)	>50 (*3*)
Albumin (g/L (*g/dL*))	>35 (*3.5*)	28–35 (*2.8–3.5*)	<28 (*2.8*)
Prothrombin time (secs prolonged)	<4	4–6	>6
Ascites	None	Mild	Marked

Add the individual scores:
<7 = Child's A, 7–9 = Child's B, >9 = Child's C

*To convert bilirubin in µmol/L to mg/dL, divide by 17.

can be seen early in the disease but is of limited diagnostic value, as it occurs in many other conditions associated with a hyper-dynamic circulation, including normal pregnancy, as well as being found in some healthy people. Spider telangiectasias occur and comprise a central arteriole (that occasionally raises the skin surface), from which small vessels radiate. They vary in size from 1 to 2 mm in diameter and are usually found only above the nipples. One or two small spider telangiectasias may be present in about 2% of healthy people and may occur transiently in greater numbers in the third trimester of pregnancy, but otherwise they are a strong indicator of liver disease. Florid spider telangiectasia, gynaecomastia and parotid enlargement are most common in alcoholic cirrhosis. Pigmentation is most striking in haemochromatosis and in any cirrhosis associated with prolonged cholestasis. Pulmonary arteriovenous shunts also develop, leading to hypoxaemia and eventually to central cyanosis, but this is a late feature.

Endocrine changes are noticed more readily in men, who show loss of male hair distribution and testicular atrophy. Gynaecomastia is common and can be due to drugs such as spironolactone. Easy bruising becomes more frequent as cirrhosis advances.

Splenomegaly and collateral vessel formation are features of portal hypertension, which occurs in more advanced disease (see below). Ascites also signifies advanced disease. Evidence of hepatic encephalopathy also becomes common with disease progression. Non-specific features of chronic liver disease include clubbing of the fingers and toes. Dupuytren's contracture is traditionally regarded as a complication of cirrhosis but the evidence for this is weak. Chronic liver failure develops when the metabolic capacity of the liver is exceeded. It is characterised by the presence of encephalopathy and/or ascites. The term 'hepatic decompensation' or 'decompensated liver disease' is often used when chronic liver failure occurs.

Other clinical and laboratory features may be present (Box 22.28); these include peripheral oedema, renal failure, jaundice, and hypoalbuminaemia and coagulation abnormalities due to defective protein synthesis.

Management

This includes treatment of the underlying cause, maintenance of nutrition and treatment of complications, including ascites, hepatic encephalopathy, portal hypertension and varices. Once the diagnosis of cirrhosis is made, endoscopy should be performed to screen for oesophageal varices (p. 869) and repeated every 2 years. As cirrhosis is associated with an increased risk of hepatocellular carcinoma, patients should be placed under regular surveillance for it (p. 890).

Chronic liver failure due to cirrhosis can also be treated by liver transplantation. This currently accounts for about three-quarters of all liver transplants (p. 900).

Prognosis

The overall prognosis is poor. Many patients present with advanced disease and/or serious complications that carry a high mortality. Overall, only 25% of patients survive 5 years from diagnosis, but where liver function is good, 50% survive for 5 years and 25% for up to 10 years. The prognosis is more favourable when the underlying cause can be corrected, as in alcohol misuse, haemochromatosis or Wilson's disease.

Laboratory tests give only a rough guide to prognosis in individual patients. Deteriorating liver function, as evidenced by jaundice, ascites or encephalopathy, indicates a poor prognosis unless a treatable cause such as infection is found. Increasing bilirubin, falling albumin (or an albumin concentration of <30 g/L (3.0 g/dL)), marked hyponatraemia (<120 mmol/L) not due to diuretic therapy, and a prolonged PT are all bad prognostic features (Box 22.29 and Fig. 22.19). The Child–Pugh and MELD (Model for End-stage Liver Disease) scores can be used to assess prognosis. The MELD is more difficult to calculate at the bedside but, unlike the Child–Pugh score, includes renal function; if this is impaired, it is known to be a poor prognostic feature in end-stage disease (Box 22.30). Although these scores give a guide to prognosis, the course of cirrhosis can be unpredictable, as complications such as variceal bleeding may occur.

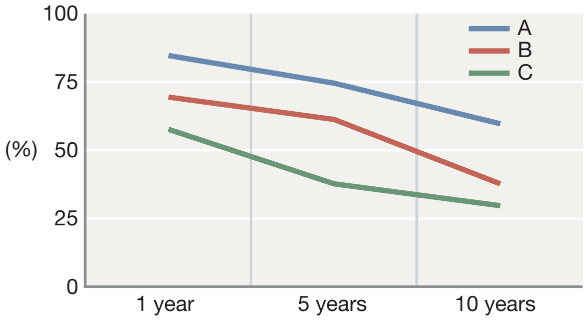

Fig. 22.19 Survival in cirrhosis by Child–Pugh score.

22.30 One-year survival rate depending on MELD score

MELD score	1-year survival (%) No complications	Complications*
<9	97	90
10–19	90	85
20–29	70	65
30–39	70	50

MELD from SI units

10×(0.378 [ln serum bilirubin (µmol/L) + 1.12 [ln INR] + 0.957 [ln serum creatinine (µmol/L)] + 0.643)

MELD from non-SI units

3.8 [ln serum bilirubin (mg/dL)] + 11.2 [ln INR] + 9.3 [ln serum creatinine (mg/dL)] + 6.4

ln = natural log. To calculate online, go to https://optn.transplant.hrsa.gov/resources/allocation-calculators/meld-calculator/

*'Complications' means the presence of ascites, encephalopathy or variceal bleeding.
(INR = International Normalised Ratio; MELD = Model for End-stage Liver Disease)

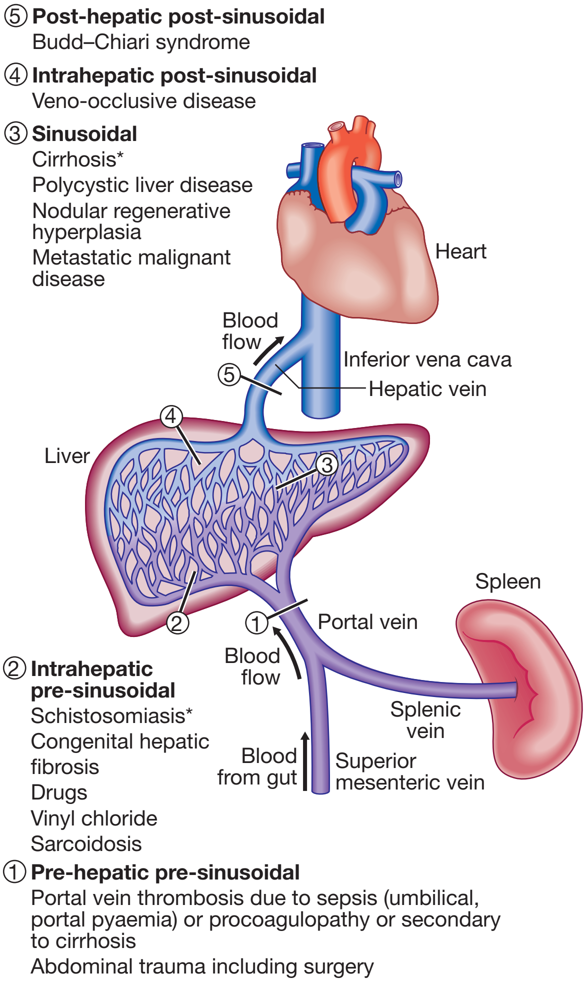

Fig. 22.20 Classification of portal hypertension according to site of vascular obstruction. *Most common cause. Note that splenic vein occlusion can also follow pancreatitis, leading to gastric varices.

Portal hypertension

Portal hypertension frequently complicates cirrhosis but has other causes. The normal hepatic venous pressure gradient (difference between the wedged hepatic venous pressure (WHVP) and free hepatic venous pressure; see below) is 5–6 mmHg. Clinically significant portal hypertension is present when the gradient exceeds 10 mmHg and risk of variceal bleeding increases beyond a gradient of 12 mmHg. Increased vascular resistance is common. Causes are classified in accordance with the main sites of obstruction to blood flow in the portal venous system (Fig. 22.20). Extrahepatic portal vein obstruction is the usual source of portal hypertension in childhood and adolescence, while cirrhosis causes at least 90% of cases of portal hypertension in adults in developed countries. Schistosomiasis is the most common cause of portal hypertension worldwide but is infrequent outside endemic areas, such as Egypt (p. 294).

Clinical features

The clinical features result principally from portal venous congestion and collateral vessel formation (Box 22.31). Splenomegaly is a cardinal finding and a diagnosis of portal hypertension is unusual when splenomegaly cannot be detected clinically or by ultrasonography. The spleen is rarely enlarged more than 5 cm below the left costal margin in adults but more marked splenomegaly can occur in childhood and adolescence. Collateral vessels may be visible on the anterior abdominal wall and occasionally several radiate from the umbilicus to form a 'caput medusae' (p. 846). Rarely, a large umbilical collateral vessel has a blood flow sufficient to give a venous hum on auscultation (Cruveilhier–Baumgarten syndrome). The most important collateral vessel formation occurs in the oesophagus and stomach, and this can be a source of severe bleeding. Rectal varices also cause bleeding and are often mistaken for haemorrhoids (which are no more common in portal hypertension than in the general population). Fetor hepaticus results from portosystemic shunting of blood, which allows mercaptans to pass directly to the lungs.

22.31 Complications of portal hypertension

- Variceal bleeding: oesophageal, gastric, other (rare)
- Congestive gastropathy
- Hypersplenism
- Ascites
- Iron deficiency anaemia
- Renal failure
- Hepatic encephalopathy

Ascites occurs as a result of renal sodium retention and portal hypertension that may be due, for example, to post-hepatic causes (hepatic outflow obstruction, p. 862) or cirrhosis.

The most important consequence of portal hypertension is variceal bleeding, which commonly arises from oesophageal varices located within 3–5 cm of the gastro-oesophageal junction, or from gastric varices. The size of the varices, endoscopic variceal features such as red spots and stripes, high portal pressure and liver failure are all general factors that predispose to bleeding. Drugs capable of causing mucosal erosion, such as salicylates and NSAIDs, can also precipitate bleeding. Variceal bleeding is often severe, and recurrent if preventative treatment is not given.

Pathophysiology

Increased portal vascular resistance leads to a gradual reduction in the flow of portal blood to the liver and simultaneously to the development of collateral vessels, allowing portal blood to bypass the liver and enter the systemic circulation directly. Portosystemic shunting occurs, particularly in the gastrointestinal tract and especially the distal oesophagus, stomach and rectum, in the anterior abdominal wall, and in the renal, lumbar, ovarian and testicular vasculature. Stomal varices can also occur at the site of an ileostomy. As collateral vessel formation progresses, more than half of the portal blood flow may be shunted directly to the systemic circulation. Increased portal flow contributes to portal hypertension but is not the dominant factor.

Investigations

The diagnosis is often made clinically. Portal venous pressure measurements are rarely needed for clinical assessment or routine management but can be used to confirm portal hypertension and to differentiate sinusoidal and pre-sinusoidal forms. Pressure measurements are made by using a balloon catheter inserted using the transjugular route (via the inferior vena cava into a hepatic vein and then hepatic venule) to measure the WHVP. This is an indirect measurement of portal vein pressure. Thrombocytopenia is common due to hypersplenism, and platelet counts are usually in the region of 100×10^9/L; values below 50×10^9/L are uncommon. Leucopenia occurs occasionally but anaemia is seldom attributed directly to hypersplenism; if anaemia is found, a source of bleeding should be sought.

Endoscopy is the most useful investigation to determine whether gastro-oesophageal varices are present (see Fig. 22.17). Once the diagnosis of cirrhosis is made, endoscopy should be performed to screen for oesophageal varices (and repeated every 2 years). Ultrasonography often shows features of portal hypertension, such as splenomegaly and collateral vessels, and can sometimes indicate the cause, such as liver disease or portal vein thrombosis. CT and magnetic resonance angiography can identify the extent of portal vein clot and are used to identify hepatic vein patency.

Management

Acute upper gastrointestinal haemorrhage from gastro-oesophageal varices is a common manifestation of chronic liver disease. In the presence of portal hypertension, the risk of a variceal bleed occurring within 2 years varies from 7% for small varices up to 30% for large varices. The mortality following a variceal bleed has improved to around 15% overall but is still about 45% in those with poor liver function (i.e. Child–Pugh C).

The management of portal hypertension is largely focused on the prevention and/or control of variceal haemorrhage. It is important to remember, though, that bleeding can also result from peptic ulceration, which is more common in patients with liver disease than in the general population. The investigation and management of gastrointestinal bleeding are dealt with in more detail on page 780.

Primary prevention of variceal bleeding

If non-bleeding varices are identified at endoscopy, β-adrenoceptor antagonist (β-blocker) therapy with propranolol (80–160 mg/day) or nadolol (40–240 mg/day) is effective in reducing portal venous pressure. Administration of these drugs at doses that reduce the heart rate by 25% has been shown to be effective in the primary prevention of variceal bleeding. In patients with cirrhosis, treatment with propranolol reduces variceal bleeding by 47% (number needed to treat for benefit (NNT_B) 10), death from bleeding by 45% (NNT_B 25) and overall mortality by 22% (NNT_B 16). The efficacy of β-blockers in primary prevention is similar to that of prophylactic banding, which may also be considered, particularly in patients who are unable to tolerate or adhere to β-blocker therapy. Carvedilol, a non-cardioselective vasodilating β-blocker, is also effective and may be better tolerated at doses of 6.25–12.5 mg/day). For these, dose should be titrated, as tolerated, to achieve a heart rate of 50–55 beats/min, if possible.

Management of acute variceal bleeding

The priority in acute bleeding is to restore the circulation with blood and plasma, not least because shock reduces liver blood flow and causes further deterioration of liver function. The source of bleeding should always be confirmed by endoscopy because about 20% of patients are bleeding from non-variceal lesions. Management of acute variceal bleeding is described in Box 22.32 and illustrated in Figure 22.21. All patients with cirrhosis and gastrointestinal bleeding should receive prophylactic broad-spectrum antibiotics, such as oral ciprofloxacin or intravenous cephalosporin or piperacillin/tazobactam, because sepsis is common and treatment with antibiotics improves outcomes. The measures used to control acute variceal bleeding include vasoactive medications (e.g. terlipressin), endoscopic therapy (banding or sclerotherapy), balloon tamponade, TIPSS and, rarely, oesophageal transection.

22.32 Emergency management of bleeding

Management	Reason
Intravenous fluids	To replace extracellular volume
Vasopressor (terlipressin)*	To reduce portal pressure, acute bleeding and risk of early rebleeding
Prophylactic antibiotics (cephalosporin IV)	To reduce incidence of spontaneous bacterial peritonitis
Emergency endoscopy	To confirm variceal rather than ulcer bleed
Variceal band ligation	To stop bleeding
Proton pump inhibitor	To prevent peptic ulcers
Phosphate enema and/or lactulose	To prevent hepatic encephalopathy

*Caution in patients with significant coronary artery, peripheral or other vascular disease.

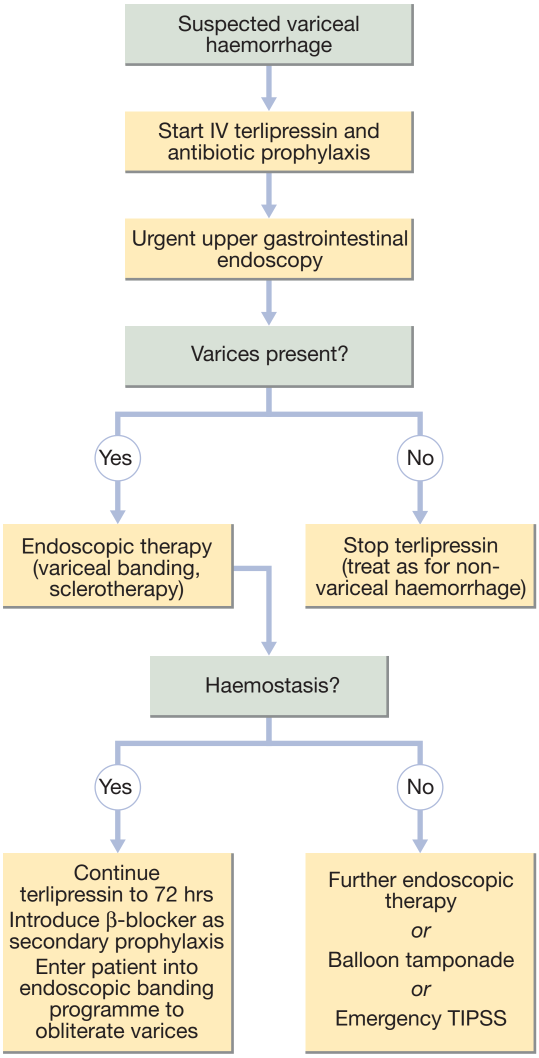

Fig. 22.21 Management of acute bleeding from oesophageal varices. (TIPSS = transjugular intrahepatic portosystemic stent shunt)

Pharmacological reduction of portal venous pressure Terlipressin is a synthetic vasopressin analogue that, in contrast to vasopressin, can be given by intermittent injection rather than continuous infusion. It reduces portal blood flow and/or intrahepatic resistance and hence brings down portal pressure. It lowers mortality in the setting of acute variceal bleeding. The dose of terlipressin is 2 mg IV 4 times daily until bleeding stops, and then 1 mg 4 times daily for up to 72 hours. Caution is needed in patients with severe ischaemic heart disease or peripheral vascular disease because of the drug's vasoconstrictor properties. In countries where terlipressin is not available, octreotide is a frequently used alternative.

Variceal ligation ('banding') and sclerotherapy This is the most widely used initial treatment and is undertaken, if possible, at the time of diagnostic endoscopy (see Fig. 22.17C). It stops variceal bleeding in 80% of patients and can be repeated if bleeding recurs. Band ligation involves the varices being sucked into a cap placed on the end of the endoscope, allowing them to be occluded with a tight rubber band. The occluded varix subsequently sloughs with variceal obliteration. Banding is repeated every 2–4 weeks until all varices are obliterated.

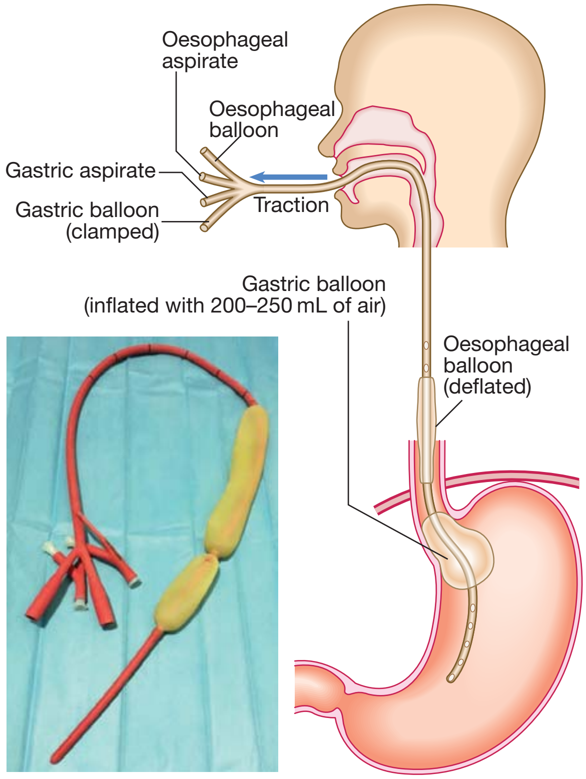

Fig. 22.22 Sengstaken–Blakemore tube.

Regular follow-up endoscopy is required to identify and treat any recurrence of varices. Band ligation has fewer side-effects than sclerotherapy, a technique in which varices are injected with a sclerosing agent, and has largely replaced it. Banding is best suited to the treatment of oesophageal varices. It is associated with a lower risk of oesophageal perforation or stricturing than sclerotherapy. Prophylactic acid suppression with proton pump inhibitors reduces the risk of secondary bleeding from banding-induced ulceration.

In the case of gastric fundal varices, banding is less effective and so endoscopic therapy relies on injection of agents such as thrombin or cyanoacrylate glue directly into the varix to induce thrombosis. Although highly effective, cyanoacrylate injection treatment may be complicated by 'glue embolism' to the lungs.

Active bleeding may make endoscopic therapy difficult. Protection of the patient's airway with endotracheal intubation aids the endoscopist, facilitating therapy and significantly reducing the risk of pulmonary aspiration.

Balloon tamponade This technique employs a Sengstaken–Blakemore tube, which consists of two balloons that exert pressure in the fundus of the stomach and in the lower oesophagus, respectively (Fig. 22.22). Additional lumens allow contents to be aspirated from the stomach and from the oesophagus above the oesophageal balloon. This technique may be used in the event of life-threatening haemorrhage if early endoscopic therapy is not available or is unsuccessful.

Endotracheal intubation prior to tube insertion reduces the risk of pulmonary aspiration. The tube should be passed through the mouth and its presence in the stomach should be checked by auscultating the upper abdomen while injecting air and by confirming with radiology. The safest technique is

to inflate the balloon in the stomach under direct endoscopic vision. Gentle traction is essential to maintain pressure on the varices. Initially, only the gastric balloon should be inflated, with 200–250 mL of air, as this will usually control bleeding. Inflation of the gastric balloon must be stopped if the patient experiences pain because inadvertent inflation in the oesophagus can cause oesophageal rupture. If the oesophageal balloon needs to be used because of continued bleeding, it should be deflated for about 10 minutes every 3 hours to avoid oesophageal mucosal damage. Pressure in the oesophageal balloon should be monitored with a sphygmomanometer and should not exceed 40 mmHg. Balloon tamponade will almost always stop oesophageal and gastric fundal variceal bleeding but is only a bridge to more definitive therapy. Self-expanding removable oesophageal stents are a new alternative in patients with bleeding oesophageal, but not gastric, varices.

TIPSS This technique uses a stent placed between the portal vein and the hepatic vein within the liver to provide a portosystemic shunt and therefore reduce portal pressure (Fig. 22.23). It is carried out under radiological control via the internal jugular vein; prior patency of the portal vein must be determined angiographically, coagulation deficiencies may require correction with fresh frozen plasma, and antibiotic cover is provided. Successful shunt placement stops and prevents further variceal bleeding, and is an effective treatment for both oesophageal and gastric varices. Further bleeding necessitates investigation and treatment (e.g. angioplasty) because it is usually associated with shunt narrowing or occlusion. Hepatic encephalopathy may occur following TIPSS and is managed by reducing the shunt diameter. Although TIPSS is associated with less rebleeding than endoscopic therapy, survival is not improved.

Portosystemic shunt surgery Surgery prevents recurrent bleeding but carries a high mortality and often leads to encephalopathy. In practice, portosystemic shunts are now reserved for when other treatments have not been successful and are offered only to patients with good liver function.

Oesophageal transection Rarely, surgical transection of the varices may be performed as a last resort when bleeding cannot be controlled by other means but operative mortality is high.

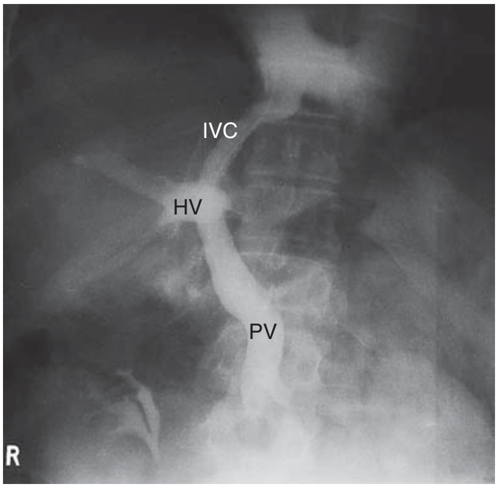

Fig. 22.23 Transjugular intrahepatic portosystemic stent shunt (TIPSS). X-ray showing placement of a TIPSS within the portal vein (PV), allowing blood to flow from the portal vein into the hepatic vein (HV) and then the inferior vena cava (IVC).

Secondary prevention of variceal bleeding

Beta-blockers are used as a secondary measure to prevent recurrent variceal bleeding. Following successful endoscopic therapy, patients should be entered into an oesophageal banding programme with repeated sessions of therapy at 12–24-week intervals until the varices are obliterated. In selected individuals, TIPSS may also be considered in this setting.

Congestive 'portal hypertensive' gastropathy

Long-standing portal hypertension causes chronic gastric congestion, which is recognisable at endoscopy as multiple areas of punctate erythema ('portal hypertensive gastropathy' or 'snakeskin gastropathy'). Rarely, similar lesions occur more distally in the gastrointestinal tract. These areas may become eroded, causing bleeding from multiple sites. Acute bleeding can occur but repeated minor bleeding causing iron deficiency anaemia is more common. Anaemia may be prevented by oral iron supplements but repeated blood transfusions can become necessary. Reduction of the portal pressure using propranolol (80–160 mg/day) is the best initial treatment. If this is ineffective, a TIPSS procedure can be undertaken.

Infections and the liver

The liver may be subject to a number of different infections. These include hepatotropic viral infections and bacterial and protozoal infections. Each has specific clinical features and requires targeted therapies.

Viral hepatitis

This must be considered in anyone presenting with hepatitic liver blood tests (high transaminases). The causes are listed in Box 22.33.

All these viruses cause illnesses that have similar clinical and pathological features and are frequently anicteric or even asymptomatic. They differ in their tendency to cause acute and chronic infections. The features of the major hepatitis viruses are shown in Box 22.34. Therapeutic developments for viral hepatitis, in particular hepatitis C, are evolving very rapidly, with several new classes of drugs entering clinical practice.

22

Clinical features of acute infection

A non-specific prodromal illness characterised by headache, myalgia, arthralgia, nausea and anorexia usually precedes the development of jaundice by a few days to 2 weeks. Vomiting and diarrhoea may follow and abdominal discomfort is common.

i 22.33 Causes of viral hepatitis

Common	
• Hepatitis A	• Hepatitis C
• Hepatitis B ± hepatitis D	• Hepatitis E
Less common	
• Cytomegalovirus	• Epstein–Barr virus
Rare	
• Herpes simplex	• Yellow fever

22.34 Features of the main hepatitis viruses

	Hepatitis A	Hepatitis B	Hepatitis C	Hepatitis D	Hepatitis E
Virus					
Group	Enterovirus	Hepadnavirus	Flavivirus	Incomplete virus	Calicivirus
Nucleic acid	RNA	DNA	RNA	RNA	RNA
Size (diameter)	27 nm	42 nm	30–38 nm	35 nm	27 nm
Incubation (weeks)	2–4	4–20	2–26	6–9	3–8
Spread*					
Faeces	Yes	No	No	No	Yes
Blood	Uncommon	Yes	Yes	Yes	No
Saliva	Yes	Yes	Yes	Unknown	Unknown
Sexual	Uncommon	Yes	Uncommon	Yes	Unknown
Vertical	No	Yes	Uncommon	Yes	No
Chronic infection	No	Yes	Yes	Yes	No (except immune-compromised)
Prevention					
Active	Vaccine	Vaccine	No	Prevented by hepatitis B vaccination	No
Passive	Immune serum globulin	Hyperimmune serum globulin	No		No

*All body fluids are potentially infectious, although some (e.g. urine) are less infectious than others.

22.35 Complications of acute viral hepatitis

- Acute liver failure
- Cholestatic hepatitis (hepatitis A)
- Aplastic anaemia
- Chronic liver disease and cirrhosis (hepatitis B and C)
- Relapsing hepatitis

Dark urine and pale stools may precede jaundice. There are usually few physical signs. The liver is often tender but only minimally enlarged. Occasionally, mild splenomegaly and cervical lymphadenopathy are seen. These features are more frequent in children or those with Epstein–Barr virus (EBV) infection. Symptoms rarely last longer than 3–6 weeks. Complications may occur but are rare (Box 22.35).

Investigations

A hepatitic pattern of LFTs develops, with serum transaminases typically between 200 and 2000 U/L in an acute infection (usually lower and fluctuating in chronic infections). The plasma bilirubin reflects the degree of liver damage. The ALP rarely exceeds twice the upper limit of normal. Prolongation of the PT indicates the severity of the hepatitis but rarely exceeds 25 seconds, except in rare cases of acute liver failure. The white cell count is usually normal with a relative lymphocytosis. Serological tests confirm the aetiology of the infection.

Management

Most individuals do not need hospital care. Drugs such as sedatives and narcotics, which are metabolised in the liver, should be avoided. No specific dietary modifications are required. Alcohol should not be taken during the acute illness. Elective surgery should be avoided in cases of acute viral hepatitis, as there is a risk of post-operative liver failure.

Liver transplantation is very rarely indicated for acute viral hepatitis complicated by liver failure, but is commonly performed for complications of cirrhosis resulting from chronic hepatitis B and C infection.

Hepatitis A

The hepatitis A virus (HAV) belongs to the picornavirus group of enteroviruses. HAV is highly infectious and is spread by the faecal–oral route. Infected individuals, who may be asymptomatic, excrete the virus in faeces for about 2–3 weeks before the onset of symptoms and then for a further 2 weeks or so. Infection is common in children but often asymptomatic, and so up to 30% of adults will have serological evidence of past infection but give no history of jaundice. Infection is also more common in areas of overcrowding and poor sanitation. In occasional outbreaks, water and shellfish have been the vehicles of transmission. In contrast to hepatitis B, a chronic carrier state does not occur.

Investigations

Only one HAV antigen has been found and infected people make an antibody to this antigen (anti-HAV). Anti-HAV is important in diagnosis, as HAV is present in the blood only transiently during the incubation period. Excretion in the stools occurs for only 7–14 days after the onset of the clinical illness and the virus cannot be grown readily. Anti-HAV of the IgM type, indicating a primary immune response, is already present in the blood at the onset of the clinical illness and is diagnostic of an acute HAV infection. Titres of this antibody fall to low levels within about 3 months of recovery. Anti-HAV of the IgG type is of no diagnostic value, as HAV infection is common and this antibody persists for years after infection, but it can be used as a marker of previous HAV infection. Its presence indicates immunity to HAV.

Management

Infection in the community is best prevented by improving social conditions, especially overcrowding and poor sanitation. Individuals can be given substantial protection from infection by active immunisation with an inactivated virus vaccine.

Immunisation should be considered for individuals with chronic hepatitis B or C infections. Immediate protection can be provided by immune serum globulin if this is given soon after exposure to the virus. The protective effect of immune serum globulin is attributed to its anti-HAV content. Immunisation should be

considered for those at particular risk, such as close contacts of HAV-infected patients, the elderly, those with other major disease and perhaps pregnant women.

Immune serum globulin can be effective in an outbreak of hepatitis, in a school or nursery, as injection of those at risk prevents secondary spread to families. People travelling to endemic areas are best protected by vaccination.

Acute liver failure is rare in hepatitis A (0.1%) and chronic infection does not occur. Infection in patients with chronic liver disease, however, may cause serious or life-threatening disease. In adults, a cholestatic phase with elevated ALP levels may complicate infection. There is no role for antiviral drugs in the therapy of HAV infection.

Hepatitis B

The hepatitis B virus consists of a core containing DNA and a DNA polymerase enzyme needed for virus replication. The core of the virus is surrounded by surface protein (Fig. 22.24). The virus, also called a Dane particle, and an excess of its surface protein (known as hepatitis B surface antigen, HBsAg) circulate in the blood. Humans are the only source of infection.

Hepatitis B is one of the most common causes of chronic liver disease and hepatocellular carcinoma worldwide. Approximately one-third of the world's population have serological evidence of past or current infection with hepatitis B and approximately 350–400 million people are chronic HBsAg carriers.

Hepatitis B may cause an acute viral hepatitis; however, acute infection is often asymptomatic, particularly when acquired at birth. Many individuals with chronic hepatitis B are also asymptomatic.

The risk of progression to chronic liver disease depends on the source and timing of infection (Box 22.36). Vertical transmission from mother to child in the perinatal period is the most common cause of infection worldwide and carries the highest risk of ongoing chronic infection. In this setting, adaptive immune responses to HBV may be absent initially, with apparent immunological tolerance. Several mechanisms contribute towards this:

- Firstly, the introduction of antigen in the neonatal period is tolerogenic.
- Secondly, the presentation of such antigen within the liver, as described above, promotes tolerance; this is particularly evident in the absence of a significant innate or inflammatory response.
- Finally, very high loads of antigen may lead to so-called 'exhaustion' of cellular immune responses. The state of tolerance is not permanent, however, and may be reversed as a result of therapy, or through spontaneous changes in innate responses, such as interferon alpha (IFN-α) and NK cells, accompanied by host-mediated immunopathology.

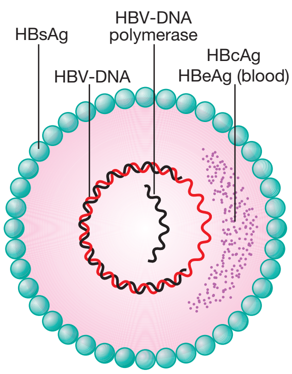

Fig. 22.24 Schematic diagram of the hepatitis B virus. Hepatitis B surface antigen (HBsAg) is a protein that makes up part of the viral envelope. Hepatitis B core antigen (HBcAg) is a protein that makes up the capsid or core part of the virus (found in the liver but not in blood). Hepatitis B e antigen (HBeAg) is part of the HBcAg that can be found in the blood and indicates infectivity.

Chronic hepatitis can lead to cirrhosis or hepatocellular carcinoma, usually after decades of infection (Fig. 22.25). Chronic HBV infection is a dynamic process that can be divided into five phases (Box 22.37); these are not necessarily sequential, however, and not all patients will go through all phases. It is important to remember that the virus is not directly cytotoxic to cells; rather, it is an immune response to viral antigens displayed on infected hepatocytes that initiates liver injury. This explains why there may be very high levels of viral replication but little hepatocellular damage during the 'immune-tolerant' phase.

Investigations

Serology

HBV contains several antigens to which infected persons can make immune responses (Fig. 22.26); these antigens and their antibodies are important in identifying HBV infection (Boxes 22.37 and 22.38), although the widespread availability of polymerase chain reaction (PCR) techniques to measure viral DNA levels in peripheral blood means that longitudinal monitoring is now also frequently guided by direct assessment of viral load.

Hepatitis B surface antigen Hepatitis B surface antigen (HBsAg) is an indicator of active infection, and a negative test for HBsAg makes HBV infection very unlikely. In acute liver failure from hepatitis B, the liver damage is mediated by viral clearance and so HBsAg is negative, with evidence of recent infection provided by the presence of hepatitis B core IgM. HBsAg appears in the blood late in the incubation period but before the prodromal phase of acute type B hepatitis; it may be present for a few days only, disappearing even before jaundice has developed, but usually lasts for 3–4 weeks and can persist for up to 5 months. The persistence of HBsAg for longer than 6 months indicates chronic infection. Antibody to HBsAg (anti-HBs) usually appears after about 3–6 months and persists for many years or perhaps permanently. Anti-HBs implies either a previous infection, in which case anti-HBc (see below) is usually also present, or previous vaccination, in which case anti-HBc is not present.

Hepatitis B core antigen Hepatitis B core antigen (HBcAg) is not found in the blood, but antibody to it (anti-HBc) appears early

22.36 Source of hepatitis B infection and risk of chronic infection

Horizontal transmission (10%)
• Injection drug use • Infected unscreened blood products • Tattoos/acupuncture needles • Sexual transmission • Close living quarters/playground play as a toddler (may contribute to high rate of horizontal transmission in Africa)
Vertical transmission (90%)
• Hepatitis B surface antigen (HBsAg)-positive mother

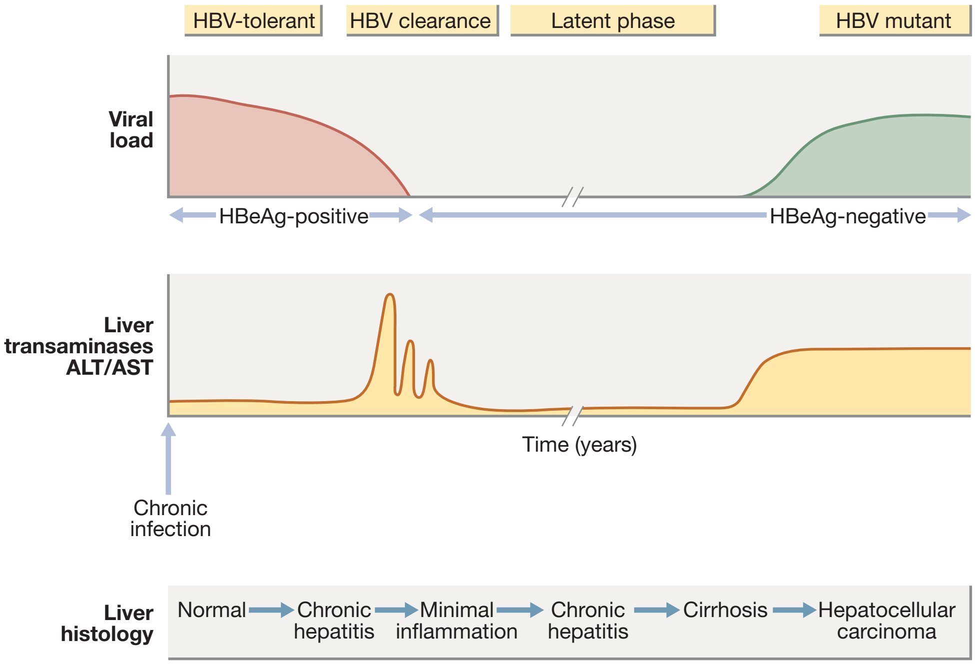

Fig. 22.25 Natural history of chronic hepatitis B virus (HBV) infection. There is an initial immunotolerant phase with high levels of virus and normal liver biochemistry. An immunological response to the virus then occurs, with elevation in serum transaminases, which causes liver damage: chronic hepatitis. If this response is sustained over many years and viral clearance does not occur promptly, chronic hepatitis may result in cirrhosis. In individuals with a successful immunological response, viral load falls, HBe antibody (HBeAg) develops and there is no further liver damage. Some individuals may subsequently develop HBV-DNA mutants that escape from immune regulation, and viral load again rises with further chronic hepatitis. Mutations in the core protein result in the virus's inability to secrete HBe antigen despite high levels of viral replication; such individuals have HBeAg-negative chronic hepatitis. (ALT = alanine aminotransferase; AST = aspartate aminotransferase)

22.37 The five phases of chronic hepatitis B virus (HBV) infection

Phase	HBsAg	HBeAg	Anti-HBe Ab	Viral load	ALT	Histology	Notes
'Immune-tolerant' phase	+	+	−	+++	Normal/ low	Normal/minimal necroinflammation	Prolonged in perinatally infected individuals; may be short or absent if infected as an adult. High viral load and so very infectious
'Immune-reactive' HBeAg-positive chronic hepatitis phase	+	+	−	++	Raised	Moderate/severe necroinflammation	May last weeks or years. High risk of cirrhosis or HCC if prolonged. Increased chance of spontaneous loss of HBeAg with seroconversion to anti-HBe antibody-positive state
'Inactive carrier' phase	+	−	+	−/+	Normal	Normal/minimal necroinflammation	Low risk of cirrhosis or HCC in majority
HBeAg-negative chronic hepatitis phase	+	−	+	Fluctuating +/++	Raised/ fluctuating	Moderate/severe necroinflammation	May represent late immune reactivation or presence of 'pre-core mutant' HBV. High risk of cirrhosis or HCC
HBsAg-negative phase	−	−	+	−/±	Normal	Normal	Ultrasensitive techniques may detect low-level HBV even after HBsAg loss

(HBeAg = hepatitis B e antigen; HBsAg = hepatitis B surface antigen; HCC = hepatocellular carcinoma)

in the illness and rapidly reaches a high titre, which subsides gradually but then persists. Anti-HBc is initially of IgM type, with IgG antibody appearing later. Anti-HBc (IgM) can sometimes reveal an acute HBV infection when the HBsAg has disappeared and before anti-HBs has developed (see Fig. 22.26 and Box 22.38).

Hepatitis B e antigen Hepatitis B e antigen (HBeAg) is an indicator of viral replication. In acute hepatitis B it may appear only transiently at the outset of the illness; its appearance is followed by the production of antibody (anti-HBe). The HBeAg reflects active replication of the virus in the liver.

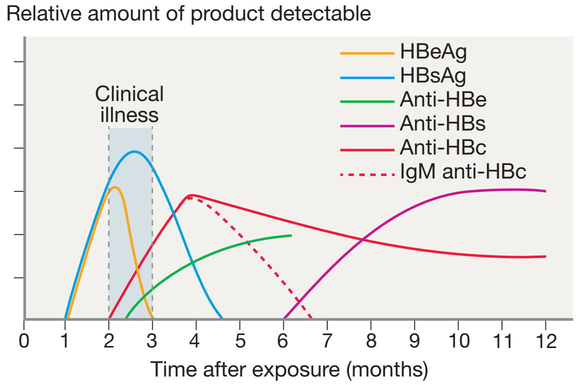

Fig. 22.26 Serological responses to hepatitis B virus infection. (anti-HBc = antibody to hepatitis B core antigen; anti-HBe = antibody to HBeAg; anti-HBs = antibody to HBsAg; HBeAg = hepatitis B e antigen; HBsAg = hepatitis B surface antigen; IgM = immunoglobulin M)

22.38 How to interpret the serological tests of acute hepatitis B virus infection

Interpretation	HBsAg	Anti-HBc IgM	Anti-HBc IgG	Anti-HBs
Incubation period	+	+	–	–
Acute hepatitis				
Early	+	+	–	–
Established	+	+	+	–
Established (occasional)	–	+	+	–
Convalescence				
(3–6 months)	–	±	+	±
(6–9 months)	–	–	+	+
Post-infection	–	–	+	±
Immunisation without infection	–	–	–	+

+ = positive; – = negative; ± = present at low titre or absent.
(anti-HBc IgM/IgG = antibody to hepatitis B core antigen of immunoglobulin M/G type; anti-HBs = antibody to HBsAg; HBsAg = hepatitis B surface antigen)

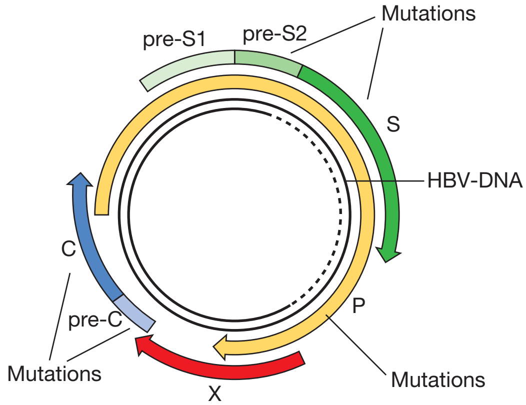

Fig. 22.27 The site of hepatitis B virus (HBV)-DNA mutations. HBV-DNA encodes four proteins: a DNA polymerase needed for viral replication (P), a surface protein (S), a core protein (C) and an X protein. The pre-C and C regions encode a core protein and an e antigen. Although mutations in the hepatitis B virus are frequent, certain mutations have important clinical consequences. Pre-C encodes a signal sequence needed for the C protein to be secreted from the liver cell into serum as e antigen. A mutation in the pre-core region leads to a failure of secretion of e antigen into serum, and so individuals have high levels of viral production but no detectable e antigen in the serum. Mutations can also occur in the surface protein and may lead to the failure of vaccination to prevent infection, since surface antibodies are produced against the native S protein. Mutations also occur in the DNA polymerase during antiviral treatment with lamivudine.

Chronic HBV infection (see below) is marked by the presence of HBsAg and anti-HBc (IgG) in the blood. Usually, HBeAg or anti-HBe is also present; HBeAg indicates continued active replication of the virus in the liver. The absence of HBeAg usually implies low viral replication; the exception is HBeAg-negative chronic hepatitis B (also called 'pre-core mutant' infection, discussed below), in which high levels of viral replication, serum HBV-DNA and hepatic necroinflammation are seen, despite negative HBeAg.

Viral load and genotype

HBV-DNA can be measured by PCR in the blood. Viral loads are usually in excess of 10^5 copies/mL in the presence of active viral replication, as indicated by the presence of e antigen. In contrast, in individuals with low viral replication, who are HBsAg- and anti-HBe-positive, viral loads are less than 10^5 copies/mL. The exception is in patients who have a mutation in the pre-core protein, which means they cannot secrete e antigen into serum (Fig. 22.27). Such individuals will be anti-HBe-positive but have a high viral load and often evidence of chronic hepatitis. These mutations are common in the Far East, and those patients affected are classified as having e antigen-negative chronic hepatitis. They respond differently to antiviral drugs from those with classical e antigen-positive chronic hepatitis.

Measurement of viral load is important in monitoring antiviral therapy and identifying patients with pre-core mutants. Specific HBV genotypes (A–H) can also be identified using PCR. In some settings, these may be useful in guiding therapy, as genotype A tends to respond better to pegylated interferon-alfa compared to genotypes C and D.

22

Management of acute hepatitis B

Treatment is supportive with monitoring for acute liver failure, which occurs in less than 1% of cases. There is no definitive evidence that antiviral therapy reduces the severity or duration of acute hepatitis B.

Full recovery occurs in 90–95% of adults following acute HBV infection. The remaining 5–10% develop a chronic hepatitis B infection that usually continues for life, although later recovery occasionally occurs. Infection passing from mother to child at birth leads to chronic infection in the child in 90% of cases and recovery is rare. Chronic infection is also common in immunodeficient individuals, such as those with Down's syndrome or human immunodeficiency virus (HIV) infection. Fulminant liver failure due to acute hepatitis B occurs in less than 1% of cases.

Recovery from acute HBV infection occurs within 6 months and is characterised by the appearance of antibody to viral antigens. Persistence of HBeAg beyond this time indicates chronic infection. Combined HBV and hepatitis delta virus (HDV) infection causes more aggressive disease.

Management of chronic hepatitis B

Treatments are still limited, as no drug is consistently able to eradicate hepatitis B infection completely (i.e. render the

patient HBsAg-negative). The goals of treatment are HBeAg seroconversion, reduction in HBV-DNA and normalisation of the LFTs. The indication for treatment is a high viral load in the presence of active hepatitis, as demonstrated by elevated serum transaminases and/or histological evidence of inflammation and fibrosis. The oral antiviral agents are more effective in reducing viral loads in patients with e antigen-negative chronic hepatitis B than in those with e antigen-positive chronic hepatitis B, as the pre-treatment viral loads are lower.

Most patients with chronic hepatitis B are asymptomatic and develop complications, such as cirrhosis and hepatocellular carcinoma, only after many years (see Fig. 22.25). Cirrhosis develops in 15–20% of patients with chronic HBV over 5–20 years. This proportion is higher in those who are e antigen-positive.

Two different types of drug are used to treat hepatitis B: direct-acting nucleoside/nucleotide analogues and pegylated interferon-alfa.

Direct-acting nucleoside/nucleotide antiviral agents

Orally administered nucleoside/nucleotide antiviral agents are the mainstay of therapy. These act by inhibiting the reverse transcription of pre-genomic RNA to HBV-DNA by HBV-DNA polymerase but do not directly affect the covalently closed circular DNA (cccDNA) template for viral replication, and so relapse is common if treatment is withdrawn. One major concern is the selection of antiviral-resistant mutations with long-term treatment. This is particularly important with some of the older agents, such as lamivudine, as mutations induced by previous antiviral exposure may also induce resistance to newer agents. Entecavir and tenofovir (see below) are potent antivirals with a high barrier to genetic resistance and so are the most appropriate first-line agents.

Lamivudine Although effective, long-term therapy is often complicated by the development of HBV-DNA polymerase mutants (e.g. the ‘YMDD variant’), which lead to viral resistance. These occur after approximately 9 months and are characterised by a rise in viral load during treatment. Outside resource-limited settings, this agent is now seldom used for the treatment of HBV but may be used to prevent reactivation of HBV in previously infected, HBsAg-negative patients if they are undergoing chemotherapy.

Entecavir and tenofovir Monotherapy with entecavir or tenofovir is substantially more effective than lamivudine in reducing viral load in HBeAg-positive and HBeAg-negative chronic hepatitis. Antiviral resistance mutations occur in only 1–2% after 3 years of entecavir drug exposure. Both drugs have anti-HIV action and so their use as monotherapy is contraindicated in HIV-positive patients, as it may lead to HIV antiviral drug resistance. Current European guidelines advise that the other nucleoside/nucleotide antivirals should not be used as first-line monotherapy due to the induction of viral mutations, unless more potent drugs with a high barrier to resistance are not available or appropriate.

Interferon-alfa

This is most effective in patients with a low viral load and serum transaminases greater than twice the upper limit of normal, in whom it acts by augmenting a native immune response. In HBeAg-positive chronic hepatitis, 33% lose e antigen after 4–6 months of treatment, compared to 12% of controls. Response rates are lower in HBeAg-negative chronic hepatitis, even when patients are given longer courses of treatment. Interferon is contraindicated in the presence of cirrhosis, as it may cause a rise in serum transaminases and precipitate liver failure. Longer-acting pegylated interferons that can be given once weekly have been evaluated in both HBeAg-positive and HBeAg-negative chronic hepatitis. Side-effects are common and include fatigue, depression, irritability, bone marrow suppression and the triggering of autoimmune thyroid disease.

Liver transplantation

Historically, liver transplantation was contraindicated in hepatitis B because infection often recurred in the graft. The use of post-liver transplant prophylaxis with direct-acting antiviral agents and hepatitis B immunoglobulins has, however, reduced the reinfection rate to 10% and increased 5-year survival to 80%, making transplantation an acceptable treatment option.

Prevention

Individuals are most infectious when markers of continuing viral replication, such as HBeAg, and high levels of HBV-DNA are present in the blood. HBV-DNA can be found in saliva, urine, semen and vaginal secretions (although urine is not usually considered to be capable of transmitting infection). The virus is about ten times more infectious than hepatitis C, which in turn is about ten times more infectious than HIV.

A recombinant hepatitis B vaccine containing HBsAg is available (Engerix) and is capable of producing active immunisation in 95% of normal individuals. The vaccine should be offered to those at special risk of infection who are not already immune, as evidenced by anti-HBs in the blood (Box 22.39). The vaccine is ineffective in those already infected by HBV. Infection can also be prevented or minimised by the intramuscular injection of specific hepatitis B immunoglobulin (HBIg) prepared from blood containing anti-HBs. This should be given within 48 hours, or at most a week, of exposure to infected blood in circumstances likely to cause infection (e.g. needlestick injury, contamination of cuts or mucous membranes). Vaccine can be given together with HBIg (active–passive immunisation).

Neonates born to hepatitis B-infected mothers should be immunised at birth and given immunoglobulin. Hepatitis B serology should then be checked at 12 months of age.

Co-infection with HIV

Around 10% of the HIV-infected population has concurrent HBV and this figure may be as high as 25% in areas where both viruses are prevalent. Up to half of injection drug users with HIV are co-infected with HBV. Co-infection increases the morbidity and mortality compared to either infection alone: there are greater levels of HBV viraemia, faster progression to chronic infection and greater risk of cirrhosis and hepatocellular carcinoma than with HBV infection alone. The immunosuppression that is seen in HIV infection can lead to loss of anti-HBs antibodies, reactivation of infection and a poorer antibody response to HBV vaccination.

i 22.39 At-risk groups meriting hepatitis B vaccination in low-endemic areas

- Parenteral drug users
- Men who have sex with men
- Close contacts of infected individuals:
  - Newborn of infected mothers
  - Regular sexual partners
- Patients on chronic haemodialysis
- Patients with chronic liver disease
- Medical, nursing and laboratory personnel

Pregnancy poses particular problems in co-infected patients, with increased risk of perinatal transmission of HBV to the child.

Treatment can also be problematic. Several nucleoside analogues have dual antiviral activity and some regimens have been associated with emergence of drug resistance. Co-infection is also associated with diminished response to interferons and increased resistance to lamivudine in some patients. Co-infection should be managed by specialists with expertise in this area and combinations of antiviral agents need to be thought through carefully. Antiviral therapy should be considered for co-infected pregnant women, using drugs with dual activity, e.g. tenofovir with emtricitabine or lamivudine.

Globally, there is a need to identify co-infected patients earlier, especially in endemic areas, as well as a need for early effective interventions, particularly in pregnant women, to reduce perinatal transmission.

Hepatitis D (Delta virus)

The hepatitis D virus (HDV) is an RNA-defective virus that has no independent existence; it requires HBV for replication and has the same sources and modes of spread. It can infect individuals simultaneously with HBV or can superinfect those who are already chronic carriers of HBV. Simultaneous infections give rise to acute hepatitis, which is often severe but is limited by recovery from the HBV infection. Infections in individuals who are chronic carriers of HBV can cause acute hepatitis with spontaneous recovery, and occasionally there is simultaneous cessation of the chronic HBV infection. Chronic infection with HBV and HDV can also occur, and this frequently causes rapidly progressive chronic hepatitis and eventually cirrhosis.

HDV has a worldwide distribution. It is endemic in parts of the Mediterranean basin, Africa and South America, where transmission is mainly by close personal contact and occasionally by vertical transmission from mothers who also carry HBV. In non-endemic areas, transmission is mainly a consequence of parenteral drug misuse.

Investigations

HDV contains a single antigen to which infected individuals make an antibody (anti-HDV). Delta antigen appears in the blood only transiently, and in practice diagnosis depends on detecting anti-HDV. Simultaneous infection with HBV and HDV, followed by full recovery, is associated with the appearance of low titres of anti-HDV of IgM type within a few days of the onset of the illness. This antibody generally disappears within 2 months but persists in a few patients. Super-infection of patients with chronic HBV infection leads to the production of high titres of anti-HDV, initially IgM and later IgG. Such patients may then develop chronic infection with both viruses, in which case anti-HDV titres plateau at high levels.

Management

Effective management of hepatitis B prevents hepatitis D.

Hepatitis C

This is caused by an RNA flavivirus. Acute symptomatic infection with hepatitis C is rare. Most individuals are unaware of when they became infected and are identified only when they develop chronic liver disease. Eighty per cent of individuals exposed to the virus become chronically infected and late spontaneous viral clearance is rare. There is no active or passive protection against hepatitis C virus (HCV).

i 22.40 Risk factors for the acquisition of chronic hepatitis C infection

- Intravenous drug misuse (95% of new cases in the UK)
- Unscreened blood products
- Vertical transmission (3% risk)
- Needlestick injury (3% risk)
- Iatrogenic parenteral transmission (e.g. contaminated vaccination needles)
- Sharing toothbrushes/razors

Hepatitis C infection is usually identified in asymptomatic individuals screened because they have risk factors for infection, such as previous injecting drug use (Box 22.40), or have incidentally been found to have abnormal liver blood tests. Although most people remain asymptomatic until progression to cirrhosis occurs, fatigue can complicate chronic infection and is unrelated to the degree of liver damage. Hepatitis C is the most common cause of what used to be known as 'non-A, non-B hepatitis'.

If hepatitis C infection is left untreated, progression from chronic hepatitis to cirrhosis occurs over 20–40 years. Risk factors for progression include male gender, immunosuppression (such as co-infection with HIV), prothrombotic states and heavy alcohol misuse. Not everyone with hepatitis C infection will necessarily develop cirrhosis but approximately 20% do so within 20 years. Once cirrhosis has developed, the 5- and 10-year survival rates are 95% and 81%, respectively. One-quarter of people with cirrhosis will develop complications within 10 years and, once complications such as ascites develop, the 5-year survival is around 50%. Once cirrhosis is present, 2–5% per year will develop primary hepatocellular carcinoma.

Investigations

Serology and virology

The HCV genome encodes a large polypeptide precursor that is modified post-translationally to at least ten proteins, including several antigens that give rise to antibodies in an infected person; these are used in diagnosis. It may take 6–12 weeks for antibodies to appear in the blood following acute infection, such as a needlestick injury. In these cases, hepatitis C RNA can be identified in the blood as early as 2–4 weeks after infection. Active infection is confirmed by the presence of serum hepatitis C RNA in anyone who is antibody-positive. Anti-HCV antibodies persist in serum even after viral clearance, whether spontaneous or post-treatment.

Molecular analysis

There are six common viral genotypes, the distribution of which varies worldwide. Genotype has no effect on progression of liver disease but does affect response to treatment. Genotype 1 is most common in northern Europe and was less easy to eradicate than genotypes 2 and 3 with traditional pegylated interferon alfa-/ribavirin-based treatments. Knowledge of viral genotype still remains relevant in guiding selection of drugs to treat HCV.

Liver function tests

LFTs may be normal or show fluctuating serum transaminases between 50 and 200 U/L. Jaundice is rare and only usually appears in end-stage cirrhosis.

Liver histology

Serum transaminase levels in hepatitis C are a poor predictor of the degree of liver fibrosis and so a liver biopsy may be required to stage the extent of liver damage. The degree of inflammation and fibrosis can be scored histologically. The most common way of doing this in hepatitis C is the Metavir system, which scores fibrosis from 1 to 4, the latter equating to cirrhosis. Recently, non-invasive markers and fibrosis scoring systems have been used routinely, with biopsy being reserved for cases where these give conflicting results.

Management

The aim of treatment is to eradicate infection. In recent years, there have been substantial advances, so much so that rates of viral clearance achieved 6 months after finishing treatment (termed sustained virological response, SVR) have risen from less than 40% a decade ago to levels approaching 100% with some of the newer direct-acting antivirals. The infection is cured in more than 99% of patients who achieve an SVR. These newer drugs are extremely expensive, however, and so their use is placing substantial strain on the finite health-care resources of developed countries and has severely limited their availability in resource-poor settings.

Until 2011, the treatment of choice was dual therapy with pegylated interferon-alfa, given as a weekly subcutaneous injection, together with oral ribavirin, a synthetic nucleotide analogue. Treatment was long – up to 12 months for genotype 1 infection, and both agents had significant side-effects that limited tolerability: ribavirin induces haemolytic anaemia and is teratogenic, while interferon induces influenza-like symptoms, irritability and depression, all of which can affect quality of life. As already mentioned, efficacy of these agents was poor (12 months' treatment for genotype 1 resulted in only a 40% SVR, rising to an SVR of over 70% for genotypes 2 or 3 after 6 months' treatment).

i 22.41 Direct-acting antiviral agents for hepatitis C

Drug class	Therapeutic target	Selected drugs
Protease inhibitors (PIs)	Non-structural viral protein NS3/4A (protease that cleaves the HCV polyprotein)	Telaprevir Boceprevir Simeprevir Paritaprevir Grazoprevir
Nucleoside polymerase inhibitors (NPIs)	Non-structural viral protein NS5B (RNA-dependent RNA polymerase needed for viral replication)	Sofosbuvir
Non-nucleoside polymerase inhibitors (NNPIs)	Non-structural viral protein NS5B (RNA-dependent RNA polymerase needed for viral replication)	Dasabuvir
NS5A replication complex inhibitors	Non-structural viral protein NS5A (assembly of viral replication complex)	Daclatasvir Velpatasvir Ledipasvir Ombitasvir Elbasvir
Host-targeting antiviral drugs (HTAs)	Cyclophilin (pharmacological inhibitor targets host cell functions involved in the HCV life cycle)	Alisporivir

(HCV = hepatitis C virus)

Since 2011, new classes of direct-acting antiviral agents (DAAs) have been developed. There are four main classes of DAA, which are defined according to their mechanism of action and therapeutic target (Box 22.41). These compounds are targeted to specific steps in the hepatitis C viral life cycle to disrupt viral replication (Fig. 22.28). Initially, DAAs were added to interferon-/ribavirin-based regimens; more recently, however, combinations of DAAs have increasingly been used in 'interferon-free' regimens. This maximises treatment efficacy by directly interfering with replication at multiple points in the viral life cycle without exposing patients to the side-effect profile of interferon-alfa therapy. For example, 12 weeks of treatment with oral sofosbuvir plus ledipasvir plus ribavirin can achieve a 99% SVR in treatment-naïve genotype 1 patients. Sofosbuvir plus velpatasvir achieves similar results and is pan-genotypic. Although not without side-effects, DAAs are often orally administered, efficacious and, in general, well tolerated.

Liver transplantation should be considered when complications of cirrhosis occur, such as diuretic-resistant ascites. Unfortunately, if the virus is not cleared, hepatitis C will infect the transplanted liver and up to 15% of patients then develop cirrhosis in the liver graft within 5 years of transplantation. This should no longer happen, as modern antiviral therapy post-transplant achieves excellent results.

Hepatitis E

Hepatitis E is caused by an RNA virus that is endemic in India and the Middle East. Prevalence is now increasing across Asia and Europe, especially south-west France, so it is important to note that infection is no longer seen only in travellers from an endemic area.

The clinical presentation and management of hepatitis E are similar to those of hepatitis A. Disease is spread via the faecal–oral route or through contaminated food; the virus is commonly present in uncooked game and pig-liver sausage in southern France, and this may be a route of infection. In most cases, it presents as a self-limiting acute hepatitis and does not usually cause chronic liver disease. There is increasing recognition that hepatitis E may develop into chronic infection, usually in immunocompromised patients and especially in organ-transplant recipients, although this remains uncommon. If treatment is required for chronic infection, agents such as ribavirin may be used. Blood donations are now routinely screened for hepatitis E.

Hepatitis E differs from hepatitis A in that infection during pregnancy is associated with the development of acute liver failure, which has a high mortality. In acute infection, IgM antibodies to hepatitis E virus (HEV) are positive.

Other forms of viral hepatitis

Non-A, non-B, non-C (NANBNC) or non-A–E hepatitis is the term used to describe hepatitis thought to be due to a virus that is not HAV, HBV, HCV or HEV. Other viruses that affect the liver probably exist but the viruses described above now account for the majority of hepatitis infections. Cytomegalovirus and EBV infection causes abnormal LFTs in most patients and occasionally jaundice occurs. Herpes simplex is a rare cause of hepatitis in adults, most of whom are immunocompromised. Herpes simplex virus hepatitis can be very severe in pregnancy. Abnormal LFTs are also common in chickenpox, measles, rubella and acute HIV infection.

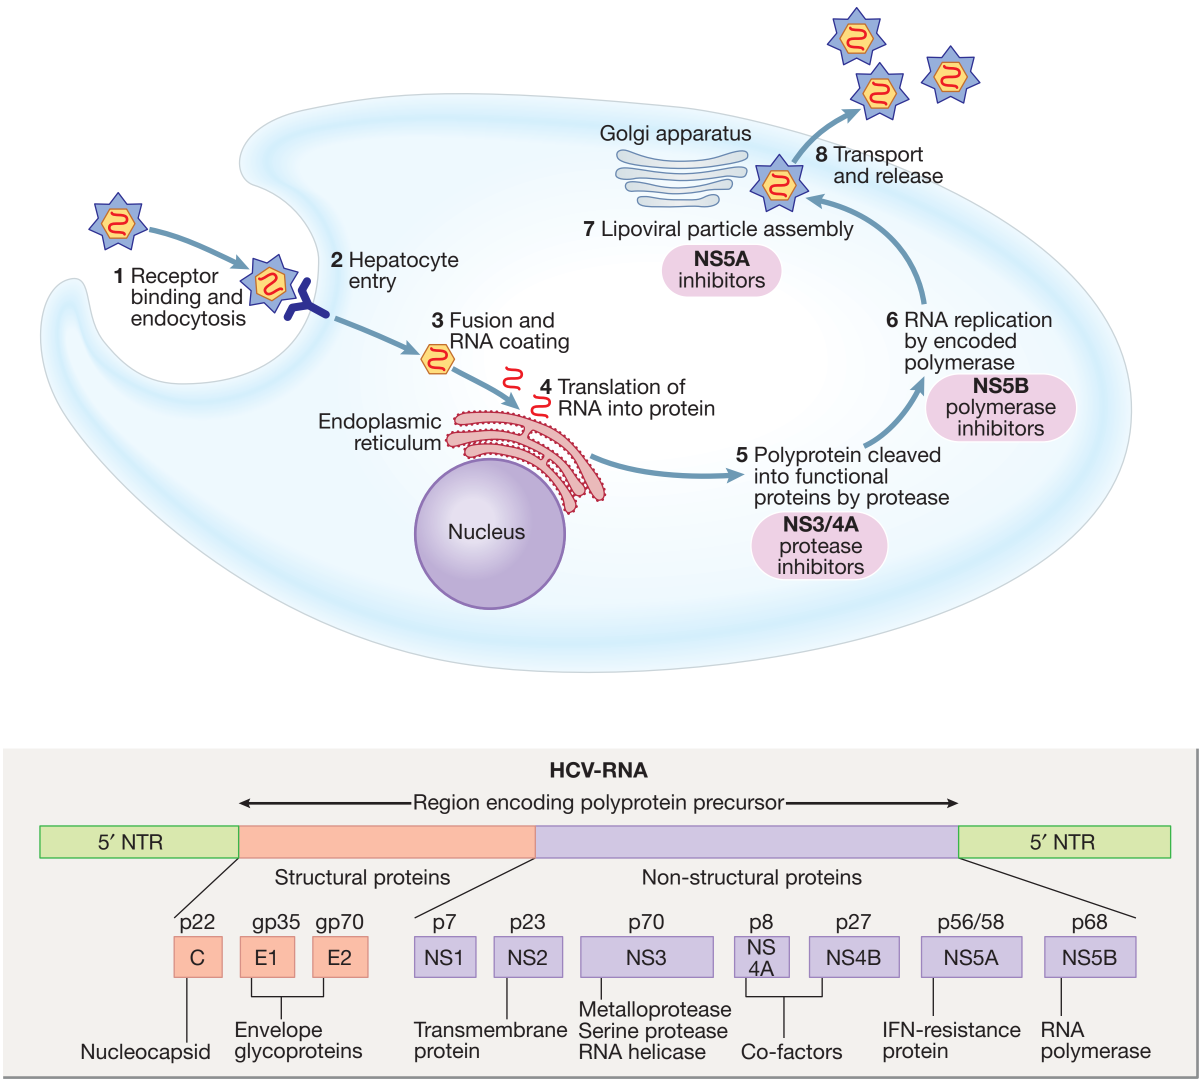

Fig. 22.28 Direct-acting antiviral agents. These compounds are targeted to specific steps in the hepatitis C viral life cycle to disrupt replication. (5′NTR = 5′ non-translated region; HCV = hepatitis C virus; IFN = interferon)

i 22.42 Causes of abnormal liver blood tests in HIV infection

Hepatitic blood tests	
• Chronic hepatitis C • Chronic hepatitis B	• Antiretroviral drugs • Cytomegalovirus
Cholestatic blood tests	
• Tuberculosis • Atypical mycobacterium	• Sclerosing cholangitis due to cryptosporidia

HIV infection and the liver

Several causes of abnormal LFTs occur in HIV infection, as shown in Box 22.42. This topic is discussed in more detail on page 317. Co-infection with HIV and HBV is discussed on page 876.

Liver abscess

Liver abscesses are classified as pyogenic, hydatid or amoebic.

Pyogenic liver abscess

Pyogenic liver abscesses are uncommon but important because they are potentially curable, carry significant morbidity and mortality if untreated, and are easily overlooked. The mortality of liver abscesses is 20–40%; failure to make the diagnosis is the most common cause of death. Older patients and those with multiple abscesses have a higher mortality.

Pathophysiology

Infection can reach the liver in several ways (Box 22.43). Pyogenic abscesses are most common in older patients and usually result from ascending infection due to biliary obstruction (cholangitis) or contiguous spread from an empyema of the gallbladder. They can also complicate dental sepsis or colonic pathology, e.g. cancer, diverticulitis or inflammatory bowel disease causing portal pyaemia.

22.43 Causes of pyogenic liver abscesses

- Biliary obstruction (cholangitis)
- Haematogenous:
  - Portal vein (intra-abdominal infections)
  - Hepatic artery (bacteraemia)
- Direct extension
- Trauma:
  - Penetrating or non-penetrating
- Infection of liver tumour or cyst

Abscesses complicating suppurative appendicitis used to be common in young adults but are now rare. Immunocompromised patients are particularly likely to develop liver abscesses. Single lesions are more common in the right liver; multiple abscesses are usually due to infection secondary to biliary obstruction. *Escherichia coli* and various streptococci, particularly *Strep. milleri*, are the most common organisms; anaerobes, including streptococci and *Bacteroides*, can often be found when infection has been transmitted from large bowel pathology via the portal vein, and multiple organisms are present in one-third of patients.

Clinical features

Patients are generally ill with fever and sometimes rigors and weight loss. Abdominal pain is the most common symptom and is usually in the right upper quadrant, sometimes with radiation to the right shoulder. The pain may be pleuritic in nature. Tender hepatomegaly is found in more than 50% of patients. Mild jaundice may be present, becoming severe if large abscesses cause biliary obstruction. Atypical presentations are common and explain the frequency with which the diagnosis is made only at autopsy. This is a particular problem in patients with gradually developing illnesses or pyrexia of unknown origin without localising features. Necrotic colorectal metastases can be misdiagnosed as hepatic abscess.

Investigations

Liver imaging is the most revealing investigation and shows 90% or more of symptomatic abscesses. Needle aspiration under ultrasound guidance confirms the diagnosis and provides pus for culture. A leucocytosis is frequently found, plasma ALP activity is usually increased, and the serum albumin is often low. The chest X-ray may show a raised right diaphragm and lung collapse, or an effusion at the base of the right lung. Blood cultures are positive in 50–80%. Abscesses caused by gut-derived organisms require active exclusion of significant colonic pathology, such as a colonoscopy to exclude colorectal carcinoma.

Management

Pending the results of culture of blood and pus from the abscess, treatment should be commenced with a combination of antibiotics, such as ampicillin, gentamicin and metronidazole. Aspiration or drainage with a catheter placed in the abscess under ultrasound guidance is required if the abscess is large or if it does not respond to antibiotics. Any associated biliary obstruction and cholangitis require biliary drainage (preferably endoscopically). Surgical abscess drainage is rarely undertaken, although hepatic resection may be indicated for a chronic persistent abscess or 'pseudotumour'.

Hydatid cysts and amoebic liver abscesses

These are described on pages 299 and 287.

Leptospirosis

This is described on page 257.

Alcoholic liver disease

Alcohol is one of the most common causes of chronic liver disease worldwide, with consumption continuing to increase in many countries. Patients with alcoholic liver disease (ALD) may also have risk factors for other liver diseases (e.g. coexisting NAFLD or chronic viral hepatitis infection), and these may interact to increase disease severity.

In the UK, a unit of alcohol contains 8 g of ethanol (Box 22.44). An upper threshold of 14 units/week in women and 21 units/week in men is generally considered safe. Recently, however, Public Health England advice has adopted a more conservative threshold of 14 units/week for both men and women. The risk threshold for developing ALD is variable but begins at 30 g/day of ethanol. There is no clear linear relationship between dose and liver damage, however. For many, consumption of more than 80 g/day, for more than 5 years, is required to confer significant risk of advanced liver disease. The average alcohol consumption of a man with cirrhosis is 160 g/day for over 8 years. Some of the risk factors for ALD are:

- *Drinking pattern*. ALD and alcohol dependence are not synonymous; many of those who develop ALD are not alcohol-dependent and most dependent drinkers have normal liver function. Liver damage is more likely to occur in continuous rather than intermittent or 'binge' drinkers, as this pattern gives the liver a chance to recover. It is therefore recommended that people should have at least two alcohol-free days each week. The type of beverage does not affect risk.
- *Gender*. The incidence of ALD is increasing in women, who have higher blood ethanol levels than men after consuming the same amount of alcohol. This may be related to the reduced volume of distribution of alcohol.
- *Genetics*. Alcoholism is more concordant in monozygotic than dizygotic twins. While polymorphisms in the genes involved in alcohol metabolism, such as aldehyde dehydrogenase, may alter drinking behaviour, they have not been linked to ALD. The patatin-like phospholipase domain-containing 3 (*PNPLA3*) gene, also known as adiponutrin, has been implicated in the pathogenesis of both ALD and NAFLD (p. 883).
- *Nutrition*. Obesity increases the incidence of liver-related mortality by over fivefold in heavy drinkers. Ethanol itself produces 7 kcal/g (29.3 kJ/g) and many alcoholic drinks also contain sugar, which further increases the calorific

22.44 Amount of alcohol in an average drink

Alcohol type	% Alcohol by volume	Amount	Units*
Beer	3.5	568 mL (1 pint)	2
	9	568 mL (1 pint)	4
Wine	10	125 mL	1
	12	750 mL	9
'Alcopops'	6	330 mL	2
Sherry	17.5	750 mL	13
Vodka/rum/gin	37.5	25 mL	1
Whisky/brandy	40	700 mL	28

*1 unit = 8 g.

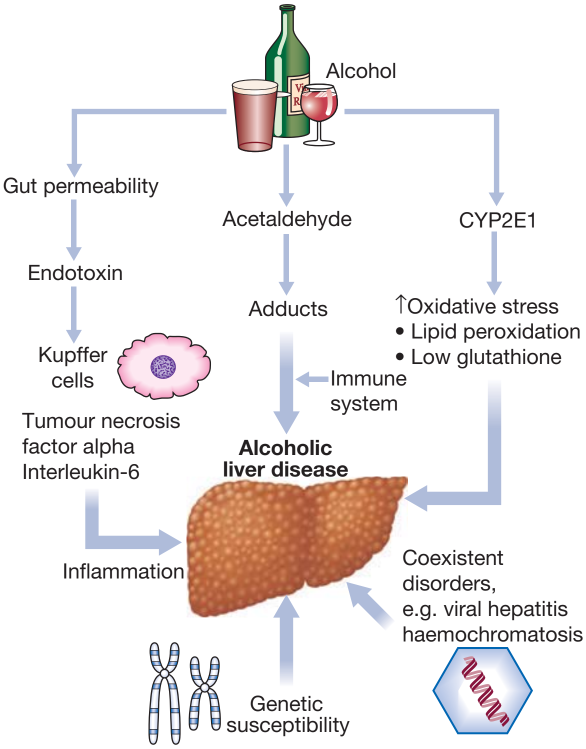

Fig. 22.29 Factors involved in the pathogenesis of alcoholic liver disease.

value and may contribute to weight gain. Excess alcohol consumption is frequently associated with nutritional deficiencies that contribute to morbidity.

Pathophysiology

Alcohol reaches peak blood concentrations after about 20 minutes, although this may be influenced by stomach contents. It is metabolised almost exclusively by the liver via one of two pathways (Fig. 22.29).

Approximately 80% of alcohol is metabolised to acetaldehyde by the mitochondrial enzyme, alcohol dehydrogenase. Acetaldehyde is then metabolised to acetyl-CoA and acetate by aldehyde dehydrogenase. This generates NADH from NAD (nicotinamide adenine dinucleotide), which changes the redox potential of the cell. Acetaldehyde forms adducts with cellular proteins in hepatocytes that activate the immune system, contributing to cell injury.

The remaining 20% of alcohol is metabolised by the microsomal ethanol-oxidising system (MEOS) pathway. Cytochrome CYP2E1 is an enzyme that oxidises ethanol to acetate. It is induced by alcohol, and during metabolism of ethanol it releases oxygen free radicals, leading to lipid peroxidation and mitochondrial damage. The CYP2E1 enzyme also metabolises acetaminophen, and hence chronic alcoholics are more susceptible to hepatotoxicity from low doses of paracetamol.

It is thought that pro-inflammatory cytokines may also be involved in inducing hepatic damage in alcoholic hepatitis, since endotoxin is released into the blood because of increased gut permeability, leading to release of tumour necrosis factor alpha (TNF-α) and interleukin 1 (IL-1), IL-2 and IL-8 from immune cells. All of these cytokines have been implicated in the pathogenesis of liver fibrosis (see Fig. 22.4, p. 849).

22.45 Pathological features of alcoholic liver disease

• Alcoholic hepatitis: Lipogranuloma Neutrophil infiltration Mallory's hyaline Pericellular fibrosis	• Macrovesicular steatosis • Fibrosis and cirrhosis • Central hyaline sclerosis

22.46 Clinical syndromes of alcoholic liver disease

Fatty liver	
• Asymptomatic abnormal liver biochemistry	• Normal/large liver
Alcoholic hepatitis	
• Jaundice • Malnutrition • Hepatomegaly	• Features of portal hypertension (e.g. ascites, encephalopathy)
Cirrhosis	
• Stigmata of chronic liver disease • Ascites/varices/encephalopathy	• Large, normal or small liver • Hepatocellular carcinoma

The pathological features of ALD are shown in Box 22.45. In about 80% of patients with severe alcoholic hepatitis, cirrhosis will coexist at presentation. Iron deposition is common and does not necessarily indicate haemochromatosis. Figure 22.30A below shows the histological features of alcoholic liver disease, which are identical to those of non-alcoholic steatohepatitis.

Clinical features

ALD has a wide clinical spectrum, ranging from mild abnormalities of LFTs on biochemical testing to advanced cirrhosis. The liver is often enlarged in ALD, even in the presence of cirrhosis. Stigmata of chronic liver disease, such as palmar erythema, are more common in alcoholic cirrhosis than in cirrhosis of other aetiologies. Alcohol misuse may also cause damage of other organs and this should be specifically looked for (see Box 28.22, p. 1194). Three types of ALD are recognised (Box 22.46) but these overlap considerably, as do the pathological changes seen in the liver.

Alcoholic fatty liver disease

Alcoholic fatty liver disease (AFLD) usually presents with elevated transaminases in the absence of hepatomegaly. It has a good prognosis and steatosis usually disappears after 3 months of abstinence.

Alcoholic hepatitis

This presents with jaundice and hepatomegaly; complications of portal hypertension may also be present. It has a significantly worse prognosis than AFLD. About one-third of patients die in the acute episode, particularly those with hepatic encephalopathy or a prolonged PT. Cirrhosis often coexists; if not present, it is the likely outcome if drinking continues. Patients with acute alcoholic hepatitis often deteriorate during the first 1–3 weeks in hospital. Even if they abstain, it may take up to 6 months for jaundice to resolve. In patients presenting with jaundice who subsequently abstain, the 3- and 5-year survival is 70%. In contrast, those who continue to drink have 3- and 5-year survival rates of 60% and 34%, respectively.

22

Alcoholic cirrhosis

Alcoholic cirrhosis often presents with a serious complication, such as variceal haemorrhage or ascites, and only half of such patients will survive for 5 years from presentation. However, most who survive the initial illness and who become abstinent will survive beyond 5 years.

Investigations

Investigations aim to establish alcohol misuse, exclude alternative or additional coexistent causes of liver disease, and assess the severity of liver damage. The clinical history from patient, relatives and friends is important to establish alcohol misuse duration and severity. Biological markers, particularly macrocytosis in the absence of anaemia, may suggest and support a history of alcohol misuse. A raised GGT is not specific for alcohol misuse and may also be elevated in the presence of other conditions, including NAFLD. The level may therefore not return to normal with abstinence if chronic liver disease is present, and GGT should not be relied on as an indicator of ongoing alcohol consumption. The presence of jaundice may suggest alcoholic hepatitis. Determining the extent of liver damage often requires a liver biopsy.

In alcoholic hepatitis, PT and bilirubin are used to calculate a 'discriminant function' (DF), also known as the Maddrey score, which enables the clinician to assess prognosis (PT = prothrombin time; serum bilirubin in μmol/L is divided by 17 to convert to mg/dL):

$$DF = [4.6 \times \text{Increase in PT (sec)}] + \text{Bilirubin (mg/dL)}$$

A value over 32 implies severe liver disease with a poor prognosis and is used to guide treatment decisions (see below). A second scoring system, the Glasgow score, uses the age, white cell count and renal function, in addition to PT and bilirubin, to assess prognosis and has a cut-off of 9 (Box 22.47).

Management

Cessation of alcohol consumption is the single most important treatment and prognostic factor. Life-long abstinence is the best advice. General health and life expectancy are improved when this occurs, irrespective of the stage of liver disease. Abstinence is even effective at preventing progression, hepatic decompensation and death once cirrhosis is present. Treatment of alcohol dependency is discussed on page 1195. In the acute presentation of ALD it is important to identify and anticipate alcohol withdrawal and Wernicke's encephalopathy, which need treating in parallel with the liver disease and any complications of cirrhosis.

Nutrition

Good nutrition is very important, and enteral feeding via a fine-bore nasogastric tube may be needed in severely ill patients.

Drug therapy

The optimum treatment of severe alcoholic hepatitis (Maddrey's discriminative score >32) has been debated for some time. The STOPAH study was a large, multicentre, double-blind, randomised trial to evaluate the relative merits of glucocorticoids and/or a weak anti-TNF agent (pentoxifylline), alone or in combination. In a cohort of 1103 patients, no significant benefit from pentoxifylline treatment was identified but treatment with prednisolone (40 mg daily for 28 days) led to a modest reduction in short-term mortality, from 17% in placebo-treated patients to 14% in the prednisolone group. These findings were consistent with earlier studies where an improvement in 28-day survival from 52% to 78% is seen when glucocorticoids are given to those with a Glasgow score of more than 9. Neither glucocorticoids nor pentoxifylline improved survival at 90 days or 1 year, however. Sepsis is the main side-effect of glucocorticoids, and existing sepsis and variceal haemorrhage are the main contraindications to their use. If the bilirubin has not fallen 7 days after starting glucocorticoids, the drugs are unlikely to reduce mortality and should be stopped.

Liver transplantation

The role of liver transplantation in the management of ALD remains controversial. In many centres, ALD is a common indication for liver transplantation. The challenge is to identify patients with an unacceptable risk of returning to harmful alcohol consumption. Many programmes require a 6-month period of abstinence from alcohol before a patient is considered for transplantation. Although this relates poorly to the incidence of alcohol relapse after transplantation, liver function may improve to the extent that transplantation is no longer necessary. The outcome of transplantation for ALD is good and if the patient remains abstinent there is no risk of disease recurrence. Transplantation for alcoholic hepatitis has been thought to have a poorer outcome and is seldom performed due to concerns about recidivism; studies to quantify this are ongoing.

22.47 How to assess prognosis using the Glasgow alcoholic hepatitis score

Score	1	2	3
Age	<50	>50	
White cell count ($\times 10^9$/L)	<15	>15	
Urea (mmol/L *(BUN mg/dl)*)	<5 (*14*)	>5 (*14*)	
PT ratio	<1.5	1.5–2.0	>2.0
Bilirubin (μmol/L *(mg/dL)*)	<125 (*7.4*)	125–250 (*7.4–14.8*)	>250 (*14.8*)

A score of ≥9 is associated with a 40% 28-day survival, compared to 80% for patients with a score of <9.

(BUN = blood urea nitrogen; PT = prothrombin time)

Non-alcoholic fatty liver disease

Increasingly sedentary lifestyles and changing dietary patterns mean that the prevalence of obesity and insulin resistance has increased worldwide, and so fat accumulation in the liver is a common finding during abdominal imaging studies and on liver biopsy. In the absence of high alcohol consumption (typically, a threshold of <20 g/day for women and <30 g/day for men is adopted), this is called non-alcoholic fatty liver disease (NAFLD).

NAFLD includes a spectrum of progressive liver disease ranging from fatty infiltration alone (steatosis) to fatty infiltration with inflammation (non-alcoholic steatohepatitis, NASH) and may progress to cirrhosis and primary liver cancer (Fig. 22.30B). NAFLD is considered by many to be the hepatic manifestation of the 'metabolic syndrome' (p. 730), as it is strongly associated with obesity, dyslipidaemia, type 2 diabetes and hypertension. Estimates vary between populations, although one large European study found NAFLD to be present in 94% of obese patients

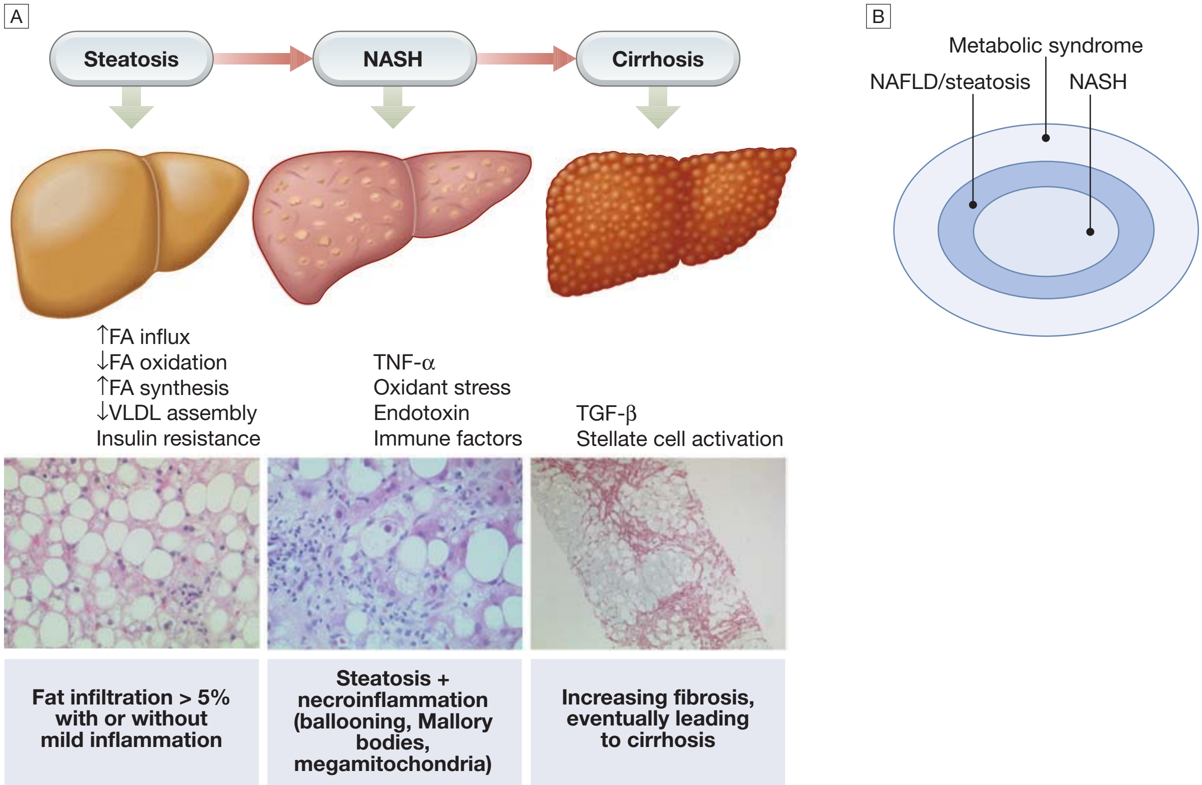

Fig. 22.30 Non-alcoholic fatty liver disease (NAFLD) and non-alcoholic steatohepatitis (NASH). A Features. Rate of progression is determined by environmental (dietary) and genetic factors. B The spectrum of NAFLD. (FA = fatty acid; TGF-β = transforming growth factor beta; TNF-α = tumour necrosis factor alpha; VLDL = very low-density lipoprotein)

(body mass index (BMI) >30 kg/m^2), 67% of overweight patients (BMI >25 kg/m^2) and 25% of normal-weight patients. The overall prevalence of NAFLD in patients with type 2 diabetes ranges from 40% to 70%. Histological NASH has been found in 3–16% of apparently healthy potential living liver donors in Europe and 6–15% in the USA.

Overall, NAFLD is estimated to affect 20–30% of the general population in Western countries and 5–18% in Asia, with about 1 in 10 NAFLD cases exhibiting NASH. The frequency of steatosis varies with ethnicity (45% in Hispanics, 33% in whites and 24% in blacks) and gender (42% white males versus 24% white females) but only a minority of patients will progress to cirrhosis and end-stage liver disease. However, because obesity is common and the prevalence of NAFLD is rising, this still represents a large number of patients, placing a substantial burden on health-care resources. Over a median 12-year follow-up period in a cohort of 619 NAFLD patients, an overall 33.2% risk of death or liver transplantation was observed, with liver-related mortality being the third most common cause of death after cardiovascular disease and extra-hepatic malignancy. NAFLD is the leading cause of liver dysfunction in the non-alcoholic, viral hepatitis-negative population in Europe and North America, and is predicted to become the main aetiology in patients undergoing liver transplantation during the next 5 years.

Pathophysiology

The initiating events in NAFLD are based on the development of obesity and insulin resistance, leading to increased hepatic free fatty acid flux. This imbalance between the rate of import/synthesis and the rate of export/catabolism of fatty acids in the liver leads to the development of steatosis. This may be an adaptive response through which hepatocytes store potentially toxic lipids as relatively inert triglyceride. A ‘two-hit’ hypothesis has been proposed to describe the pathogenesis of NAFLD, the ‘first hit’ causing steatosis that then progresses to NASH if a ‘second hit’ occurs. In reality, progression probably follows hepatocellular injury caused by a combination of several different ‘hits’, including:

- oxidative stress due to free radicals produced during fatty acid oxidation
- direct lipotoxicity from fatty acids and other metabolites in the liver
- endoplasmic reticulum stress
- gut-derived endotoxin
- cytokine release (TNF-α etc.) and immune-mediated hepatocellular injury.

Cellular damage triggers cell death and inflammation, which leads to stellate cell activation and development of hepatic fibrosis that culminates in cirrhosis (Fig. 22.30A). As with many other liver diseases, subtle inter-patient genetic variations and environmental factors interact to determine disease progression. Several genetic modifiers of disease severity have been identified, with *PNPLA3* and its product, adiponutrin, being the best validated.

This should not be confused with acute fatty liver, which can occur in hepatic mitochondrial cytopathies, e.g. acute fatty liver of pregnancy (p. 1283), or in other situations, e.g. Reye’s syndrome (p. 241) or drug toxicity (sodium valproate, tetracyclines), or with bacterial toxins (e.g. *Bacillus cereus*). In these, defective mitochondrial beta-oxidation of lipids leads to fat droplet accumulation in hepatocytes and microvesicular steatosis.

Clinical features

NAFLD is frequently asymptomatic, although it may be associated with fatigue and mild right upper quadrant discomfort. It is commonly identified as an incidental biochemical abnormality during routine blood tests or as a fatty liver during an ultrasound or CT scan of the abdomen. Alternatively, patients with progressive NASH may present late in the natural history of the disease with complications of cirrhosis and portal hypertension, such as variceal haemorrhage, or with hepatocellular carcinoma.

The average age of NASH patients is 40–50 years (50–60 years for NASH–cirrhosis); however, the emerging epidemic of childhood obesity means that NASH is present in increasing numbers of younger patients. Recognised independent risk factors for disease progression are age over 45 years, presence of diabetes (or severity of insulin resistance), obesity (BMI >30 kg/m^2) and hypertension. These factors help with identification of 'high-risk' patient groups. NAFLD is also associated with polycystic ovary syndrome, obstructive sleep apnoea and small-bowel bacterial overgrowth.

Investigations

Investigation of patients with suspected NAFLD should be directed first towards exclusion of excess alcohol consumption and other liver diseases (including viral, autoimmune and other metabolic causes) and then at confirming the presence of NAFLD, discriminating simple steatosis from NASH and determining the extent of any hepatic fibrosis that is present.

Biochemical tests

There is no single diagnostic blood test for NAFLD. Elevations of serum ALT and AST are modest, and usually less than twice the upper limit of normal. ALT levels fall as hepatic fibrosis increases and the characteristic AST : ALT ratio of <1 seen in NASH reverses (AST : ALT >1) as disease progresses towards cirrhosis, meaning that steatohepatitis with advanced disease may be present even in those with normal-range ALT levels. Other laboratory abnormalities that may be present include non-specific elevations of GGT, low-titre antinuclear antibody (ANA) in 20–30% of patients and elevated ferritin levels.

Although routine blood tests are unable to determine the degree of liver fibrosis/cirrhosis accurately, calculated scores, such as the NAFLD Fibrosis Score and FIB-4 Score, which are based on the results of routinely available blood tests and anthropometrics, have a high negative predictive value for advanced fibrosis/cirrhosis (Box 22.48) and so can be used to rule out advanced fibrosis in many NAFLD patients. This allows care to focus on those most likely to have advanced disease.

Imaging

Ultrasound is most often used and provides a qualitative assessment of hepatic fat content, as the liver appears 'bright' due to increased echogenicity; sensitivity is limited when fewer than 33% of hepatocytes are steatotic, however. CT, MRI or MR spectroscopy offer greater sensitivity for detecting lesser degrees of steatosis, but these are resource-intensive and not widely used. No routine imaging modality can distinguish simple steatosis from steatohepatitis or accurately quantify hepatic fibrosis short of cirrhosis.

Liver biopsy

Liver biopsy remains the 'gold standard' investigation for diagnosis and assessment of degree of inflammation and extent of liver fibrosis. The histological definition of NASH is based on a combination of three lesions (steatosis, hepatocellular injury and inflammation; see Fig. 22.30A) with a mainly centrilobular, acinar zone 3 distribution. Specific features include hepatocyte ballooning degeneration with or without acidophil bodies or spotty necrosis and a mild, mixed inflammatory infiltrate. These may be accompanied by Mallory–Denk bodies (also known as Mallory's hyaline). Perisinusoidal fibrosis is a characteristic feature of NASH. Histological scoring systems are widely used to assess disease severity semi-quantitatively.

It is important to note that hepatic fat content tends to diminish as cirrhosis develops and so NASH is likely to be under-diagnosed in the setting of advanced liver disease, where it is thought to be the underlying cause of 30–75% of cases in which no specific aetiology is readily identified (so-called 'cryptogenic cirrhosis').

Management

As it is a marker of the metabolic syndrome, identification of NAFLD should prompt screening for and treatment of cardiovascular risk factors in all patients. It is also necessary to assess whether patients have progressive disease and advanced fibrosis so that liver-targeted treatment can be focused particularly on those patients. While liver biopsy is best able to do this, it is invasive and unsuitable for widespread use outside the specialist care setting. An example of an algorithm for the assessment and risk stratification of patients with NAFLD is provided in Figure 22.31.

Non-pharmacological treatment

Current treatment comprises lifestyle interventions to promote weight loss and improve insulin sensitivity through dietary changes

22.48 Simple non-invasive scores for non-alcoholic fatty liver disease (NAFLD)/fibrosis*

Test	Formula	Thresholds: Age <65 years	Thresholds: Age >65 years
NAFLD Fibrosis Score (NFS)	–1.675 + 0.037 × Age (years) + 0.094 × BMI (kg/m^2) + 1.13 × IFG or diabetes (yes = 1, no = 0) + 0.99 × AST/ALT ratio – 0.013 × platelet count (× 10^9/L) – 0.66 × albumin (g/dL)	High risk (NFS >0.676) Indeterminate risk (NFS –1.455–0.676) Low risk (NFS <–1.455)	High risk (NFS >0.676) Indeterminate risk (NFS 0.12–0.676) Low risk (NFS <0.12)
FIB-4 Score	Age (years) × AST (IU/L)/platelet count (× 10^9/L) × √ALT (IU/L)	High risk (FIB-4 >2.67) Indeterminate risk (FIB-4 1.30–2.67) Low risk (FIB-4 <1.30)	High risk (FIB-4 >2.67) Indeterminate risk (2.00–2.67) Low risk (FIB-4 <2.00)

*Predict advanced fibrosis and cirrhosis (F3–4). Simple scores like NFS and FIB-4 are based on the results of routinely available blood tests and anthropometrics. Online calculators for these are widely available.
(ALT = alanine aminotransferase; AST = aspartate aminotransferase; BMI = body mass index; IFG = impaired fasting glucose)

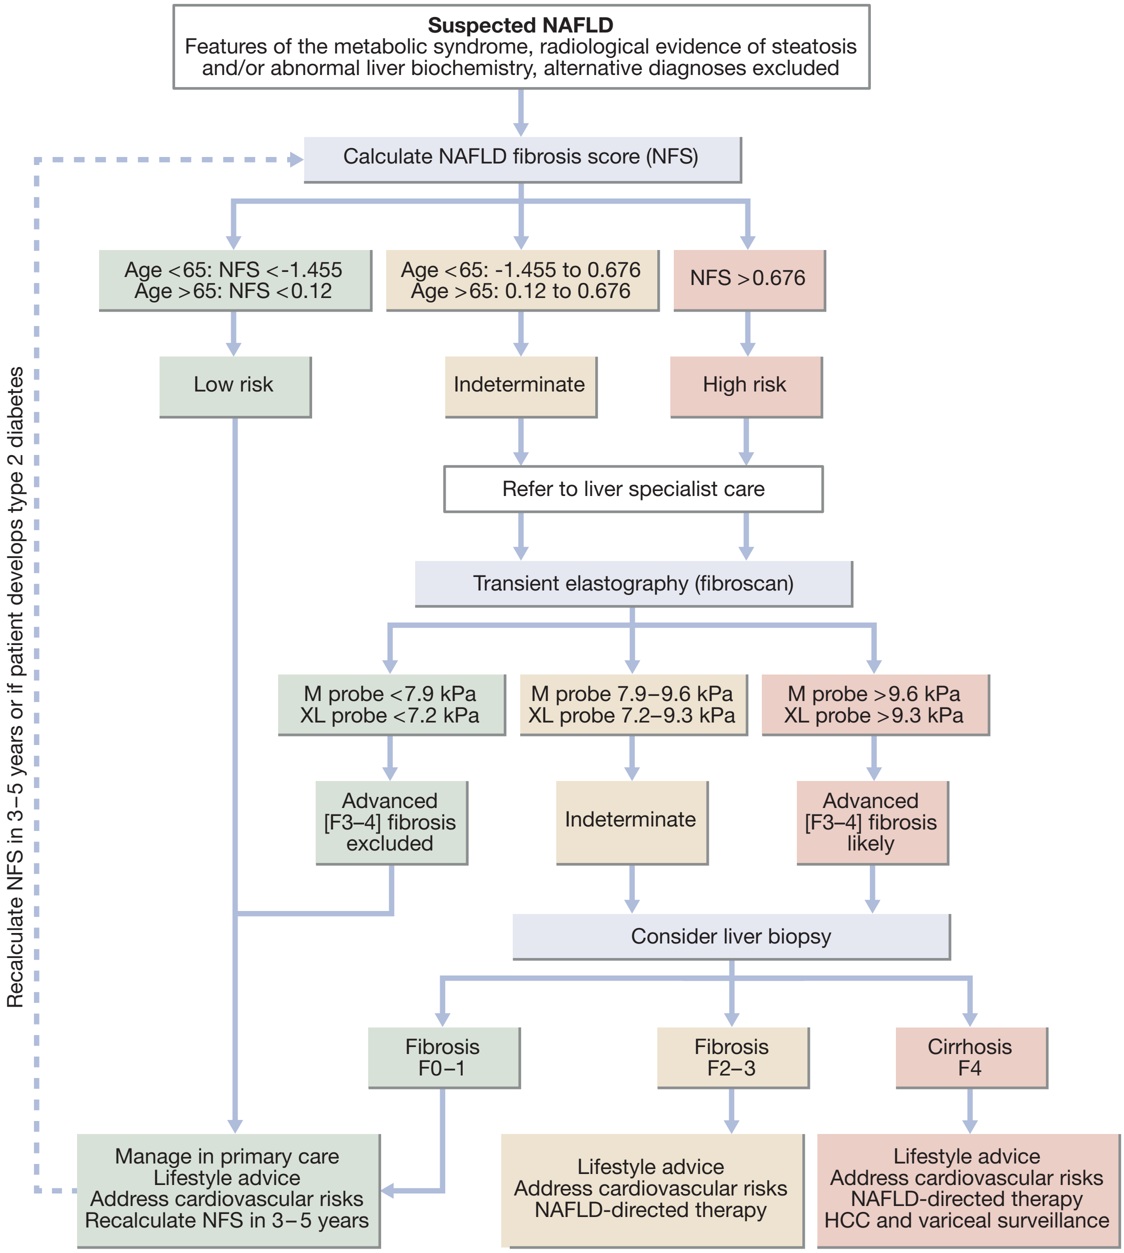

Fig. 22.31 Assessment and risk stratification of patients with non-alcoholic fatty liver disease (NAFLD). (HCC = hepatocellular carcinoma; M probe = medium probe; XL = large probe)

and physical exercise. Sustained weight reduction of 7–10% is associated with significant improvement in histological and biochemical NASH severity.

Pharmacological treatment

No pharmacological agents are currently licensed specifically for NASH therapy. Treatment directed at coexisting metabolic disorders, such as dyslipidaemia and hypertension, should be given. Although use of HMG-CoA reductase inhibitors (statins) does not ameliorate NAFLD, there does not appear to be any increased risk of hepatotoxicity or other side-effects from these agents, and so they may be used to treat dyslipidaemia. Specific insulin-sensitising agents, in particular glitazones, may help selected patients, while recent results with bezafibrate, a lipid-lowering fibrate, have been encouraging. Positive results with high-dose vitamin E (800 U/day) have been tempered by evidence that high doses may be associated with an increased risk of prostate cancer and all-cause mortality, which has limited its use. Several new medicines are currently in late-phase clinical trials and so liver-targeted pharmacological treatments are likely to be available within the next few years.

Autoimmune liver and biliary disease

The liver is an important target for autoimmune injury. The clinical picture is dictated by the nature of the autoimmune process and, in particular, the target cell for immune injury. The disease patterns are quite distinctive for primary hepatocellular injury (in the context of autoimmune hepatitis) and biliary epithelial cell injury (primary biliary cholangitis and primary sclerosing cholangitis).

Autoimmune hepatitis

Autoimmune hepatitis is a disease of immune-mediated liver injury characterised by the presence of serum antibodies and peripheral blood T lymphocytes reactive with self-proteins, a strong association with other autoimmune diseases (Box 22.49), and high levels of serum immunoglobulins – in particular, elevation of IgG. Although most commonly seen in women, particularly in the second and third decades of life, it can develop in either sex at any age. The reasons for the breakdown in immune tolerance in autoimmune hepatitis remain unclear, although cross-reactivity with viruses such as HAV and EBV in immunogenetically susceptible individuals (typically those with human leucocyte antigen (HLA)-DR3 and DR4, particularly HLA-DRB3*0101 and HLA-DRB1*0401) has been suggested as a mechanism.

Pathophysiology

Several subtypes of this disorder have been proposed that have differing immunological markers. Although the different patterns can be associated with variation in disease aspects, such as response to immunosuppressive therapy, histological patterns are similar in the different settings and the basic approach to treatment (complete control of liver injury using immunosuppressive drugs and maintained with appropriate therapy) is the same. The formal classification into disease types has fallen out of favour in recent years.

The most frequently seen autoantibody pattern is high titre of antinuclear and anti-smooth muscle antibodies, typically associated with IgG hyperglobulinaemia (type I autoimmune hepatitis in the old classification), frequently seen in young adult females. Disease characterised by the presence of anti-liver–kidney microsomal (LKM) antibodies, recognising cytochrome P450-IID6 expressed on the hepatocyte membrane, is typically seen in paediatric populations and can be more resistant to treatment than ANA-positive disease. Adult onset of anti-LKM can be seen in chronic HCV infection. This was classified as type II disease in the old system. More recently, a pattern of antibody reactivity with anti-soluble liver antigen (anti-SLA) has been described in typically adult patients, often with aggressive disease and usually lacking autoantibodies of other specificities.

Clinical features

The onset is usually insidious, with fatigue, anorexia and eventually jaundice. The non-specific nature of the early features can lead to the diagnosis being missed in the early disease stages. In about one-quarter of patients the onset is acute, resembling viral hepatitis, but resolution does not occur. This acute presentation can lead to extensive liver necrosis and liver failure. Other features include fever, arthralgia, vitiligo and epistaxis. Amenorrhoea can occur. Jaundice is mild to moderate or occasionally absent, but signs of chronic liver disease, especially spider naevi and hepatosplenomegaly, can be present. Associated autoimmune disease, such as Hashimoto's thyroiditis or rheumatoid arthritis, is often present and can modulate the clinical presentation.

Investigations

Serological tests for autoantibodies are often positive (Box 22.50), but low titres of these antibodies occur in some healthy people and in patients with other inflammatory liver diseases. ANA also occur in connective tissue diseases and other autoimmune diseases (with an identical pattern of homogenous nuclear staining) while anti-smooth muscle antibody has been reported in infectious mononucleosis and a variety of malignant diseases. Anti-microsomal antibodies (anti-LKM) occur particularly in children and adolescents. Elevated serum IgG levels are an important diagnostic and treatment response feature if present, but the diagnosis is still possible in the presence of normal IgG levels. If the diagnosis of autoimmune hepatitis is suspected, liver biopsy should be performed. It typically shows interface hepatitis, with or without cirrhosis. Scoring systems, such as the International Autoimmune Hepatitis Group (IAIHG) criteria, are useful for epidemiological study and for assessing trial eligibility but are complex for normal clinical practice.

Management

Treatment with glucocorticoids is life-saving in autoimmune hepatitis, particularly during exacerbations of active and symptomatic disease. Initially, prednisolone (40 mg/day) is given orally; the dose is then gradually reduced as the patient and LFTs improve. Maintenance therapy should only be instituted once LFTs are normal (as well as IgG if elevated). Approaches to maintenance include reduced-dose prednisolone (ideally, below 5–10 mg/day), usually in the context of azathioprine (1.0–1.5 mg/kg/day). Azathioprine can also be used as the sole maintenance immunosuppressive agent in patients with low-activity disease. Newer agents, such as mycophenolate mofetil (MMF), are increasingly being used but formal evidence to inform practice in this area is lacking. Patients should be monitored for acute exacerbations (LFT and IgG screening with patients alerted

22.49 Conditions associated with autoimmune hepatitis

- Migrating polyarthritis
- Urticarial rashes
- Lymphadenopathy
- Hashimoto's thyroiditis
- Thyrotoxicosis
- Myxoedema
- Pleurisy
- Coombs-positive haemolytic anaemia
- Transient pulmonary infiltrates
- Ulcerative colitis
- Glomerulonephritis
- Nephrotic syndrome

22.50 Frequency of autoantibodies in chronic non-viral liver diseases and in healthy people

Disease	Antinuclear antibody (%)	Anti-smooth muscle antibody (%)	Antimitochondrial antibody*
Healthy controls	5	1.5	0.01
Autoimmune hepatitis	80	70	15
Primary biliary cholangitis	25	35	95
Cryptogenic cirrhosis	40	30	15

*Patients with antimitochondrial antibody frequently have cholestatic liver function tests and may have primary biliary cholangitis (see text).

to the possible symptoms) and such exacerbations should be treated with glucocorticoids. Although treatment can significantly reduce the rate of progression to cirrhosis, end-stage disease can be seen in patients despite treatment.

Primary biliary cholangitis

Primary biliary cholangitis (PBC, known as primary biliary cirrhosis until 2015, when the name was changed to reflect more accurately the disease seen in the modern era) is a chronic, progressive cholestatic liver disease that predominantly affects women aged 30 and over. It is strongly associated with the presence of antimitochondrial antibodies (AMA), which are diagnostic, and is characterised by a granulomatous inflammation of the portal tracts, leading to progressive damage and eventually loss of the small and middle-sized bile ducts. This, in turn, leads to fibrosis and cirrhosis of the liver. The condition can present with an insidious onset of itching and/or tiredness; it may also frequently be found incidentally as the result of routine blood tests.

Epidemiology

The prevalence of PBC varies across the world. It is relatively common in northern Europe and North America but is rare in Africa and Asia. There is a strong female-to-male predominance of 9:1; it is also more common among cigarette smokers. Clustering of cases has been reported, suggesting an environmental trigger in susceptible individuals.

Pathophysiology

Immune mechanisms are clearly involved. The condition is closely associated with other autoimmune non-hepatic diseases, such as thyroid disease, and there is a genetic association with HLA-DR8, together with polymorphisms in a number of other genes regulating the nature of the immune response (e.g. IL-12 and its receptor). AMA is directed at pyruvate dehydrogenase complex, a mitochondrial enzyme complex that plays a key role in cellular energy generation. PBC-specific ANAs (such as those directed at the nuclear pore antigen gp210) have a characteristic staining pattern in immunofluorescence assays (selectively binding to the nuclear rim or nuclear dots), which means that they should not be mistaken for the homogenously staining ANA seen in autoimmune hepatitis. Increases in serum immunoglobulin levels are frequent but, unlike in autoimmune hepatitis, it is typically IgM that is elevated.

Pathologically, chronic granulomatous inflammation destroys the interlobular bile ducts; progressive lymphocyte-mediated inflammatory damage causes fibrosis, which spreads from the portal tracts to the liver parenchyma and eventually leads to cirrhosis. A model of the natural history of the disease process is shown in Figure 22.32.

Clinical features

Systemic symptoms such as fatigue are common and may precede diagnosis by years. Pruritus, which can be a feature of any cholestatic disease, is a common presenting complaint and may precede jaundice by months or years. Jaundice is rarely a presenting feature. The itching is usually worse on the limbs. Although there may be right upper abdominal discomfort, fever and rigors do not occur. Bone pain or fractures can rarely result from osteomalacia (fat-soluble vitamin malabsorption) or, more commonly, from osteoporosis (hepatic osteodystrophy).

Initially, patients are well nourished but weight loss can occur as the disease progresses. Scratch marks may be found in

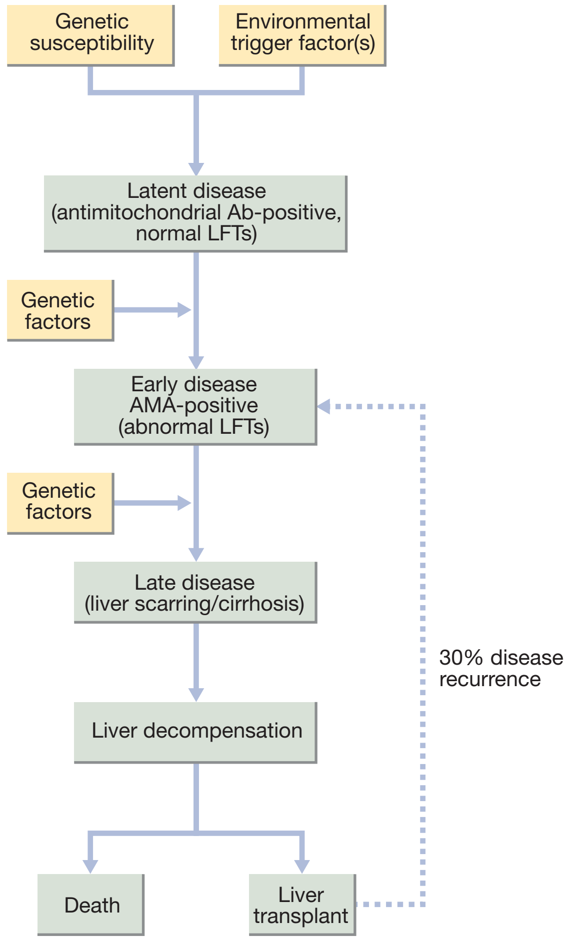

Fig. 22.32 Natural history of primary biliary cholangitis. (AMA = antimitochondrial antibody; LFTs = liver function tests)

patients with severe pruritus. Jaundice is prominent only late in the disease and can become intense. Xanthomatous deposits occur in a minority, especially around the eyes. Mild hepatomegaly is common and splenomegaly becomes increasingly common as portal hypertension develops. Liver failure may supervene.

Associated diseases

Autoimmune and connective tissue diseases occur with increased frequency in PBC, particularly the sicca syndrome (p. 1038), systemic sclerosis, coeliac disease (p. 805) and thyroid diseases. Hypothyroidism should always be considered in patients with fatigue.

Diagnosis and investigations

The LFTs show a pattern of cholestasis (see Box 22.2, p. 853). Hypercholesterolaemia is common and worsens as disease progresses but appears not to be associated with increased cardiac risk. AMA is present in over 95% of patients; when it is absent, the diagnosis should not be made without obtaining histological evidence and considering cholangiography (typically, MRCP) to exclude other biliary disease. ANA and anti-smooth muscle antibodies are present in around 15% of patients (see Box 22.50); autoantibodies found in associated diseases may also be present. Ultrasound examination shows no sign of biliary obstruction. Liver biopsy is necessary only if there is diagnostic uncertainty. The histological features of PBC correlate poorly with

the clinical features; portal hypertension can develop before the histological onset of cirrhosis.

Management

The hydrophilic bile acid ursodeoxycholic acid (UDCA), at a dose of 13–15 mg/kg/day, improves bile flow, replaces toxic hydrophobic bile acids in the bile acid pool, and reduces apoptosis of the biliary epithelium. Clinically, UDCA improves LFTs, may slow down histological progression and has few side-effects; it is therefore widely used in the treatment of PBC and should be regarded as the optimal first-line treatment. Its use is recommended in all clinical guidelines. A significant minority of patients either fail to normalise their LFTs with UDCA or show an inadequate response, and such individuals have an increased risk of developing end-stage liver disease compared to those showing a full response. Obeticholic acid (OCA) is a second-generation bile acid therapeutic that acts as an agonist for the nuclear farnesoid X receptor. It reduces hepatocyte synthesis of bile acids and was approved in 2016 for use in patients showing an inadequate response to UDCA. Immunosuppressants, such as glucocorticoids, azathioprine, penicillamine and ciclosporin, have all been trialled in PBC. None shows overall benefit when given to unselected patients. It is unclear whether these drugs offer benefit to the specific subgroup of patients who do not respond to UDCA and require second-line approaches to treatment.

Liver transplantation should be considered once liver failure has developed and may be indicated in patients with intractable pruritus. Serum bilirubin remains the most reliable marker of declining liver function. Transplantation is associated with an excellent 5-year survival of over 80%, although the disease will recur in over one-third of patients at 10 years.

Pruritus

This is the main symptom requiring treatment. The cause is unknown, but up-regulation of opioid receptors and increased levels of endogenous opioids may play a role. First-line treatment is with the anion-binding resin colestyramine, which probably acts by binding potential pruritogens in the intestine and increasing their excretion in the stool. A dose of 4–16 g/day orally is used. The powder is mixed in orange juice and the main dose (8 g) taken before and after breakfast, when maximal duodenal bile acid concentrations occur. Colestyramine may bind other drugs in the gut (most obviously UDCA) and adequate spacing should be used between drugs. Colestyramine is sometimes ineffective, especially in complete biliary obstruction, and can be difficult for some patients to tolerate. Alternative treatments include rifampicin (150 mg/day, titrated up to a maximum of 600 mg/day as required and contingent on there being no deterioration in LFTs), naltrexone (an opioid antagonist; 25 mg/day initially, increasing up to 300 mg/day), plasmapheresis and a liver support device (e.g. a molecular adsorbent recirculating system, MARS).

Fatigue

Fatigue affects about one-third of patients with PBC. The cause is unknown but it may reflect intracerebral changes due to cholestasis. Unfortunately, once depression, hypothyroidism and coeliac disease have been excluded, there is currently no specific treatment. The impact on patients' lives can be substantial.

Malabsorption

Prolonged cholestasis is associated with steatorrhoea and malabsorption of fat-soluble vitamins, which should be replaced as necessary. Coeliac disease should be excluded since its incidence is increased in PBC.

Bone disease

Osteopenia and osteoporosis are common and normal post-menopausal bone loss is accelerated. Baseline bone density should be measured (p. 989) and treatment started with replacement calcium and vitamin D_3. Bisphosphonates should be used if there is evidence of osteoporosis. Osteomalacia is rare.

Overlap syndromes

AMA-negative PBC ('autoimmune cholangitis')

A few patients demonstrate the clinical, biochemical and histological features of PBC but do not have detectable AMA in the serum. Serum transaminases, serum immunoglobulin levels and titres of ANA tend to be higher than in AMA-positive PBC. The clinical course mirrors classical PBC, however, and these patients should be considered as having a variant of PBC.

PBC/autoimmune hepatitis overlap

A few patients with AMA and cholestatic LFTs have elevated transaminases, high serum immunoglobulins and interface hepatitis on liver histology. In such individuals, a trial of glucocorticoid therapy may be beneficial.

Primary sclerosing cholangitis

Primary sclerosing cholangitis (PSC) is a cholestatic liver disease caused by diffuse inflammation and fibrosis; it can involve the entire biliary tree and leads to the gradual obliteration of intrahepatic and extrahepatic bile ducts, and ultimately biliary cirrhosis, portal hypertension and hepatic failure. Although considered as an autoimmune disease, evidence for an autoimmune pathophysiology is weaker than is the case for PBC and autoimmune hepatitis. The incidence is about 6.3/100 000 in Caucasians. Cholangiocarcinoma develops in about 10–30% of patients during the course of the disease.

PSC is twice as common in young men. Most patients present at age 25–40 years, although the condition may be diagnosed at any age and is an important cause of chronic liver disease in children. The generally accepted diagnostic criteria are:

- generalised beading and stenosis of the biliary system on cholangiography (Fig. 22.33)
- absence of choledocholithiasis (or history of bile duct surgery)
- exclusion of bile duct cancer, by prolonged follow-up.

The term 'secondary sclerosing cholangitis' is used to describe the typical changes described above when a clear predisposing factor for duct fibrosis can be identified. The causes of secondary sclerosing cholangitis are shown in Box 22.51.

Pathophysiology

The cause of PSC is unknown but there is a close association with inflammatory bowel disease, particularly ulcerative colitis (Box 22.52). About two-thirds of patients have coexisting ulcerative colitis, and PSC is the most common form of chronic liver disease in ulcerative colitis. Between 3% and 10% of patients with ulcerative colitis develop PSC, particularly those with extensive colitis or pancolitis. The prevalence of PSC is lower in patients with Crohn's colitis (about 1%). Patients with PSC and ulcerative colitis are at greater risk of colorectal neoplasia than those with ulcerative colitis alone, and individuals who develop colorectal neoplasia are at greater risk of cholangiocarcinoma.

It is currently believed that PSC is an immunologically mediated disease, triggered in genetically susceptible individuals by toxic

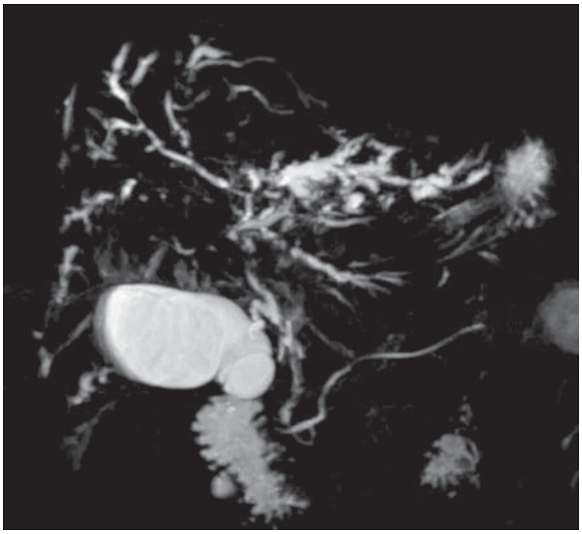

Fig. 22.33 Magnetic resonance cholangiopancreatogram showing typical changes of primary sclerosing cholangitis. There is intrahepatic bile duct beading, stricturing and dilatation. The extrahepatic bile duct is also diffusely strictured. *Courtesy of Dr Dilip Patel, Royal Infirmary of Edinburgh.*

i 22.51 Causes of secondary sclerosing cholangitis

- Previous bile duct surgery with stricturing and cholangitis
- Bile duct stones causing cholangitis
- Intrahepatic infusion of 5-fluorodeoxyuridine
- Insertion of formalin into hepatic hydatid cysts
- Insertion of alcohol into hepatic tumours
- Parasitic infections (e.g. *Clonorchis*)
- Autoimmune pancreatitis/immunoglobulin G4-associated cholangitis
- Acquired immunodeficiency syndrome (AIDS; probably infective as a result of cytomegalovirus or *Cryptosporidium*)

i 22.52 Diseases associated with primary sclerosing cholangitis

- Ulcerative colitis
- Crohn's colitis
- Chronic pancreatitis
- Retroperitoneal fibrosis
- Riedel's thyroiditis
- Retro-orbital tumours
- Immune deficiency states
- Sjögren's syndrome
- Angio-immunoblastic lymphoma
- Histiocytosis X
- Autoimmune haemolytic anaemia
- Autoimmune pancreatitis/ immunoglobulin G4-associated cholangitis

or infectious agents, which may gain access to the biliary tract through a leaky, diseased colon. A close link with HLA haplotype A1-B8-DR3-DRW52A has been identified. This haplotype is commonly found in association with other organ-specific autoimmune diseases (e.g. autoimmune hepatitis).

The importance of immunological factors has been emphasised by reports showing humoral and cellular abnormalities in PSC. Perinuclear antineutrophil cytoplasmic antibodies (ANCA) have been detected in the sera of 60–80% of patients with PSC with or without ulcerative colitis, and in 30–40% of patients with ulcerative colitis alone. The antibody is not specific for PSC and is found in other chronic liver diseases (e.g. 50% of patients with autoimmune hepatitis).

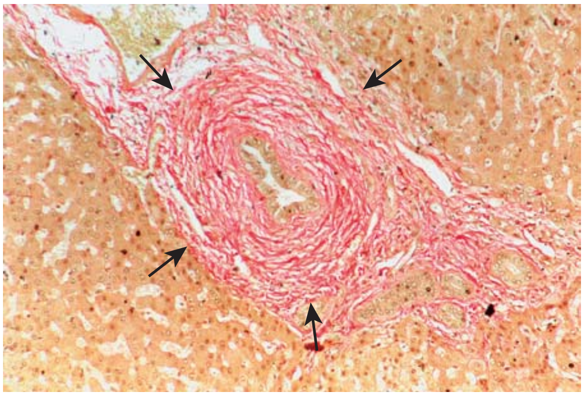

Fig. 22.34 Primary sclerosing cholangitis. Note onion skin scarring (arrows) surrounding a bile duct.

Clinical features

The diagnosis is often made incidentally when persistently raised serum ALP is discovered in an individual with ulcerative colitis. Common symptoms include fatigue, intermittent jaundice, weight loss, right upper quadrant abdominal pain and pruritus. Attacks of acute cholangitis are uncommon and usually follow biliary instrumentation. Physical examination is abnormal in about 50% of symptomatic patients; the most common findings are jaundice and hepatomegaly/splenomegaly. The condition may be associated with many other diseases (Box 22.52).

Investigations

Biochemical screening usually reveals a cholestatic pattern of LFTs but ALP and bilirubin levels may vary widely in individual patients during the course of the disease. For example, ALP and bilirubin values increase during acute cholangitis, decrease after therapy, and sometimes fluctuate for no apparent reason. Modest elevations in serum transaminases are usually seen, whereas hypoalbuminaemia and clotting abnormalities are found at a late stage only. In addition to ANCA, low titres of serum ANA and anti-smooth muscle antibodies may be found in PSC but have no diagnostic significance; serum AMA is absent.

The key investigation is now MRCP, which is usually diagnostic and reveals multiple irregular stricturing and dilatation (Fig. 22.33). ERCP should be reserved for when therapeutic intervention is likely to be necessary and should follow MRCP.

On liver biopsy, the characteristic early features of PSC are periductal 'onion skin' fibrosis and inflammation, with portal oedema and bile ductular proliferation resulting in expansion of the portal tracts (Fig. 22.34). Later, fibrosis spreads, progressing inevitably to biliary cirrhosis; obliterative cholangitis leads to the so-called 'vanishing bile duct syndrome'.

Management

There is no cure for PSC but management of cholestasis and its complications and specific treatment of the disease process are indicated. UDCA is widely used, although the evidence to support this is limited. UDCA may have benefit in terms of reducing colon carcinoma risk.

The course of PSC is variable. In symptomatic patients, median survival from presentation to death or liver transplantation is about 12 years. About 75% of asymptomatic patients survive 15 years or more. Most patients die from liver failure, about 30% die from bile duct carcinoma, and the remainder die from colonic cancer or complications of colitis. Immunosuppressive agents, including

prednisolone, azathioprine, methotrexate and ciclosporin, have been tried; results have generally been disappointing.

Symptomatic patients often have pruritus. Management is as for PBC. Fatigue appears to be less prominent than in PBC, although it is still present in some patients.

Management of complications

Broad-spectrum antibiotics (e.g. ciprofloxacin) should be given for acute attacks of cholangitis but have no proven value in preventing attacks. If cholangiography shows a well-defined obstruction to the extrahepatic bile ducts ('dominant stricture'), mechanical relief can be obtained by placement of a stent or by balloon dilatation performed at ERCP. It is important, in this situation, to give active consideration to the possibility of cholangiocarcinoma (the differential diagnosis for a dominant extrahepatic stricture). Fat-soluble vitamin replacement is necessary in jaundiced patients. Metabolic bone disease (usually osteoporosis) is a common complication that requires treatment (p. 1044).

Surgical treatment

Surgical resection of the extrahepatic bile duct and biliary reconstruction have a limited role in the management of non-cirrhotic patients with dominant extrahepatic disease. Orthotopic transplantation is the only surgical option in patients with advanced liver disease; 5-year survival is 80–90% in most centres. Unfortunately, the condition may recur in the graft and there are no identified therapies able to prevent this. Cholangiocarcinoma is a contraindication to transplantation. Colon carcinoma risk can be increased in patients following transplantation because of the effects of immune suppression, and enhanced surveillance should be instituted.

IgG4-associated cholangitis

This disease (as well as its nomenclature) is closely related to autoimmune pancreatitis (which is present in more than 90% of the patients; p. 841). IgG4-associated cholangitis (IAC) often presents with obstructive jaundice (due to either hilar stricturing/intrahepatic sclerosing cholangitis or a low bile duct stricture), and cholangiographic appearances suggest PSC with or without hilar cholangiocarcinoma. The serum IgG4 is often raised and liver biopsy shows a lymphoplasmacytic infiltrate, with IgG4-positive plasma cells. An important observation is that, compared to PSC, IAC appears to respond well to glucocorticoid therapy.

Liver tumours and other focal liver lesions

Identification of a hepatic mass lesion is common, both in patients with known pre-existing liver disease and as a primary presentation. Although primary and secondary malignant tumours are important potential diagnoses, benign disease is frequent. The finding of a liver mass, with its association in the minds of patients with metastatic malignant disease, creates a high level of anxiety, a factor that should always be borne in mind. The critical steps to be taken in diagnosing hepatic mass lesions are:

- determining the presence, nature and severity of any underlying chronic liver disease, as the differential diagnosis is very different in patients with and those without chronic liver disease
- using optimal (usually multiple) imaging modalities.

Primary malignant tumours

Hepatocellular carcinoma

Hepatocellular carcinoma (HCC) is the most common primary liver tumour, and the sixth most frequent cause of cancer worldwide. Cirrhosis is present in 75–90% of individuals with HCC and is an important risk factor for the disease. The risk is between 1% and 5% in cirrhosis caused by hepatitis B and C. There is also an increased risk in cirrhosis due to haemochromatosis, alcohol, NASH and α_1-antitrypsin deficiency. In northern Europe, 90% of those with HCC have underlying cirrhosis, compared with 30% in Taiwan, where hepatitis B is the main risk factor. The age-adjusted incidence rates vary from 28 per 100 000 in South-east Asia (reflecting the prevalence of hepatitis B) to 10 per 100 000 in southern Europe and 5 per 100 000 in northern Europe. Chronic hepatitis B infection increases the risk of HCC 100-fold and is the major risk factor worldwide. The risk of HCC is 0.4% per year in the absence of cirrhosis and 2–6% in cirrhosis. The risk is four times higher in HBeAg-positive individuals than in those who are HBeAg-negative. Hepatitis B vaccination has led to a fall in HCC in countries with a high prevalence of hepatitis B. The incidence in Europe and North America has risen recently, probably related to the increased prevalence of hepatitis C and NASH cirrhosis. The risk is higher in men and rises with age.

Macroscopically, the tumour usually appears as a single mass in the absence of cirrhosis, or as a single nodule or multiple nodules in the presence of cirrhosis. It takes its blood supply from the hepatic artery and tends to spread by invasion into the portal vein and its radicals. Lymph node metastases are common, while lung and bone metastases are rare. Well-differentiated tumours can resemble normal hepatocytes and can be difficult to distinguish from normal liver.

Clinical features

Patients typically present with HCC in one of two ways. Commonly, liver function deteriorates in those with underlying cirrhosis, with worsening ascites and/or jaundice or variceal haemorrhage. Other characteristic symptoms can include weight loss, anorexia and abdominal pain. This often-rapid deterioration can, however, be the event that leads to previously occult cirrhosis becoming clinically apparent, meaning that absence of an established diagnosis of cirrhosis does not preclude a diagnosis of HCC complicating cirrhosis. Examination may reveal hepatomegaly or a right hypochondrial mass. Tumour vascularity can lead to an abdominal bruit, and hepatic rupture with intra-abdominal bleeding may occur. The advanced nature of disease that presents in this way makes curative therapy unlikely.

The second presentation is through screening of patients at risk of HCC. The disease is typically detected much earlier in its natural history, significantly increasing the treatment options.

Investigations

Serum markers

Alpha-fetoprotein (AFP) is produced by 60% of HCCs. Levels increase with the size of the tumour and are often normal or only minimally elevated in small tumours detected by ultrasound screening. Serum AFP can also rise in the presence of active hepatitis B and C viral replication; very high levels are seen in acute hepatic necrosis, such as that following paracetamol toxicity. AFP is used in conjunction with ultrasound in screening but, in view of low sensitivity and specificity, levels need to

be interpreted with caution. Nevertheless, in the absence of a marked hepatic flare of disease, a progressively rising AFP, or AFP of >400 ng/mL (330 IU/mL; normal is <10 ng/mL (8 IU/mL), warrants an aggressive search for HCC. In HCC patients with elevated AFP levels, serial measurements can be a useful biomarker of disease progression or response to treatment.

Imaging

Ultrasound will detect focal liver lesions as small as 2–3 cm. The use of ultrasound contrast agents has increased sensitivity and specificity but is highly user-dependent. Ultrasound may also show evidence of portal vein involvement and features of coexistent cirrhosis. Multidetector row CT, following intravenous contrast, identifies HCC by its classical hypervascular appearance (Fig. 22.35). Small lesions of less than 2 cm can be difficult to differentiate from hyperplastic nodules in cirrhosis. MRI can be used instead. Angiography is now seldom performed and has been superseded by the above techniques. A combination of imaging modalities more accurately diagnoses and stages the extent of disease, and use of at least two modalities (typically, CT or MRI following initial screening ultrasound identification of a mass lesion) is recommended.

Liver biopsy

Histological confirmation is advisable in patients with large tumours who do not have cirrhosis or hepatitis B, in order to confirm the diagnosis and exclude metastatic tumour. Biopsy should be avoided in patients who may be eligible for transplantation or surgical resection because there is a small (<2%) risk of tumour seeding along the needle tract. In all cases of potential HCC where biopsy is being considered, the impact that a confirmed diagnosis will have on therapy must be weighed against the risks of bleeding. If biopsy will not change management, then its appropriateness should be considered carefully.

Role of screening

Screening for HCC, by ultrasound scanning and AFP measurements at 6-month intervals, is indicated in high-risk patients who would be suitable for therapy if diagnosed with HCC. These include individuals with cirrhosis caused by hepatitis B and C, haemochromatosis, alcohol, NASH and α_1-antitrypsin deficiency.

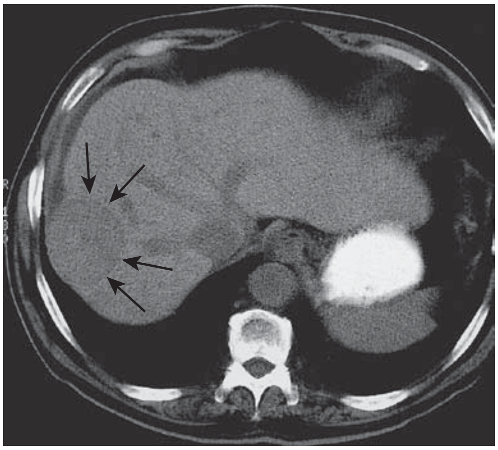

Fig. 22.35 Computed tomogram showing a large hepatocellular carcinoma (arrows). *Courtesy of Dr D. Redhead, Royal Infirmary of Edinburgh.*

Screening may also be indicated in those with chronic hepatitis B (who carry an increased risk of HCC, even in the absence of cirrhosis). Although no randomised controlled studies of outcome have been undertaken, screening identifies smaller tumours, often less than 3 cm in size, which are more likely to be cured by surgical resection, local ablative therapy or transplantation. The role of screening in other forms of chronic liver disease, such as autoimmune hepatitis and PBC, is unclear. This is compounded by the fact that disease staging by biopsy is no longer standard practice in conditions such as PBC, so formal documentation of the presence of cirrhosis, which might be the trigger for commencement of HCC screening, rarely takes place.

Management

This is different for patients with cirrhosis and those without. In the presence of cirrhosis, tumour size, multicentricity, extent of liver disease (Child–Pugh score) and performance status dictate therapy. An algorithm for managing those with cirrhosis is shown in Figure 22.36.

Prognosis depends on tumour size, the presence of vascular invasion, and liver function in those with cirrhosis. Screening has improved the outlook through early detection.

Hepatic resection

This is the treatment of choice for non-cirrhotic patients. The 5-year survival in this group is about 50%. There is a 50% recurrence rate at 5 years, however, which may be due to a second de novo tumour or recurrence of the original tumour. Few patients with cirrhosis are suitable for hepatic resection because of the high risk of hepatic failure; nevertheless, surgery is offered, particularly in the Far East, to some cirrhotic patients with small tumours and good liver function (Child–Pugh A with no portal hypertension).

Liver transplantation

Transplantation has the benefit of curing underlying cirrhosis and removing the risk of a second, de novo tumour in an at-risk patient. The requirement for immunosuppression creates its own risks of reactivation, however, if residual or metastatic disease is present, and assessment of patients for suitability for liver transplantation focuses on the exclusion of extrahepatic disease and vascular invasion. The 5-year survival following liver transplantation is 75% for patients with single tumours of less than 5 cm in size or three tumours smaller than 3 cm (the Milan criteria). Unfortunately, the underlying liver disease, in particular hepatitis C, may recur in the transplanted liver and can result in recurrent cirrhosis that gives rise to a de novo HCC risk, now complicated by the presence of immunosuppression.

Percutaneous therapy

Percutaneous ethanol injection into the tumour under ultrasound guidance is efficacious (80% cure rate) for tumours of 3 cm or less. Recurrence rates (50% at 3 years) are similar to those following surgical resection. Radiofrequency ablation, using a single electrode inserted into the tumour under radiological guidance, is an alternative that takes longer to perform but may cause more complete tumour necrosis. Improvements in percutaneous therapy, with the combination of low patient impact, relative efficacy and capacity for repeat treatment, are making these approaches attractive, particularly when major surgery would be inappropriate. Their role in primary therapy as an alternative to curative resection or transplantation is yet to be established.

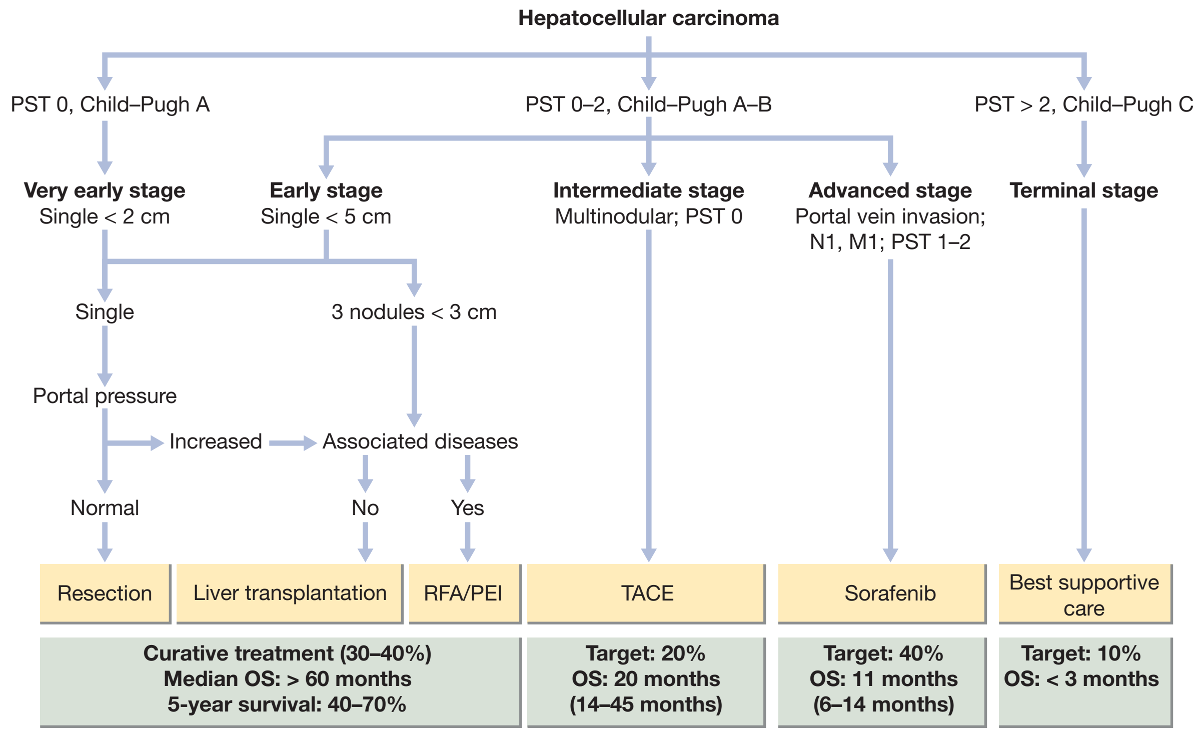

Fig. 22.36 Management of hepatocellular carcinoma complicating cirrhosis. Performance status (PST; see Box 33.3, p. 1322): 0 = fully active, no symptoms; >2 = limited self-care, confined to bed or chair for 50% of waking hours. Child–Pugh score: see Box 22.29, p. 867. N1, M1: lymph node involvement and metastases (for TNM classification, see Box 33.4, p. 1322) (OS = overall survival; PEI = percutaneous ethanol injection; RFA = radiofrequency ablation; TACE = trans-arterial chemo-embolisation). *Based on European Association for the Study of the Liver, European Organisation for Research and Treatment of Cancer. EASL–EORTC clinical practice guidelines: Management of hepatocellular carcinoma. J Hepatol 2012; 56:908–943.*

Trans-arterial chemo-embolisation

Hepatocellular cancers are not radiosensitive and the response rate to chemotherapy with drugs, such as doxorubicin, is only around 30%. In contrast, hepatic artery embolisation with absorbable gelatin powder (Gelfoam) and doxorubicin is more effective, with survival rates of 60% in cirrhotic patients with unresectable HCC and good liver function (compared with 20% in untreated patients) at 2 years. Unfortunately, any survival benefit is lost at 4 years. Trans-arterial chemo-embolisation (TACE) is contraindicated in decompensated cirrhosis and multifocal HCC. TACE is now most frequently used as a holding first intervention while the tumour is being assessed and the definitive management plan is being developed.

Chemotherapy

Sorafenib improves survival from 7.9 to 10.7 months in cirrhotic patients. The drug is a multikinase inhibitor with activity against Raf, vascular endothelial growth factor (VEGF) and platelet-derived growth factor (PDGF) signalling, and is the first systemic therapy to prolong survival in HCC. The ultimate role of sorafenib in HCC – in particular, when and how best to use it – is yet to be established.

Fibrolamellar hepatocellular carcinoma

This rare variant differs from HCC in that it occurs in young adults, equally in males and females, in the absence of hepatitis B infection and cirrhosis. The tumours are often large at presentation and the AFP is usually normal. Histology of the tumour reveals malignant hepatocytes surrounded by a dense fibrous stroma. The treatment of choice is surgical resection. This variant of HCC has a better prognosis following surgery than an equivalent-sized HCC, two-thirds of patients surviving beyond 5 years.

Other primary malignant tumours

These are rare but include haemangio-endothelial sarcomas. Cholangiocarcinoma (bile duct cancer) typically presents with bile duct obstruction rather than as a hepatic mass lesion, although the latter occasionally occurs.

Secondary malignant tumours

These are common and usually originate from carcinomas in the lung, breast, abdomen or pelvis. They may be single or multiple. Peritoneal dissemination frequently results in ascites.

Clinical features

The primary neoplasm is asymptomatic in 50% of patients, being detected on either radiological, endoscopic or blood biochemistry screening. There is liver enlargement and weight loss; jaundice may be present.

Investigations

A raised ALP activity is the most common biochemical abnormality but LFTs may be normal. Ascitic fluid, if present, has a high protein content and may be blood-stained; cytology sometimes reveals malignant cells. Imaging shows filling defects (Fig. 22.37); laparoscopy may reveal the tumour and facilitates liver biopsy.

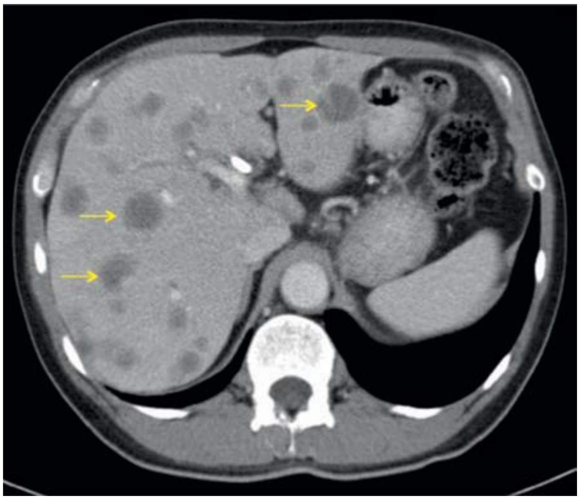

Fig. 22.37 **Computed tomogram showing multiple liver metastases (arrows).**

Management

Hepatic resection can improve survival for slow-growing tumours, such as colonic carcinomas, and is an approach that should be actively explored in patients who are fit for liver resection and have had the primary tumour resected once extrahepatic disease has been excluded. Patients with neuro-endocrine tumours, such as gastrinomas, insulinomas and glucagonomas, and those with lymphomas may benefit from surgery, hormonal treatment or chemotherapy. Unfortunately, palliative treatment to relieve pain is all that is available for most patients; this may include arterial embolisation of the tumour masses.

Benign tumours

The increasing use of ultrasound scanning has led to more frequent identification of incidental benign focal liver lesions.

Hepatic adenomas

These are rare vascular tumours that may present as an abdominal mass, or with abdominal pain or intraperitoneal bleeding. They are more common in women and may be caused by oral contraceptives, androgens and anabolic glucocorticoids. Resection is indicated for the relief of symptoms. Hepatic adenomas can increase in size during pregnancy. Large or rapidly growing adenomas can rarely rupture, causing intraperitoneal bleeding.

Haemangiomas

These are the most common benign liver tumours and are present in 1–20% of the population. Most are smaller than 5 cm and rarely cause symptoms (Fig. 22.38). The diagnosis is usually made by ultrasound but CT may show a low-density lesion with delayed arterial filling. Surgery is needed only for very large symptomatic lesions or where the diagnosis is in doubt.

Focal nodular hyperplasia

Focal nodular hyperplasia is common in women under the age of 40. The lesions are usually asymptomatic but can be up to 10 cm in diameter; they can be differentiated from adenoma by a focal central scar seen on CT or MRI. Histologically, they consist of nodular regeneration of hepatocytes without fibrosis. They may be multiple but only rarely need resection.

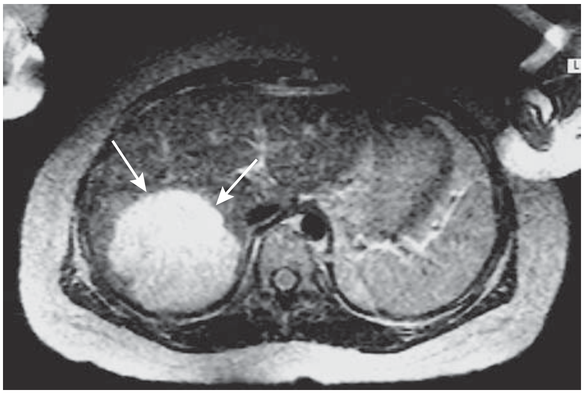

Fig. 22.38 **Magnetic resonance image showing a haemangioma (arrows) in the liver.** *Courtesy of Dr D. Redhead, Royal Infirmary of Edinburgh.*

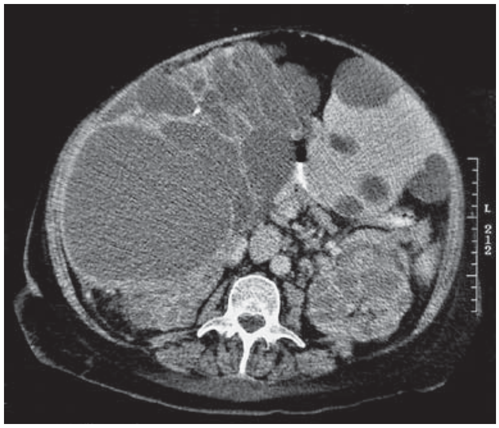

Fig. 22.39 **Computed tomogram showing multiple cysts in the liver and kidneys in polycystic disease.**

Cystic liver disease and liver abscess

Isolated or multiple simple cysts are common in the liver and are a relatively frequent finding on ultrasound screening. They can be associated with polycystic renal disease (Fig. 22.39). They are intrinsically benign and require no therapy, other than in rare cases where the mass effect of very large or multiple cysts causes abdominal discomfort. In such cases, percutaneous or surgical debulking can be attempted but recurrence is typical. Liver abscesses are discussed on page 879.

Drugs and the liver

The liver is the primary site of drug metabolism and an important target for drug-induced injury. Pre-existing liver disease may affect the capacity of the liver to metabolise drugs and unexpected toxicity may occur when patients with liver disease are given drugs in normal doses (p. 32). Box 22.53 also shows drugs that should be avoided in patients with cirrhosis, as they can exacerbate known complications of cirrhosis. The possibility of undiagnosed underlying liver injury should always be considered in patients exhibiting unexpected effects following drug exposure.

22.53 Drugs to be avoided in cirrhosis

Drug	Problem	Toxicity
Non-steroidal anti-inflammatory drugs	Reduced renal blood flow Mucosal ulceration	Hepatorenal failure Bleeding varices
Angiotensin-converting enzyme inhibitors	Reduced renal blood flow	Hepatorenal failure
Codeine	Constipation	Hepatic encephalopathy
Narcotics	Constipation, drug accumulation	Hepatic encephalopathy
Anxiolytics	Drug accumulation	Hepatic encephalopathy

Drug-induced liver injury

Drug toxicity should always be considered in the differential diagnosis of patients presenting with acute liver failure, jaundice or abnormal liver biochemistry. Some typical patterns of drug toxicity are listed in Box 22.54; the most common picture is a mixed cholestatic hepatitis. The presence of jaundice indicates more severe liver damage. Although acute liver failure can occur, most drug reactions are self-limiting and chronic liver damage is rare. Abnormal LFTs often take weeks to normalise following a drug-induced hepatitis, and it may be months before they normalise after a cholestatic hepatitis. Occasionally, permanent bile duct loss (ductopenia) follows a cholestatic drug reaction, such as that due to co-amoxiclav, resulting in chronic cholestasis with persistent symptoms such as itching.

The key to diagnosing acute drug-induced liver disease is to take a detailed drug history (Box 22.55), looking for temporal relationships between drug exposure and onset of liver abnormality (bearing in mind the fact that liver injury can frequently take weeks or even months to develop following exposure). A liver biopsy should be considered if there is suspicion of pre-existing liver disease or if blood tests fail to improve when the suspect drug is withdrawn.

Where drug-induced liver injury is suspected or cannot be excluded, the potential culprit drug should be discontinued unless it is impossible to do so safely.

Types of liver injury

Different histological patterns of liver injury may occur with drug injury.

Cholestasis

Pure cholestasis (selective interference with bile flow in the absence of liver injury) can occur with oestrogens; this was common when high concentrations of oestrogens (50 μg/day) were used as contraceptives. Both the current oral contraceptive pill and hormone replacement therapy can be safely used in chronic liver disease.

Chlorpromazine and antibiotics such as flucloxacillin are examples of drugs that cause cholestatic hepatitis, which is characterised by inflammation and canalicular injury. Co-amoxiclav is the most common antibiotic to cause abnormal LFTs but, unlike other antibiotics, it may not produce symptoms until 10–42 days after it is stopped. Anabolic glucocorticoids used by body-builders may also cause a cholestatic hepatitis. In some cases (e.g. NSAIDs and cyclo-oxygenase 2 (COX-2) inhibitors), there is overlap with acute hepatocellular injury.

22.54 Examples of common causes of drug-induced hepatotoxicity

Pattern	Drug
Cholestasis	Chlorpromazine High-dose oestrogens
Cholestatic hepatitis	Non-steroidal anti-inflammatory drugs Co-amoxiclav Statins
Acute hepatitis	Rifampicin Isoniazid
Non-alcoholic steatohepatitis	Amiodarone
Venous outflow obstruction	Busulfan Azathioprine
Fibrosis	Methotrexate

22.55 Diagnosing acute drug-induced liver disease

- Tabulate the drugs taken:
  - Prescribed and self-administered
- Establish whether hepatotoxicity is reported in the literature
- Relate the time the drugs were taken to the onset of illness: 4 days to 8 weeks (usual)
- Establish the effect of stopping the drugs on normalisation of liver biochemistry:
  - Hepatitic liver function tests (2 months)
  - Cholestatic/mixed liver function tests (6 months)

N.B. *Challenge tests with drugs should be avoided*

- Exclude other causes:
  - Viral hepatitis
  - Biliary disease
- Consider liver biopsy

Hepatocyte necrosis

Many drugs cause an acute hepatocellular necrosis with high serum transaminase concentrations; paracetamol is the best known. Inflammation is not always present but does accompany necrosis in liver injury due to diclofenac (an NSAID) and isoniazid (an anti-tuberculous drug). Granulomas may be seen in liver injury following the use of allopurinol. Acute hepatocellular necrosis has also been described following the use of several herbal remedies, including germander, comfrey and jin bu huan. Recreational drugs, including cocaine and ecstasy, can also cause severe acute hepatitis.

Steatosis

Microvesicular hepatocyte fat deposition, due to direct effects on mitochondrial beta-oxidation, can follow exposure to tetracyclines and sodium valproate. Macrovesicular hepatocyte fat deposition has been described with tamoxifen, and amiodarone toxicity can produce a similar histological picture to NASH.

Vascular/sinusoidal lesions

Drugs such as the alkylating agents used in oncology can damage the vascular endothelium and lead to hepatic venous

outflow obstruction. Chronic overdose of vitamin A can damage the sinusoids and trigger local fibrosis that can result in portal hypertension.

Hepatic fibrosis

Most drugs cause reversible liver injury and hepatic fibrosis is very uncommon. Methotrexate, however, as well as causing acute liver injury when it is started, can lead to cirrhosis when used in high doses over a long period of time. Risk factors for drug-induced hepatic fibrosis include pre-existing liver disease and a high alcohol intake.

Inherited liver diseases

The inherited diseases are an important and probably under-diagnosed group of liver diseases. In addition to the 'classical' conditions, such as haemochromatosis and Wilson's disease, the important role played by the liver in the expression of the inborn errors of metabolism should be remembered, as should the potential for genetic underpinning for intrahepatic cholestasis.

Haemochromatosis

Haemochromatosis is a condition in which the amount of total body iron is increased; the excess iron is deposited in, and causes damage to, several organs, including the liver. It may be primary or secondary to other diseases (Box 22.56).

Hereditary haemochromatosis

In hereditary haemochromatosis (HHC), iron is deposited throughout the body and total body iron may reach 20–60 g (normally 4 g). The important organs involved are the liver, pancreatic islets, endocrine glands, joints and heart. In the liver, iron deposition occurs first in the periportal hepatocytes, extending later to all hepatocytes. The gradual development of fibrous septa leads to the formation of irregular nodules, and finally regeneration results in macronodular cirrhosis. An excess of liver iron can occur in alcoholic cirrhosis but this is mild in comparison with haemochromatosis.

22.56 Causes of haemochromatosis

Primary haemochromatosis

- Hereditary haemochromatosis
- Congenital acaeruloplasminaemia
- Congenital atransferrinaemia

Secondary iron overload

- Parenteral iron loading (e.g. repeated blood transfusion)
- Iron-loading anaemia (thalassaemia, sideroblastic anaemia, pyruvate kinase deficiency)
- Liver disease

Complex iron overload

- Juvenile haemochromatosis
- Neonatal haemochromatosis
- Alcoholic liver disease
- Porphyria cutanea tarda
- African iron overload (Bantu siderosis)

Pathophysiology

The disease is caused by increased absorption of dietary iron and is inherited as an autosomal recessive trait. Approximately 90% of patients are homozygous for a single point mutation resulting in a cysteine to tyrosine substitution at position 282 (C282Y) in the HFE protein, which has structural and functional similarity to the HLA proteins. The mechanisms by which HFE regulates iron absorption are unclear. It is believed, however, that HFE normally interacts with the transferrin receptor in the basolateral membrane of intestinal epithelial cells. In HHC, it is thought that the lack of functional HFE causes a defect in uptake of transferrin-associated iron, leading to up-regulation of enterocyte iron-specific divalent metal transporters and excessive iron absorption. A histidine-to-aspartic acid mutation at position 63 (H63D) in HFE causes a less severe form of haemochromatosis that is most commonly found in patients who are compound heterozygotes also carrying a C282Y mutated allele. Fewer than 50% of C282Y homozygotes will develop clinical features of haemochromatosis; therefore other factors must also be important. HHC may promote accelerated liver disease in patients with alcohol excess or hepatitis C infection. Iron loss in menstruation and pregnancy can delay the onset of HHC in females.

Clinical features

Symptomatic disease usually presents in men over 40 years of age with features of liver disease (often with hepatomegaly), type 2 diabetes or heart failure. Fatigue and arthropathy are early symptoms but are frequently absent. Leaden-grey skin pigmentation due to excess melanin occurs, especially in exposed parts, axillae, groins and genitalia: hence the term 'bronzed diabetes'. Once again, absence of this feature does not preclude the diagnosis. Impotence, loss of libido and testicular atrophy are recognised complications, as are early-onset osteoarthritis targeting unusual sites such as the metacarpophalangeal joints, chondrocalcinosis and pseudogout. Cardiac failure or cardiac dysrhythmia may occur due to iron deposition in the heart.

Investigations

Serum iron studies show a greatly increased ferritin, a raised plasma iron and saturated plasma iron-binding capacity. Transferrin saturation of more than 45% is suggestive of iron overload. Significant liver disease is unusual in patients with ferritin lower than 1000 μg/L (100 μg/dL). The differential diagnoses for elevated ferritin are inflammatory disease or excess ethanol consumption for modest elevations (<1000 μg/L (100 μg/dL)). Very significant ferritin elevation can be seen in adult Still's disease. In terms of imaging techniques, MRI has high specificity for iron overload but poor sensitivity. Liver biopsy allows assessment of fibrosis and distribution of iron (hepatocyte iron characteristic of haemochromatosis). The Hepatic Iron Index (HII) provides quantification of liver iron (μmol of iron per g dry weight of liver/age in years). An HII of more than 1.9 suggests genetic haemochromatosis (Fig. 22.40). Both the C282Y and the H63D mutations can be identified by genetic testing, which is now in routine clinical use.

Management

Treatment consists of weekly venesection of 500 mL blood (250 mg iron) until the serum iron is normal; this may take 2 years or more. The aim is to reduce ferritin to under 50 μg/L (5 μg/dL). Thereafter, venesection is continued as required to keep the serum ferritin normal. Liver and cardiac problems

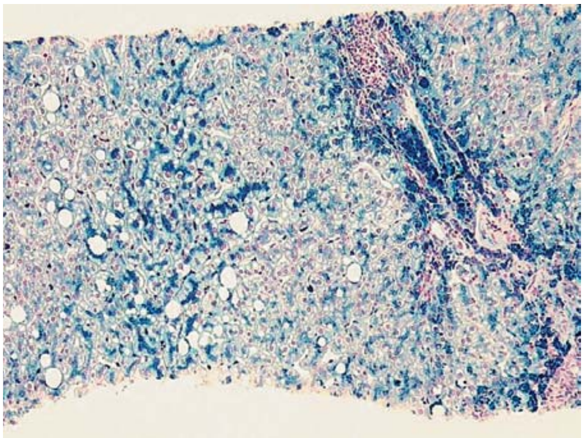

Fig. 22.40 Liver histology: haemochromatosis. This Perls stain shows accumulating iron within hepatocytes, which is stained blue. There is also accumulation of large fat globules in some hepatocytes (macrovesicular steatosis). Iron also accumulates in Kupffer cells and biliary epithelial cells.

improve after iron removal, but joint pain is less predictable and can improve or worsen after iron removal. Type 2 diabetes does not resolve after venesection. Other therapy includes that for cirrhosis and diabetes. First-degree family members should be investigated, preferably by genetic screening and also by checking the plasma ferritin and iron-binding saturation. Liver biopsy is indicated in asymptomatic relatives only if the LFTs are abnormal and/or the serum ferritin is greater than 1000 μg/L (100 μg/dL) because these features are associated with significant fibrosis or cirrhosis. Asymptomatic disease should also be treated by venesection until the serum ferritin is normal.

Pre-cirrhotic patients with HHC have a normal life expectancy, and even cirrhotic patients have a good prognosis compared with other forms of cirrhosis (three-quarters of patients are alive 5 years after diagnosis). This is probably because liver function is well preserved at diagnosis and improves with therapy. Screening for hepatocellular carcinoma (p. 890) is mandatory because this is the main cause of death, affecting one-third of patients with cirrhosis, irrespective of therapy. Venesection reduces but does not abolish the risk of hepatocellular carcinoma in the presence of cirrhosis.

Secondary haemochromatosis

Many conditions, including chronic haemolytic disorders, sideroblastic anaemia, other conditions requiring multiple blood transfusion (generally over 50 L), porphyria cutanea tarda, dietary iron overload and occasionally alcoholic cirrhosis, are associated with widespread secondary siderosis. The features are similar to those of primary haemochromatosis but the history and clinical findings point to the true diagnosis. Some patients are heterozygotes for the *HFE* gene and this may contribute to the development of iron overload.

Wilson's disease

Wilson's disease (hepatolenticular degeneration) is a rare but important autosomal recessive disorder of copper metabolism caused by a variety of mutations in the *ATP7B* gene on chromosome 13. Total body copper is increased, with excess copper deposited in, and causing damage to, several organs.

Pathophysiology

Normally, dietary copper is absorbed from the stomach and proximal small intestine and is rapidly taken into the liver, where it is stored and incorporated into caeruloplasmin, which is secreted into the blood. The accumulation of excessive copper in the body is ultimately prevented by its excretion, the most important route being via bile. In Wilson's disease, there is almost always a failure of synthesis of caeruloplasmin; however, some 5% of patients have a normal circulating caeruloplasmin concentration and this is not the primary pathogenic defect. The amount of copper in the body at birth is normal but thereafter it increases steadily; the organs most affected are the liver, basal ganglia of the brain, eyes, kidneys and skeleton.

The *ATP7B* gene encodes a member of the copper-transporting P-type adenosine triphosphatase family, which functions to export copper from various cell types. At least 200 different mutations have been described. Most cases are compound heterozygotes with two different mutations in *ATP7B.* Attempts to correlate the genotype with the mode of presentation and clinical course have not shown any consistent patterns. The large number of culprit mutations means that, in contrast to haemochromatosis, genetic diagnosis is not routine in Wilson's disease, although it may have a role in screening families following identification of the genotype in an index patient.

Clinical features

Symptoms usually arise between the ages of 5 and 45 years. Hepatic disease occurs predominantly in childhood and early adolescence, although it can present in adults in their fifties. Neurological damage causes basal ganglion syndromes and dementia, which tends to present in later adolescence. These features can occur alone or simultaneously. Other manifestations include renal tubular damage and osteoporosis, but these are rarely presenting features.

Liver disease

Episodes of acute hepatitis, sometimes recurrent, can occur, especially in children, and may progress to fulminant liver failure. The latter is characterised by the liberation of free copper into the blood stream, causing massive haemolysis and renal tubulopathy. Chronic hepatitis can also develop insidiously and eventually present with established cirrhosis; liver failure and portal hypertension may supervene. The possibility of Wilson's disease should be considered in any patient under the age of 40 presenting with recurrent acute hepatitis or chronic liver disease of unknown cause, especially when this is accompanied by haemolysis.

Neurological disease

Clinical features include a variety of extrapyramidal features, particularly tremor, choreoathetosis, dystonia, parkinsonism and dementia (Ch. 25). Unusual clumsiness for age may be an early symptom. Neurological disease typically develops after the onset of liver disease and can be prevented by effective treatment started following diagnosis in the liver disease phase. This increases the importance of diagnosis in the liver phase beyond just allowing effective management of liver disease.

Kayser–Fleischer rings

These constitute the most important single clinical clue to the diagnosis and can be seen in 60% of adults with Wilson's disease (less often in children but almost always in neurological

Wilson's disease), albeit sometimes only by slit-lamp examination. Kayser–Fleischer rings are characterised by greenish-brown discoloration of the corneal margin appearing first at the upper periphery (p. 846). They disappear with treatment.

Investigations

A low serum caeruloplasmin is the best single laboratory clue to the diagnosis. Advanced liver failure from any cause can, however, reduce the serum caeruloplasmin and occasionally it is normal in Wilson's disease. Other features of disordered copper metabolism should therefore be sought; these include a high free serum copper concentration, a high urine copper excretion of greater than 0.6 μmol/24 hrs (38 μg/24 hrs) and a very high hepatic copper content. Measuring 24-hour urinary copper excretion while giving D-penicillamine is a useful confirmatory test; more than 25 μmol/24 hrs is considered diagnostic of Wilson's disease.

Management

The copper-binding agent penicillamine is the drug of choice. The dose given must be sufficient to produce cupriuresis and most patients require 1.5 μg/day (range 1–4 μg). The dose can be reduced once the disease is in remission but treatment must continue for life, even through pregnancy. Care must be taken to ensure that re-accumulation of copper does not occur. Abrupt discontinuation of treatment must be avoided because this may precipitate acute liver failure. Toxic effects occur in one-third of patients and include rashes, protein-losing nephropathy, lupus-like syndrome and bone marrow depression. If these do arise, trientine dihydrochloride (1.2–2.4 μg/day) and zinc (50 mg 3 times daily) are potential alternatives.

Liver transplantation is indicated for fulminant liver failure or for advanced cirrhosis with liver failure. The value of liver transplantation in severe neurological Wilson's disease is unclear. Prognosis is excellent, provided treatment is started before there is irreversible damage. Siblings and children of patients with Wilson's disease must be investigated and treatment should be given to all affected individuals, even if they are asymptomatic.

Alpha$_1$-antitrypsin deficiency

Alpha$_1$-antitrypsin (α_1-AT) is a serine protease inhibitor (Pi) produced by the liver. One of its main anti-protease functions is the breakdown of neutrophil elastase. The mutated form of α_1-AT (PiZ) cannot be secreted into the blood by liver cells because it is retained within the endoplasmic reticulum of the hepatocyte. Homozygous individuals (PiZZ) have low plasma α_1-AT concentrations, although globules containing α_1-AT are found in the liver, and these people may develop hepatic and pulmonary disease. Liver manifestations include cholestatic jaundice in the neonatal period (neonatal hepatitis), which can resolve spontaneously; chronic hepatitis and cirrhosis in adults; and, in the long term, HCC. Alpha$_1$-AT deficiency is a not uncommon exacerbating factor for liver disease of other aetiologies, and the possibility of dual pathology should be considered when severity of disease, such as ALD, appears disproportionate to the level of underlying insult.

There are no clinical features that distinguish liver disease due to α_1-AT deficiency from liver disease due to other causes, and the diagnosis is made from the low plasma α_1-AT concentration and genotyping for the presence of the mutation. Alpha$_1$-AT-containing globules can be demonstrated in the liver (Fig. 22.41) but this is not necessary to make the diagnosis. Occasionally, patients with liver disease and minor reductions of plasma α_1-AT concentrations have α_1-AT variants other than PiZZ, but the relationship of these to liver disease is uncertain.

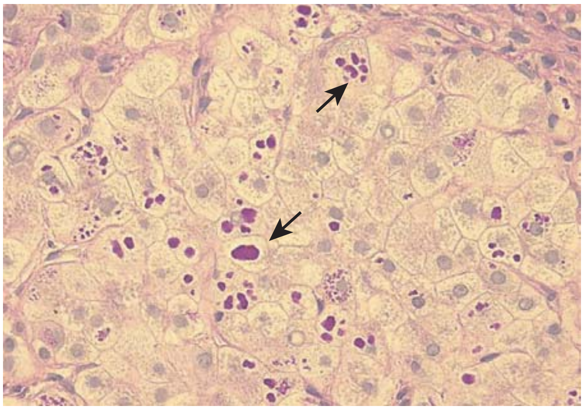

Fig. 22.41 Liver histology in α_1-antitrypsin deficiency. Accumulation of periodic acid–Schiff-positive granules (arrows) within individual hepatocytes is shown in this section from a patient with α_1-AT deficiency.

There is no specific treatment. The risk of severe and early-onset emphysema means that all patients should be advised to stop smoking.

Gilbert's syndrome

Gilbert's syndrome is by far the most common inherited disorder of bilirubin metabolism (see Box 22.17, p. 860). It is an autosomal recessive trait when caused by a mutation in the promoter region of the gene for UDP-glucuronyl transferase enzyme (*UGT1A1*), which leads to reduced enzyme expression. It can be inherited in a dominant fashion when there is a missense mutation in the gene. This results in decreased conjugation of bilirubin, which accumulates as unconjugated bilirubin in the blood. The levels of unconjugated bilirubin increase during fasting, as fasting reduces levels of UDP-glucuronyl transferase.

22

Clinical features

The typical presentation is with isolated elevation of bilirubin, typically, although not exclusively, in the setting of physical stress or illness. There are no stigmata of chronic liver disease other than jaundice. Increased excretion of bilirubin and hence stercobilinogen leads to normal-coloured or dark stools, and increased urobilinogen excretion causes the urine to turn dark on standing as urobilin is formed. In the presence of haemolysis, pallor due to anaemia and splenomegaly due to excessive reticulo-endothelial activity are usually present.

Investigations

The plasma bilirubin is usually less than 100 μmol/L (~6 mg/dL) and the LFTs are otherwise normal. There is no bilirubinuria because the hyperbilirubinaemia is predominantly unconjugated. Hepatic histology is normal and liver biopsy is not recommended for the investigation of patients with possible Gilbert's syndrome. The condition is not associated with liver injury and thus has an excellent prognosis, needs no treatment, and is clinically important only because it may be mistaken for more serious liver disease.

Vascular liver disease

Metabolically, the liver is highly active and has large oxygen requirements. This places it at risk of ischaemic injury in settings of impaired perfusion. The risk is mitigated, however, by the dual perfusion of the liver (via the portal vein as well as hepatic artery), with the former representing a low-pressure perfusion system that offers protection against the potential effects of arterial hypotension. The single outflow through the hepatic vein and the low-pressure perfusion system of the portal vein make the liver vulnerable to venous thrombotic ischaemia in the context of Budd–Chiari syndrome and portal vein thrombosis, respectively.

Hepatic arterial disease

Liver ischaemia

Liver ischaemic injury is relatively common during hypotensive or hypoxic events and is under-diagnosed. The characteristic pattern is one of rising transaminase values in the days following such an event (e.g. prolonged seizures). Liver synthetic dysfunction and encephalopathy are uncommon but can occur. Liver failure is very rare. Diagnosis typically rests on clinical suspicion and exclusion of other potential aetiologies. Treatment is aimed at optimising liver perfusion and oxygen delivery. Outcome is dictated by the morbidity and mortality associated with the underlying disease, given that liver ischaemia frequently occurs in the context of other organ ischaemia in high-risk patients.

Liver arterial disease

Hepatic arterial disease is rare outside the setting of liver transplantation and is difficult to diagnose. It can cause significant liver damage. Hepatic artery occlusion may result from inadvertent injury during biliary surgery or may be caused by emboli, neoplasms, polyarteritis nodosa, blunt trauma or radiation. It usually causes severe upper abdominal pain with or without signs of circulatory shock. LFTs show raised transaminases (AST or ALT usually >1000 U/L), as in other causes of acute liver damage. Patients usually survive if the liver and portal blood supply are otherwise normal.

Hepatic artery aneurysms are extrahepatic in three-quarters of cases and intrahepatic in one-quarter. Atheroma, vasculitis, bacterial endocarditis and surgical or biopsy trauma are the main causes. They usually lead to bleeding into the biliary tree, peritoneum or intestine and are best diagnosed by angiography. Treatment is radiological or surgical. Any of the vasculitides can affect the hepatic artery but this rarely causes symptoms.

Hepatic artery thrombosis is a recognised complication of liver transplantation and typically occurs in the early post-transplant period. Clinical features are often related to bile duct rather than liver ischaemia because of the dominant role of the hepatic artery in extrahepatic bile duct perfusion. Manifestations can include bile duct anastomotic failure with bile leak or the development of late bile duct strictures. Diagnosis and initial intervention are radiological in the first instance, with ERCP and biliary stenting being the principal approaches to the treatment of bile duct injury.

Portal venous disease

Portal hypertension

See page 868.

Portal vein thrombosis

Portal venous thrombosis as a primary event is rare but can occur in any condition predisposing to thrombosis. It may also complicate intra-abdominal inflammatory or neoplastic disease and is a recognised cause of portal hypertension. Acute portal venous thrombosis causes abdominal pain and diarrhoea, and may rarely lead to bowel infarction, requiring surgery. Treatment is otherwise based on anticoagulation, although there are no randomised data that demonstrate efficacy. An underlying thrombophilia needs to be excluded. Subacute thrombosis can be asymptomatic but may subsequently lead to extrahepatic portal hypertension (p. 868). Ascites is unusual in non-cirrhotic portal hypertension, unless the albumin is particularly low.

Portal vein thrombosis can arise as a secondary event in patients with cirrhosis and portal hypertension, and is a recognised cause of decompensation in patients with previously stable cirrhosis. In individuals showing such decompensation, portal vein patency should be assessed by ultrasound with Doppler flow studies.

Chronic portal vein thrombosis can be a cause of portal hypertension.

Hepatopulmonary syndrome

This condition is characterised by resistant hypoxaemia (PaO_2 <9.3 kPa (70 mmHg)), intrapulmonary vascular dilatation in patients with cirrhosis, and portal hypertension. Clinical features include finger clubbing, cyanosis, spider naevi and a characteristic reduction in arterial oxygen saturation on standing. The hypoxia is due to intrapulmonary shunting through direct arteriovenous communications. Nitric oxide (NO) over-production may be important in pathogenesis. The hepatopulmonary syndrome can be treated by liver transplantation but, if severe (PaO_2 <6.7 kPa (50 mmHg)), is associated with an increased operative risk.

Portopulmonary hypertension

This unusual complication of portal hypertension is similar to 'primary pulmonary hypertension' (p. 621). It is defined as pulmonary hypertension with increased pulmonary vascular resistance and a normal pulmonary artery wedge pressure in a patient with portal hypertension. The condition is caused by vasoconstriction and obliteration of the pulmonary arterial system and leads to breathlessness and fatigue.

Hepatic venous disease

Obstruction to hepatic venous blood flow can occur in the small central hepatic veins, the large hepatic veins, the inferior vena cava or the heart (see Fig. 22.20, p. 868). The clinical features depend on the cause and on the speed with which obstruction develops, and can mimic many other forms of chronic liver disease, sometimes leading to delayed diagnosis. Congestive hepatomegaly and ascites are, however, the most consistent features. The possibility of hepatic venous obstruction should always be considered in patients with an atypical liver presentation.

Budd–Chiari syndrome

This uncommon condition is caused by thrombosis of the larger hepatic veins and sometimes the inferior vena cava. Many patients have haematological disorders such as myelofibrosis, primary proliferative polycythaemia, paroxysmal nocturnal haemoglobinuria,

or antithrombin III, protein C or protein S deficiencies (Ch. 23). Pregnancy and oral contraceptive use, obstruction due to tumours (particularly carcinomas of the liver, kidneys or adrenals), congenital venous webs and occasionally inferior vena caval stenosis are the other main causes. The underlying cause cannot be found in about 50% of patients, although this percentage is falling as molecular diagnostic tools (such as the *JAK2* mutation in myelofibrosis) increase our capacity to diagnose underlying haematological disorders. Hepatic congestion affecting the centrilobular areas is followed by centrilobular fibrosis, and eventually cirrhosis supervenes in those who survive long enough.

Clinical features

Acute venous occlusion causes rapid development of upper abdominal pain, marked ascites and occasionally acute liver failure. More gradual occlusion causes gross ascites and, often, upper abdominal discomfort. Hepatomegaly, frequently with tenderness over the liver, is almost always present. Peripheral oedema occurs only when there is inferior vena cava obstruction. Features of cirrhosis and portal hypertension develop in those who survive the acute event.

Investigations

The LFTs vary considerably, depending on the presentation, and can show the features of acute hepatitis. Ascitic fluid analysis shows a protein concentration above 25 g/L (2.5 g/dL) (exudate) in the early stages; this often falls later in the disease, however. Doppler ultrasound may reveal obliteration of the hepatic veins and reversed flow or associated thrombosis in the portal vein. CT may show enlargement of the caudate lobe, as this often has a separate venous drainage system that is not involved in the disease. CT and MRI may also demonstrate occlusion of the hepatic veins and inferior vena cava. Liver biopsy demonstrates centrilobular congestion with fibrosis, depending on the duration of the illness. Venography is needed only if CT and MRI are unable to demonstrate the hepatic venous anatomy clearly.

Management

Predisposing causes should be treated as far as possible; where recent thrombosis is suspected, thrombolysis with streptokinase, followed by heparin and oral anticoagulation, should be considered. Ascites is initially treated medically but often with only limited success. Short hepatic venous strictures can be treated with angioplasty. In the case of more extensive hepatic vein occlusion, many patients can be managed successfully by insertion of a covered TIPSS, followed by anticoagulation. Surgical shunts, such as portacaval shunts, are less commonly performed now that TIPSS is available. Occasionally, a web can be resected or an inferior vena caval stenosis dilated. Progressive liver failure is an indication for liver transplantation and life-long anticoagulation.

Prognosis without transplantation or shunting is poor, particularly following an acute presentation with liver failure. A 3-year survival of 50% is reported in those who survive the initial event. The 1- and 10-year survival following liver transplantation is 85% and 69%, respectively, and this compares with a 5- and 10-year survival of 87% and 37%, respectively, following surgical shunting.

Sinusoidal obstruction syndrome (veno-occlusive disease)

Sinusoidal obstruction syndrome (SOS; previously known as veno-occlusive disease) is a rare condition characterised by widespread occlusion of the small central hepatic veins. Pyrrolizidine alkaloids in *Senecio* and *Heliotropium* plants used to make teas, as well as cytotoxic drugs and hepatic irradiation, are all recognised causes. SOS may develop in 10–20% of patients following haematopoietic stem cell transplantation (usually within the first 20 days) and carries a 90% mortality in severe cases. Pathogenesis involves obliteration and fibrosis of terminal hepatic venules due to deposition of red cells, haemosiderin-laden macrophages and coagulation factors. In this setting, SOS is thought to relate to pre-conditioning therapy with irradiation and cytotoxic chemotherapy. The clinical features are similar to those of the Budd–Chiari syndrome (see above). Investigations show evidence of venous outflow obstruction histologically but, in contrast to Budd–Chiari, the large hepatic veins appear patent radiologically. Transjugular liver biopsy (with portal pressure measurements) may facilitate the diagnosis. Traditionally, treatment has been supportive but defibrotide shows promise (the drug binds to vascular endothelial cells, promoting fibrinolysis and suppressing coagulation).

Cardiac disease

Hepatic damage, due primarily to congestion, may develop in all forms of right heart failure (p. 461); usually, the clinical features are predominantly cardiac. Very rarely, long-standing cardiac failure and hepatic congestion give rise to cardiac cirrhosis. Severe left ventricular dysfunction is a cause of ischaemic hepatitis. Cardiac causes of acute and chronic liver disease are typically under-diagnosed. Treatment is principally that of the underlying heart disease with supportive treatment for the liver component.

Nodular regenerative hyperplasia of the liver

This is the most common cause of non-cirrhotic portal hypertension in developed countries; it is characterised by small hepatocyte nodules throughout the liver without fibrosis, which can result in sinusoidal compression. It is believed to be due to damage to small hepatic arterioles and portal venules. It occurs in older people and is associated with many conditions, including connective tissue disease, haematological diseases and immunosuppressive drugs, such as azathioprine. The condition is usually asymptomatic but occasionally presents with portal hypertension or with an abdominal mass. The diagnosis is made by liver biopsy, which, in contrast to cirrhosis, shows nodule formation in the absence of fibrous septa. Liver function is good and the prognosis is very favourable. Management is based on treatment of the portal hypertension.

Pregnancy and the liver

The inter-relationship between liver disease and pregnancy can be a complex one and a source of real anxiety for both patient and clinician. Three possibilities need to be borne in mind when treating a pregnant woman with a liver abnormality:

- This represents a worsening of pre-existing chronic liver or biliary disease (although pregnancy may be the first time a woman's liver biochemistry has been tested, so this may not have previously been diagnosed).
- This represents a genuine first presentation of liver disease that is not intrinsically related to pregnancy.
- This represents a genuine pregnancy-associated liver injury process.

It is critical to obtain information relating to liver disease risk factors and pre-pregnancy liver status to establish whether any abnormality was present before pregnancy. In general, the earlier in pregnancy that liver abnormality presents, the more likely it is to represent either pre-existing liver disease or non-pregnancy-related acute liver disease. Equally, the best outcome for both mother and baby results from optimising the physical condition of the mother, and in situations of deteriorating liver function (which can be steep in late pregnancy) consideration should always be given to early delivery if the fetus is viable. Joint management between hepatologists and obstetricians is essential.

Intercurrent and pre-existing liver disease

Acute hepatitis A can occur during pregnancy but has no effect on the fetus. Chronic hepatitis B requires identification in pregnancy because of long-term health implications for the mother and the effectiveness of perinatal vaccination (with or without pre-delivery maternal antiviral therapy) in reducing neonatal acquisition of chronic hepatitis B. Maternal transmission of hepatitis C occurs in 1% of cases and there is no convincing evidence that the mode of delivery affects this. Hepatitis E is reported to progress to acute liver failure much more commonly in pregnancy, with a 20% maternal mortality. Pregnancy may be associated with either worsening or improvement of autoimmune hepatitis, although improvement during pregnancy and rebound post-partum is the most common pattern seen. Complications of portal hypertension may be a particular issue in the second and third trimesters.

Gallstones (p. 903) are more common during pregnancy and may present with cholecystitis or biliary obstruction. The diagnosis can usually be made with ultrasound. In biliary obstruction due to gallstones, therapeutic ERCP can be safely performed but lead protection for the fetus is essential and X-ray screening must be kept to a minimum.

Pregnancy-associated liver disease

Several conditions occur only during pregnancy, may recur in subsequent pregnancies and resolve after delivery of the baby, and these are discussed on page 1283. The causes of abnormal LFTs in pregnancy, which include pregnancy-associated liver disease, are shown in Box 22.57.

22.57 Abnormal liver function tests in pregnancy

- **Liver function tests**: alkaline phosphatase (ALP) levels and albumin normally fall in pregnancy. ALP levels can rise due to the contribution of placental ALP.
- **Pre-existing liver disease**: pregnancy is uncommon in cirrhosis because cirrhosis causes relative infertility. Varices can enlarge in pregnancy, and ascites should be treated with amiloride rather than spironolactone. Penicillamine for Wilson's disease and azathioprine for autoimmune liver disease should be continued during pregnancy. Autoimmune liver disease can flare up post-partum.
- **Incidental**: viral, autoimmune and drug-induced hepatitis must be excluded in the presence of an elevated alanine aminotransferase (ALT). Immunoglobulin/vaccination given to the fetus at birth prevents transmission of hepatitis B to the fetus if the mother is infected. Gallstones are more common in pregnancy and post-partum, and are a cause of a raised ALP level. Biliary imaging with ultrasound and magnetic resonance cholangiopancreatography is safe. Endoscopic retrograde cholangiopancreatography to remove stones can be performed safely with shielding of the fetus from radiation.
- **Pregnancy-related liver diseases**: occur predominantly in the third trimester and resolve post-partum. Maternal and fetal mortality and morbidity are reduced by expediting delivery.

Liver transplantation

The outcome following liver transplantation has improved significantly over the last decade so that elective transplantation in low-risk individuals now has a 1-year survival rate of more than 90% and is an effective treatment for end-stage liver disease. The number of procedures is limited by cadaveric donor availability and in many parts of the world this has led to living donor transplant programmes. Despite this, 10% of those listed for liver transplantation will die while awaiting a donor liver. The main complications of liver transplantation relate to rejection, complications of long-term immunosuppression and disease recurrence in the liver graft.

Indications and contraindications

Currently, around 9500 liver transplants are undertaken in Europe and the USA annually. About 10% are performed for acute liver failure, 6% for metabolic diseases, 71% for cirrhosis and 11% for hepatocellular carcinoma. Most patients are under 60 years of age and only 10% are aged between 60 and 70 years. Indications for elective transplant assessment are listed in Box 22.58. In North America, the most common indication is hepatitis C cirrhosis, about 10–20% of transplants being for alcoholic cirrhosis (Fig. 22.42). Patients with alcoholic liver disease need to show a capacity for abstinence.

The main contraindications to transplantation are sepsis, extrahepatic malignancy, active alcohol or other substance misuse, and marked cardiorespiratory dysfunction.

Patients are matched for ABO blood group and size but do not require HLA matching with donors, as the liver is a relatively immune-privileged organ compared with the heart or kidneys.

In many parts of the world, the MELD score (see Box 22.30, p. 868) is used to identify and prioritise patients for transplantation. In the UK, a similar system that also incorporates serum sodium, the United Kingdom End-stage Liver Disease (UKELD) score, is used to guide recipient selection. To be listed for elective (non-super-urgent) transplantation in the UK, patients must have a greater than 50% projected post-transplant 5-year survival and must fall into one of three categories:

- *Category 1*: estimated 1-year mortality without transplantation of more than 9% (equivalent to a UKELD score of more than 49 points)

22.58 Indications for liver transplant assessment for cirrhosis

Complications

- First episode of bacterial peritonitis
- Diuretic-resistant ascites
- Recurrent variceal haemorrhage
- Hepatocellular carcinoma <5 cm
- Persistent hepatic encephalopathy

Poor liver function

- Bilirubin >100 μmol/L (5.8 mg/dL) in primary biliary cholangitis
- MELD score >12 (Box 22.30, p. 868)
- Child–Pugh grade C (Box 22.29, p. 867)

(MELD = Model for End-stage Liver Disease)

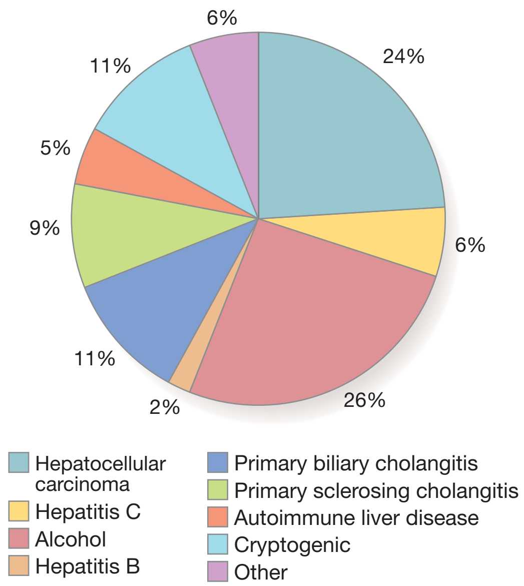

Fig. 22.42 Indications for elective adult liver transplantation in the UK, 2016.

- *Category 2*: HCC diagnosed radiologically by two concordant modalities; based on CT, a single lesion of less than 5 cm maximum diameter, or fewer than three lesions each less than 3 cm in diameter, without macrovascular invasion or metastases.
- *Category 3*: 'variant syndromes', including diuretic-resistant ascites, hepatopulmonary syndrome, chronic hepatic encephalopathy, intractable pruritus, familial amyloidosis, primary hyperlipidaemia, polycystic liver disease and recurrent cholangitis.

Super-urgent listing is reserved for patients with acute liver failure, according to specific criteria.

Two types of transplant are increasingly used because of insufficient cadaveric donors:

- *Split liver transplantation.* A cadaveric donor liver can be split into two, with the larger right lobe used in an adult and the smaller left lobe used in a child. This practice has led to an increase in procedures despite a shortage of donor organs.
- *Living donor transplantation.* This is normally performed using the left lateral segment or the right lobe. The donor mortality is significant at 0.5–1%. Pre-operative assessment includes looking at donor liver size and psychological status.

Complications

Early complications

Primary graft non-function

This is a state of hepatocellular dysfunction arising as a consequence of liver paresis, which results from ischaemia following removal from the donor and prior to reperfusion in the recipient. Factors that increase the likelihood of primary non-function include increasing donor age, degree of steatosis in the liver and the length of ischaemia. Treatment is supportive until recovery of function. Occasionally, recovery is not seen and re-transplantation is necessary.

Technical complications

These include hepatic artery thrombosis, which may necessitate re-transplantation. Anastomotic biliary strictures can also occur; these may respond to endoscopic balloon dilatation and stenting, or require surgical reconstruction. Portal vein thrombosis is rare.

Rejection

Less immunosuppression is needed following liver transplantation than with kidney or heart/lung grafting. Initial immunosuppression is usually with tacrolimus or ciclosporin, prednisolone and azathioprine or mycophenolate. Some patients can eventually be maintained on a single agent. Acute cellular rejection occurs in 60–80% of patients, commonly at 5–10 days post-transplant and usually within the first 6 weeks, but can arise at any point. This normally responds to 3 days of high-dose intravenous methylprednisolone.

Infections

Bacterial infections, such as pneumonia and wound infections, can occur in the first few weeks after transplantation. Cytomegalovirus (primary infection or reactivation) is a common infection in the 3 months after transplantation and can cause hepatitis. Patients who have never had cytomegalovirus infection but who receive a liver from a donor who has been exposed are at greatest risk of infection and are usually given prophylactic antiviral therapy, such as valganciclovir. Herpes simplex virus reactivation or, rarely, primary infection may occur. Prophylaxis is given to recipients who have had previous exposure to tuberculosis for the first 6 months after transplantation to prevent reactivation.

Late complications

These include recurrence of the initial disease in the graft and complications due to the immunosuppressive therapy, such as renal impairment from ciclosporin. Metabolic syndrome (p. 730) is common, being described in about 50% of transplant recipients within 6 months in the USA. Chronic vascular rejection is rare, occurring in only 5% of cases.

Prognosis

The outcome following transplantation for acute liver failure is worse than that for chronic liver disease because most patients have multi-organ failure at the time of transplantation. The 1-year survival is 65% and falls only a little to 59% at 5 years. The 1-year survival for patients with cirrhosis is over 90%, falling to 70–75% at 5 years.

22.59 Liver disease in old age

- **Alcoholic liver disease**: 10% of cases present over the age of 70 years, when disease is more likely to be severe and has a worse prognosis.
- **Hepatitis A**: causes more severe illness and runs a more protracted course.
- **Primary biliary cholangitis**: one-third of cases are over 65 years.
- **Liver abscess**: more than 50% of all cases in the UK are over 60 years.
- **Hepatocellular carcinoma**: approximately 50% of cases in the UK present over the age of 65 years.
- **Surgery**: older people are less likely to survive liver surgery (including transplantation) because comorbidity is more prevalent.

Cholestatic and biliary disease

The concepts of biliary and cholestatic disease, and the important distinctions between them, can be a source of confusion. 'Cholestasis' relates to a biochemical abnormality (typically, elevation of ALP and elevation in serum bile acid levels and bilirubin) that results from an abnormality in bile flow. The cause can range from inherited or acquired dysfunction of transporter molecules responsible for the production of canalicular bile to physical obstruction of the extrahepatic bile duct. 'Biliary disease' relates to pathology at any level from the small intrahepatic bile ducts to the sphincter of Oddi. Although there is very significant overlap between cholestatic and biliary disease, there are scenarios where cholestasis can exist without biliary disease (transporter disease or pure drug-induced cholestasis) and where biliary disease can exist without cholestasis (when disease of the bile duct does not impact on bile flow). These anomalies should always be borne in mind and cholestasis and biliary disease always effectively distinguished.

Chemical cholestasis

Pure cholestasis can occur as an inherited condition (p. 895), as a consequence of cholestatic drug reactions (p. 894) or as acute cholestasis of pregnancy (p. 1284). A more frequent, but less recognised, acquired biochemical cholestasis occurs in sepsis ('cholangitis lente'). This biochemical phenomenon is one of the causes of LFT abnormality in sepsis, does not require specific treatment, and has a prognostic significance conferred by the underlying septic process.

Mutations in the biliary transporter proteins on the hepatocyte canalicular membrane (familial intrahepatic cholestasis 1, FIC1), illustrated in Figure 22.7 (p. 851), have been shown to cause an inherited intrahepatic biliary disease in childhood, characterised by raised ALP levels and progression to a biliary cirrhosis. It is also becoming increasingly clear that these proteins contribute to intrahepatic biliary disease in adulthood.

Benign recurrent intrahepatic cholestasis

This rare condition usually presents in adolescence and is characterised by recurrent episodes of cholestasis, lasting 1–6 months. It is now known to be mediated by mutations in the *ATP8B1* gene, which lies on chromosome 18 and encodes FIC1.

Episodes start with pruritus, while painless jaundice develops later. LFTs show a cholestatic pattern. Liver biopsy shows cholestasis during an episode but is normal between episodes. Treatment is required to relieve the symptoms of cholestasis, such as pruritus, and the long-term prognosis is good.

Intrahepatic biliary disease

Inflammatory and immune disease

The small intrahepatic bile ducts appear to be specifically vulnerable to immune injury, and ductopenic injury ('vanishing bile duct syndrome') can be a feature of a number of chronic conditions, including graft-versus-host disease (GVHD), sarcoidosis and, in the setting of liver transplantation, ductopenic rejection. Intrahepatic small bile duct injury occurs most frequently in primary biliary cholangitis, an autoimmune cholestatic disease, and less frequently in primary sclerosing cholangitis (Box 22.60).

22.60 Comparison of primary biliary cholangitis (PBC) and primary sclerosing cholangitis (PSC)

	PBC	PSC
Gender (F : M)	10 : 1	1 : 3
Age	Older: median age 50–55 years	Younger: median age 20–40 years
Disease associations	Non-organ-specific autoimmune disease (e.g. Sjögren's syndrome) and autoimmune thyroid disease	Ulcerative colitis
Autoantibody profile	90% AMA +ve	65–85% pANCA +ve (but this is non-specific and not diagnostic)
Predominant bile-duct injury	Intrahepatic	Extrahepatic > intrahepatic

(AMA = antimitochondrial antibody; pANCA = perinuclear antineutrophil cytoplasmic antibody)

Caroli's disease

This very rare disease is characterised by segmental saccular dilatations of the intrahepatic biliary tree. The whole liver is usually affected and extrahepatic biliary dilatation occurs in about one-quarter of patients. Recurrent attacks of cholangitis (see Box 22.18, p. 861) may cause hepatic abscesses. Complications include biliary stones and cholangiocarcinoma. Antibiotics are required for episodes of cholangitis. Occasionally, localised disease can be treated by segmental liver resection, and liver transplantation may sometimes be required.

Congenital hepatic fibrosis

This is characterised by broad bands of fibrous tissue linking the portal tracts in the liver, abnormalities of the interlobular bile ducts and sometimes a lack of portal venules. The renal tubules may show cystic dilatation (medullary sponge kidney; p. 433), and eventually renal cysts may develop. The condition can be inherited as an autosomal recessive trait. Liver involvement causes portal hypertension with splenomegaly and bleeding from oesophageal varices that usually presents in adolescence or in early adult life. The prognosis is good because liver function is preserved. Treatment may be required for variceal bleeding and occasionally cholangitis. Patients can present during childhood with renal failure if the kidneys are severely affected.

Cystic fibrosis

Cystic fibrosis (p. 580) is associated with biliary cirrhosis in about 5% of individuals. Splenomegaly and an elevated ALP are characteristic. Complications do not normally arise until late adolescence or early adulthood, when bleeding due to variceal haemorrhage may occur. UDCA improves liver blood tests but it is not known whether the drug can prevent progression of liver disease. Deficiency of fat-soluble vitamins (A, D, E and K) may need to be treated in view of both biliary and pancreatic disease.

Extrahepatic biliary disease

Diseases of the extrahepatic biliary tree typically present with the clinical features of impaired bile flow (obstructive jaundice and fat

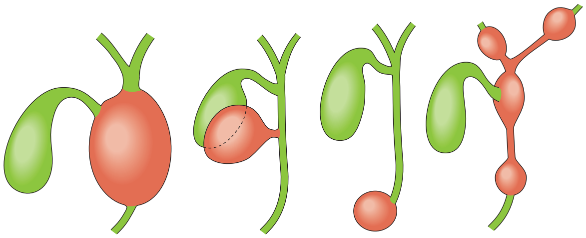

Fig. 22.43 Classification and frequency of choledochal cysts. *From Shearman DC, Finlayson NDC. Diseases of the gastrointestinal tract and liver, 2nd edn. Edinburgh: Churchill Livingstone, Elsevier Ltd; 1989.*

malabsorption). Obstructive disease is frequently a consequence of stricturing following gallstone passage and associated infection and inflammation or post-surgical intervention. PSC frequently involves the extrahepatic biliary tree and its differential, IgG4 disease, is an important and potentially treatable cause of disease (p. 890). Malignant diseases (cholangiocarcinoma or carcinoma of the head of pancreas) should be considered in all patients with extrahepatic biliary obstruction).

Choledochal cysts

This term applies to cysts anywhere in the biliary tree (Fig. 22.43). The great majority cause diffuse dilatation of the common bile duct (type I) but others take the form of biliary diverticula (type II), dilatation of the intraduodenal bile duct (type III) and multiple biliary cysts (type IV). The last type merges with Caroli's disease (see above). In the neonate, they may present with jaundice or biliary peritonitis. Recurrent jaundice, abdominal pain and cholangitis may arise in the adult. Liver abscess and biliary cirrhosis may develop and there is an increased incidence of cholangiocarcinoma. Excision of the cyst with hepatico-jejunostomy is the treatment of choice.

Secondary biliary cirrhosis

Secondary biliary cirrhosis develops after prolonged large duct biliary obstruction due to gallstones, benign bile duct strictures or sclerosing cholangitis (see below). Carcinomas rarely cause secondary biliary cirrhosis because few patients survive long enough. The clinical features are those of chronic cholestasis with episodes of ascending cholangitis or even liver abscess (p. 879). Cirrhosis, ascites and portal hypertension are late features. Relief of biliary obstruction may require endoscopic or surgical intervention. Cholangitis dictates treatment with antibiotics, which can be given continuously if attacks recur frequently.

Gallstones

Gallstone formation is the most common disorder of the biliary tree and it is unusual for the gallbladder to be diseased in the absence of gallstones. In developed countries, gallstones occur in 7% of males and 15% of females aged 18–65 years, with an overall prevalence of 11%. In individuals under 40 years there is a 3 : 1 female preponderance, whereas in the elderly the sex ratio is about equal. Gallstones are less frequent in India, the Far East and Africa. There has been much debate over the role of diet in cholesterol gallstone disease; an increase in dietary cholesterol, fat, total calories and refined carbohydrate or lack of dietary fibre has been implicated.

22.61 Risk factors and mechanisms for cholesterol gallstones

↑Cholesterol secretion

Age	Stasis
Hepatic cirrhosis	
Ileal resection/disease	

*Major component.

Pathophysiology

Gallstones are conventionally classified into cholesterol or pigment stones, although the majority are of mixed composition. Gallstones contain varying quantities of calcium salts, including calcium bilirubinate, carbonate, phosphate and palmitate, which are radio-opaque. Gallstone formation is multifactorial and the factors involved are related to the type of gallstone (Boxes 22.61 and 22.62).

Cholesterol gallstones

Cholesterol is held in solution in bile by its association with bile acids and phospholipids in the form of micelles and vesicles. Biliary lipoproteins may also have a role in solubilising cholesterol. In gallstone disease, the liver produces bile that contains an excess of cholesterol because there is either a relative deficiency of bile salts or a relative excess of cholesterol ('lithogenic' bile). Abnormalities of bile salt synthesis and circulation, cholesterol secretion and gallbladder function may make production of lithogenic bile more likely.

Pigment stones

Brown, crumbly pigment stones are almost always the consequence of bacterial or parasitic biliary infection. They are common in the Far East, where infection allows bacterial β-glucuronidase to hydrolyse conjugated bilirubin to its free form,

which then precipitates as calcium bilirubinate. The mechanism of black pigment gallstone formation in developed countries is not satisfactorily explained. Haemolysis is important as a contributing factor for the development of black pigment stones that occur in chronic haemolytic disease.

Biliary sludge

This describes gelatinous bile that contains numerous microspheroliths of calcium bilirubinate granules and cholesterol crystals, as well as glycoproteins; it is an important precursor to the formation of gallstones in the majority of patients. Biliary sludge is frequently formed under normal conditions but then either dissolves or is cleared by the gallbladder; only in about 15% of patients does it persist to form cholesterol stones. Fasting, parenteral nutrition and pregnancy are also associated with sludge formation.

Clinical features

Only 10% of individuals with gallstones develop clinical evidence of gallstone disease. Symptomatic stones within the gallbladder (Box 22.63) manifest as either biliary pain ('biliary colic') or cholecystitis (see below). If a gallstone becomes acutely impacted in the cystic duct, the patient will experience pain. The term 'biliary colic' is a misnomer because the pain does not rhythmically increase and decrease in intensity like other forms of colic. Typically, the pain occurs suddenly and persists for about 2 hours; if it continues for more than 6 hours, a complication such as cholecystitis or pancreatitis may be present. Pain is usually felt in the epigastrium (70% of patients) or right upper quadrant (20%) and radiates to the interscapular region or the tip of the right scapula, but other sites include the left upper quadrant and the lower chest. The pain can mimic intrathoracic disease, oesophagitis, myocardial infarction or dissecting aortic aneurysm.

Combinations of fatty food intolerance, dyspepsia and flatulence not attributable to other causes have been referred to as 'gallstone dyspepsia'. These symptoms are not now recognised as being caused by gallstones and are best regarded as functional dyspepsia (p. 779). Acute and chronic cholecystitis is described below.

A mucocele may develop if there is slow distension of the gallbladder from continuous secretion of mucus; if this material becomes infected, an empyema supervenes. Calcium may be secreted into the lumen of the hydropic gallbladder, causing 'limey' bile, and if calcium salts are precipitated in the gallbladder wall, the radiological appearance of 'porcelain' gallbladder results.

Gallstones in the gallbladder (cholecystolithiasis) migrate to the common bile duct (choledocholithiasis; p. 906) in approximately 15% of patients and cause biliary colic. Rarely, fistulae develop between the gallbladder and the duodenum, colon or stomach. If this occurs, air will be seen in the biliary tree on plain abdominal X-rays. If a stone larger than 2.5 cm in diameter has migrated into the gut, it may impact either at the terminal ileum or occasionally in the duodenum or sigmoid colon. The resultant intestinal obstruction may be followed by 'gallstone ileus'. Gallstones impacted in the cystic duct may cause stricturing of the common hepatic duct and the clinical picture of extrahepatic biliary diseases ('Mirizzi's syndrome', with its important differential of malignant bile duct stricture). The more common cause of jaundice due to gallstones is a stone passing from the cystic duct into the common bile duct (choledocholithiasis), which may also result in cholangitis or acute pancreatitis. It is usually very small stones that precipitate acute pancreatitis, due (it is thought) to oedema at the ampulla as the stone passes into the duodenum (no stone is seen within the bile duct in 80% of cases of presumed gallstone pancreatitis, suggesting stone passage). Previous stone passage is also the likely cause of most cases of benign papillary fibrosis, which is most commonly seen in patients with previous or present gallstone disease (it may present with jaundice, obstructive LFTs with biliary dilatation, post-cholecystectomy pain or acute pancreatitis).

Cancer of the gallbladder is growing in frequency (p. 907) but in over 95% of cases is associated with the presence of gallstones. Previously, the diagnosis was typically made as an incidental histological finding following cholecystectomy for gallstone disease. Increasing awareness of the risk of gallbladder carcinoma and of the role played by polyps in the natural history has led to an increase in screening activity and prospective diagnosis.

Investigations

Ultrasound is the investigation of choice for diagnosing gallstones. Most stones are diagnosed by transabdominal ultrasound, which has more than 92% sensitivity and 99% specificity for gallbladder stones (see Fig. 22.8, p. 854). CT, MRCP (Fig. 22.44) and, increasingly, EUS are excellent modalities for detecting complications of gallstones (distal bile duct stone or gallbladder empyema) but are inferior to ultrasound in defining

22.63 Clinical features and complications of gallstones

Clinical features	
• Asymptomatic (80%) • Biliary colic	• Acute cholecystitis • Chronic cholecystitis
Complications	
• Empyema of the gallbladder • Porcelain gallbladder • Choledocholithiasis • Acute pancreatitis • Fistulae from gallbladder to duodenum/colon	• Pressure on/inflammation of the common hepatic duct by a gallstone in the cystic duct (Mirizzi's syndrome) • Gallstone ileus • Cancer of the gallbladder

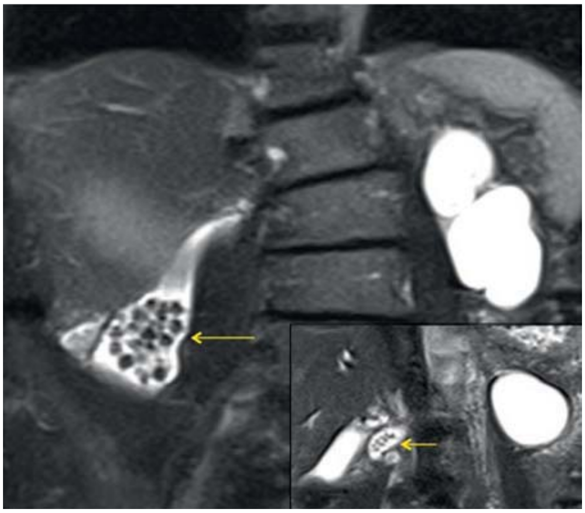

Fig. 22.44 Magnetic resonance cholangiopancreatogram showing multiple stones in the gallbladder (long arrow) and also within the distal common bile duct (inset, arrow).

i 22.64 Treatment of gallstones

Gallbladder stones	
• Cholecystectomy: laparoscopic or open	
• Oral bile acids: chenodeoxycholic or ursodeoxycholic (low rate of stone dissolution)	
Bile duct stones	
• Lithotripsy (endoscopic or extracorporeal shock wave, ESWL)	
• Endoscopic sphincterotomy and stone extraction	
• Surgical bile duct exploration	

their presence in the gallbladder. When recurrent attacks of otherwise unexplained acute pancreatitis occur, they may result from 'microlithiasis' in the gallbladder or common bile duct and are best assessed by EUS.

Management

Asymptomatic gallstones found incidentally should not be treated because the majority will never cause symptoms. Symptomatic gallstones are best treated surgically by laparoscopic cholecystectomy; the severity of symptoms should be balanced against the individual patient surgical risk in order to decide whether surgery is warranted. Various techniques can be used to treat common bile duct stones (Box 22.64).

Cholecystitis

Acute cholecystitis

Pathophysiology

Acute cholecystitis is almost always associated with obstruction of the gallbladder neck or cystic duct by a gallstone. Occasionally, obstruction may be by mucus, parasitic worms or a biliary tumour, or may follow endoscopic bile duct stenting. The pathogenesis is unclear but the initial inflammation is possibly chemically induced. This leads to gallbladder mucosal damage, which releases phospholipase, converting biliary lecithin to lysolecithin, a recognised mucosal toxin. At the time of surgery, approximately 50% of cultures of the gallbladder contents are sterile. Infection occurs eventually, and in elderly patients or those with diabetes mellitus a severe infection with gas-forming organisms can cause emphysematous cholecystitis. Acalculous cholecystitis can occur in the intensive care setting and in association with parenteral nutrition, sickle cell disease and diabetes mellitus.

Clinical features

The cardinal feature is pain in the right upper quadrant but also in the epigastrium, the right shoulder tip or the interscapular region. Differentiation between biliary colic (p. 904) and acute cholecystitis may be difficult; features suggesting cholecystitis include severe and prolonged pain, fever and leucocytosis.

Examination shows right hypochondrial tenderness, rigidity worse on inspiration (Murphy's sign) and occasionally a gallbladder mass (30% of cases). Fever is present but rigors are unusual. Jaundice occurs in less than 10% of patients and is usually due to passage of stones into the common bile duct, or to compression or even stricturing of the common bile duct following stone impaction in the cystic duct (Mirizzi's syndrome). Gallbladder perforation occurs in 10–15% of cases and gallbladder empyema may arise.

Investigations

Peripheral blood leucocytosis is common, except in the elderly patient, in whom the signs of inflammation may be minimal. Minor increases of transaminases and amylase may be encountered. Amylase should be measured to detect acute pancreatitis (p. 837), which may be a potentially serious complication of gallstones. Only when the amylase is higher than 1000 U/L can pain be confidently attributed to acute pancreatitis, since moderately elevated levels of amylase can occur with many other causes of abdominal pain. Plain X-rays of the abdomen and chest may show radio-opaque gallstones, and rarely intrabiliary gas due to fistulation of a gallstone into the intestine; they are important in excluding lower lobe pneumonia and a perforated viscus. Ultrasonography detects gallstones and gallbladder thickening due to cholecystitis but gallbladder empyema or perforation is best assessed by CT.

Management

Medical

Medical management consists of bed rest, pain relief, antibiotics and intravenous fluids. Moderate pain can be treated with NSAIDs but more severe pain should be managed with opiates. A cephalosporin (such as cefuroxime) or piperacillin/tazobactam is the usual antibiotic of choice, but metronidazole is normally added in severely ill patients and local prescribing practice may vary. Nasogastric aspiration is needed only for persistent vomiting. Cholecystitis usually resolves with medical treatment but the inflammation may progress to an empyema or perforation and peritonitis.

Surgical

Urgent surgery is the optimal treatment when cholecystitis progresses in spite of medical therapy and when complications such as empyema or perforation develop. Operation should be carried out within 5 days of the onset of symptoms. Delayed surgery after 2–3 months is no longer favoured. When cholecystectomy may be difficult due to extensive inflammatory change, percutaneous gallbladder drainage can be performed, with subsequent cholecystectomy 4–6 weeks later. Recurrent biliary colic or cholecystitis is frequent if the gallbladder is not removed.

Chronic cholecystitis

Chronic inflammation of the gallbladder is almost invariably associated with gallstones. The usual symptoms are those of recurrent attacks of upper abdominal pain, often at night and following a heavy meal. The clinical features are similar to those of acute calculous cholecystitis but milder. Patients may recover spontaneously or following analgesia and antibiotics. They are usually advised to undergo elective laparoscopic cholecystectomy.

Acute cholangitis

Acute cholangitis is caused by bacterial infection of bile ducts and occurs in patients with other biliary problems, such as choledocholithiasis (see below), biliary strictures or tumours, or after ERCP. Jaundice, fever (with or without rigors) and right upper quadrant pain are the main presenting features ('Charcot's triad'). Treatment is with antibiotics, relief of biliary obstruction and removal (if possible) of the underlying cause.

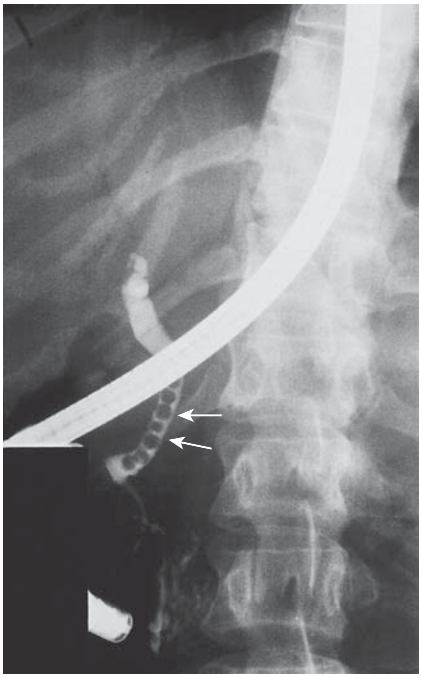

Fig. 22.45 Endoscopic retrograde cholangiopancreatogram showing common duct stones (arrows).

Choledocholithiasis

Stones in the common bile duct (choledocholithiasis) occur in 10–15% of patients with gallstones (Fig. 22.45), which have usually migrated from the gallbladder. Primary bile duct stones are rare but can develop within the common bile duct many years after a cholecystectomy, and are sometimes related to biliary sludge arising from dysfunction of the sphincter of Oddi. In Far Eastern countries, primary common bile duct stones are thought to follow bacterial infection secondary to parasitic infections with *Clonorchis sinensis*, *Ascaris lumbricoides* or *Fasciola hepatica* (pp. 297 and 289). Common bile duct stones can cause bile duct obstruction and may be complicated by cholangitis due to secondary bacterial infection, sepsis, liver abscess and biliary stricture.

Clinical features

Choledocholithiasis may be asymptomatic, may be found incidentally by operative cholangiography at cholecystectomy, or may manifest as recurrent abdominal pain with or without jaundice. The pain is usually in the right upper quadrant, and fever, pruritus and dark urine may be present. Rigors may be a feature; jaundice is common and usually associated with pain. Physical examination may show the scar of a previous cholecystectomy; if the gallbladder is present, it is usually small, fibrotic and impalpable.

Investigations

The LFTs show a cholestatic pattern and there is bilirubinuria. If cholangitis is present, the patient usually has a leucocytosis. The most convenient method of demonstrating obstruction to the common bile duct is transabdominal ultrasound. This shows dilated extrahepatic and intrahepatic bile ducts, together with gallbladder stones (Fig. 22.46), but does not always reveal the

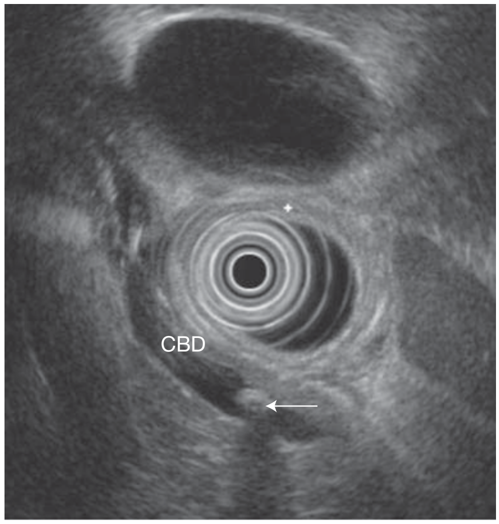

Fig. 22.46 Endoscopic ultrasound image in a patient with cholangitis. The dilated common bile duct (CBD) contains a small stone (arrow), which causes acoustic shadowing.

cause of the obstruction in the common bile duct; 50% of bile duct stones are missed on ultrasound, particularly those in the distal common bile duct. EUS is extremely accurate at identifying bile duct stones. MRCP is non-invasive and is indicated when intervention is not necessarily mandatory (e.g. the patient with possible bile duct stones but no jaundice or sepsis).

Management

Cholangitis should be treated with analgesia, intravenous fluids and broad-spectrum antibiotics, such as cefuroxime and metronidazole (local prescribing practice may vary). Blood cultures should be taken before the antibiotics are administered. Patients also require urgent decompression of the biliary tree and stone removal. ERCP with biliary sphincterotomy and stone extraction is the treatment of choice and is successful in about 90% of patients. If ERCP fails, other approaches include percutaneous transhepatic drainage and combined ('rendezvous') endoscopic procedures, extracorporeal shock wave lithotripsy (ESWL) and surgery.

Surgical treatment of choledocholithiasis is performed less frequently than ERCP, and before the common bile duct is explored the diagnosis of choledocholithiasis should be confirmed by intraoperative cholangiography. If gallstones are found, the bile duct is explored, either via the cystic duct or by opening it, all stones are removed, clearance is checked by cholangiography or choledochoscopy, and then primary closure of the duct is performed if possible. External drainage of the common bile duct by T-tube is rarely required nowadays. It is now possible to achieve these goals laparoscopically in specialist centres.

Recurrent pyogenic cholangitis

This disease occurs predominantly in South-east Asia. Biliary sludge, calcium bilirubinate concretions and stones accumulate in the intrahepatic bile ducts, with secondary bacterial infection. Patients present with recurrent attacks of upper abdominal pain, fever and cholestatic jaundice. Investigation of the biliary tree demonstrates that both the intrahepatic and the extrahepatic portions are filled with soft biliary mud. Eventually, the liver becomes scarred and liver abscesses and secondary biliary cirrhosis develop. The condition is difficult to manage and requires

drainage of the biliary tract with extraction of stones, antibiotics and, in certain patients, partial resection of damaged areas of the liver.

Tumours of the gallbladder and bile duct

Carcinoma of the gallbladder

This is an uncommon tumour, occurring more often in females and usually in those over the age of 70 years. More than 90% are adenocarcinomas; the remainder are anaplastic or, rarely, squamous tumours. Gallstones are present in 70–80% of cases and are thought to be important in the aetiology of the tumour. Individuals with a calcified gallbladder ('porcelain gallbladder'; p. 904) are at high risk of malignant change, and gallbladder polyps over 1 cm in size are associated with increased risk of malignancy; preventative cholecystectomy should be considered in such patients. Chronic infection with *Salmonella*, especially in areas where typhoid is endemic, is also a risk factor.

Carcinoma of the gallbladder may be diagnosed incidentally and is found in 1–3% of gallbladders removed at cholecystectomy for gallstone disease. It may manifest as repeated attacks of biliary pain and, later, persistent jaundice and weight loss. A gallbladder mass may be palpable in the right hypochondrium. LFTs show cholestasis, and porcelain gallbladder may be found on X-ray. The tumour can be diagnosed by ultrasonography and staged by CT. The treatment is surgical excision but local extension of the tumour beyond the wall of the gallbladder into the liver, lymph nodes and surrounding tissues is invariable and palliative management is usually all that can be offered. Survival is generally short, death typically occurring within 1 year in patients presenting with symptoms.

Cholangiocarcinoma

Cholangiocarcinoma (CCA) is an uncommon tumour that can arise anywhere in the biliary tree, from the intrahepatic bile ducts (20–25% of cases) and the confluence of the right and left hepatic ducts at the liver hilum (50–60%) to the distal common bile duct (20%). It accounts for only 1.5% of all cancers but the incidence is increasing. The cause is unknown but the tumour is associated with gallstones, primary and secondary sclerosing cholangitis, Caroli's disease and choledochal cysts (see Fig. 22.43). In the Far East, particularly northern Thailand, chronic liver fluke infection (*Clonorchis sinensis*) is a major risk factor for the development of CCA in men. Primary sclerosing cholangitis carries a lifetime risk of CCA of approximately 20%, although only 5% of CCAs relate to primary sclerosing cholangitis. Chronic biliary inflammation appears to be a common factor in the development of biliary dysplasia and cancer that is shared by all the predisposing causes.

Tumours typically invade the lymphatics and adjacent vessels, with a predilection for spread within perineural sheaths. The presentation is usually with obstructive jaundice. About 50% of patients also have upper abdominal pain and weight loss. The diagnosis is made using a combination of CT and MRI (see Fig. 22.10, p. 855) but can be difficult to confirm in patients with sclerosing cholangitis. Serum levels of the tumour marker CA19-9 are elevated in up to 80% of cases, although this may occur in biliary obstruction of any cause. In the setting of biliary obstruction, ERCP may result in positive biliary cytology. Endoscopic ultrasound–fine needle aspiration (EUS-FNA) of bile duct masses is sometimes possible, and in specialist centres single-operator cholangioscopy with biopsy is now established. CCAs can be treated surgically in about 20% of patients, which improves 5-year survival from less than 5% to 20–40%. Surgery involves excision of the extrahepatic biliary tree with or without a liver resection and a Roux loop reconstruction. However, most patients are treated by stent insertion across the malignant biliary stricture, using endoscopic or percutaneous transhepatic techniques (Fig. 22.47). Combination chemotherapy is increasingly used and palliation with endoscopic photodynamic therapy has provided encouraging results.

Carcinoma at the ampulla of Vater

Nearly 40% of all adenocarcinomas of the small intestine arise in relationship to the ampulla of Vater and present with pain, anaemia, vomiting and weight loss. Jaundice may be intermittent or persistent. The diagnosis is made by duodenal endoscopy and biopsy of the tumour but staging by CT/MRI and EUS is essential. Ampullary carcinoma must be differentiated from carcinoma of

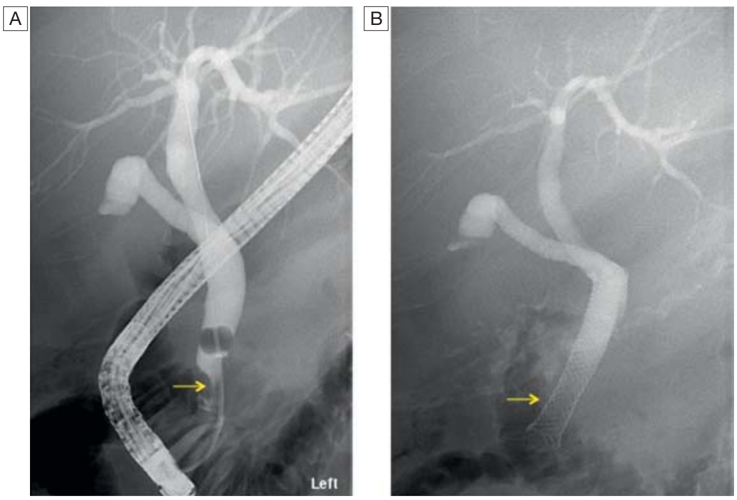

Fig. 22.47 Cholangiocarcinoma. **A** Endoscopic retrograde cholangiopancreatogram showing a malignant distal biliary stricture (arrow) and dilated duct above this. **B** A self-expanding metallic stent (SEMS) has been placed across the stricture to relieve jaundice (arrow).

the head of the pancreas and a CCA because these last two conditions both have a worse prognosis. Imaging may show a 'double duct sign' with stricturing of both the common bile duct and pancreatic duct at the ampulla and upstream dilatation of the ducts. EUS is the most sensitive method of assessing and staging ampullary or periampullary tumours.

Curative surgical treatment can be undertaken by pancreaticoduodenectomy and the 5-year survival may be as high as 50%. If resection is impossible, palliative surgical bypass or stenting may be necessary.

Benign gallbladder tumours

These are uncommon, often asymptomatic and usually found incidentally at operation or postmortem. Cholesterol polyps, sometimes associated with cholesterolosis, papillomas and adenomas, are the main types.

Miscellaneous biliary disorders

Post-cholecystectomy syndrome

Dyspeptic symptoms following cholecystectomy (post-cholecystectomy syndrome) occur in about 30% of patients, depending on how the condition is defined, how actively symptoms are sought and what the original indication for cholecystectomy was. The syndrome occurs most frequently in women, in patients who have had symptoms for more than 5 years before cholecystectomy, and in cases when the operation was undertaken for non-calculous gallbladder disease. An increase in bowel habit resulting from bile acid diarrhoea occurs in about 5–10% of patients after cholecystectomy and often responds to colestyramine (4–8 g daily). Severe post-cholecystectomy syndrome occurs in only 2–5% of patients. The main causes are listed in Box 22.65.

The usual symptoms include right upper quadrant pain, flatulence, fatty food intolerance and occasionally jaundice and cholangitis. The LFTs may be abnormal and sometimes show cholestasis. Ultrasonography is used to detect biliary obstruction, and EUS or MRCP to seek common bile duct stones. If retained bile duct stones are excluded, sphincter of Oddi dysfunction should be considered (see below). Other investigations that may be required include upper gastrointestinal endoscopy, small bowel radiology and pancreatic function tests. The possibility of a functional illness should also be considered.

22.65 Causes of post-cholecystectomy symptoms

Immediate post-surgical	
• Bleeding • Biliary peritonitis • Abscess	• Bile duct trauma/transection • Fistula
Biliary	
• Common bile duct stones • Benign stricture • Tumour • Cystic duct stump syndrome	• Disorders of the ampulla of Vater (e.g. benign papillary fibrosis; sphincter of Oddi dysfunction)
Extrabiliary	
• Functional dyspepsia • Peptic ulcer • Pancreatic disease	• Gastro-oesophageal reflux • Irritable bowel syndrome • Functional abdominal pain

Functional biliary sphincter disorders ('sphincter of Oddi dysfunction')

The sphincter of Oddi is a small smooth-muscle sphincter situated at the junction of the bile duct and pancreatic duct in the duodenum. It has been believed that sphincter of Oddi dysfunction (SOD) was characterised by an increase in contractility that produces a benign non-calculous obstruction to the flow of bile or pancreatic juice. This may cause pancreaticobiliary pain, deranged LFTs or recurrent pancreatitis. Classification systems, based on clinical history, laboratory results, findings on investigation and response to interventions, are difficult because of the fluctuating nature of symptoms and the well-recognised placebo effect of interventions. SOD was previously classified into types I–III but these have been replaced by newer terminology (Boxes 22.66 and 22.67).

Clinical features

Patients with functional biliary sphincter disorders, who are predominantly female, present with symptoms and signs suggestive of either biliary or pancreatic disease:

- *Patients with biliary sphincter disorders* experience recurrent, episodic biliary-type pain. They have often had a cholecystectomy but the gallbladder may be intact.
- *Patients with pancreatic sphincter disorders* usually present with unexplained recurrent attacks of pancreatitis.

Investigations

The diagnosis is established by excluding gallstones, including microlithiasis, and by demonstrating a dilated or slowly draining bile duct. The gold standard for diagnosis is sphincter of Oddi manometry. This is not widely available, however, and is associated with a high rate of procedure-related pancreatitis. Hepatobiliary scintigraphy (e.g. hepatobiliary iminodiacetic acid) may have value in the second-line investigation of post-cholecystectomy syndrome.

22.66 Classification of biliary sphincter of Oddi dysfunction (SOD)

Organic stenosis (formerly SOD type I)
- Biliary-type pain
- Abnormal liver enzymes (ALT/AST > twice normal on two or more occasions)
- Dilated common bile duct (>12 mm diameter)
- Delayed drainage of ERCP contrast beyond 45 mins

Functional sphincter of Oddi disorder (formerly SOD type II)
- Biliary-type pain with one or two of the above criteria

Functional biliary-type pain (formerly SOD type III)
- Biliary-type pain with no other abnormalities

22.67 Criteria for pancreatic sphincter of Oddi dysfunction

- Recurrent attacks of acute pancreatitis – pancreatic-type pain with amylase or lipase 3 times normal and/or imaging evidence of acute pancreatitis
- Other aetiologies of acute pancreatitis excluded
- Normal pancreas at endoscopic ultrasound
- Abnormal sphincter manometry

22.68 Gallbladder disease in old age

- **Gallstones**: by the age of 70 years, prevalence is around 30% in women and 19% in men.
- **Acute cholecystitis**: tends to be severe, may have few localising signs and is associated with a high frequency of empyema and perforation. If such complications supervene, mortality may reach 20%.
- **Cholecystectomy**: mortality after urgent cholecystectomy for acute uncomplicated cholecystitis is not significantly higher than in younger patients.
- **Endoscopic sphincterotomy and removal of common duct stones**: well tolerated by older patients, with lower mortality than surgical common bile duct exploration.
- **Cancer of the gallbladder**: a disease of old age, with a 1-year survival of 10%.

Management

All patients with organic stenosis are treated with endoscopic sphincterotomy. The results are good but patients should be warned that there is a high risk of complications, particularly acute pancreatitis. Manometry should ideally be performed in all suspected functional sphincter of Oddi disorder patients ('type II'), and results of sphincterotomy in those with high pressures are good, but this should be avoided in patients with functional biliary-type pain ('type III'), as it is of no benefit. Medical therapy with nifedipine and/or low-dose amitriptyline may be tried. Pancreatic SOD can be treated with biliary sphincterotomy, carried out in specialist centres, but this should be undertaken with caution and careful consideration.

Routine prophylactic pancreatic duct stenting in patients undergoing ERCP for sphincter of Oddi disorders is no longer encouraged. Prophylactic administration of rectal NSAIDs (e.g. diclofenac 100 mg) is recommended instead because this significantly reduces the risk of procedure-related acute pancreatitis.

Cholesterolosis of the gallbladder

In this condition, lipid deposits in the submucosa and epithelium appear as multiple yellow spots on the pink mucosa, giving rise to the description 'strawberry gallbladder'. Cholesterolosis of the gallbladder is usually asymptomatic but may occasionally present with right upper quadrant pain. Small, fixed filling defects may be visible on ultrasonography; the radiologist can usually differentiate between gallstones and cholesterolosis. The condition is usually diagnosed at cholecystectomy; if the diagnosis is made radiologically, cholecystectomy may be indicated, depending on symptoms.

Adenomyomatosis of the gallbladder

In this condition, there is hyperplasia of the muscle and mucosa of the gallbladder. The projection of pouches of mucous membrane through weak points in the muscle coat produces Rokitansky–Aschoff sinuses. There is much disagreement over whether adenomyomatosis is a cause of right upper quadrant pain or other gastrointestinal symptoms. It may be diagnosed by oral cholecystography, when a halo or ring of opacified diverticula can be seen around the gallbladder. Other appearances include deformity of the body of the gallbladder or marked irregularity of the outline. Localised adenomyomatosis in the region of the gallbladder fundus causes the appearance of a 'Phrygian cap'. Most patients are treated by cholecystectomy but only after other diseases in the upper gastrointestinal tract have been excluded.

IgG4-associated cholangitis

This recently reported disease often presents with obstructive jaundice and is described on page 890.

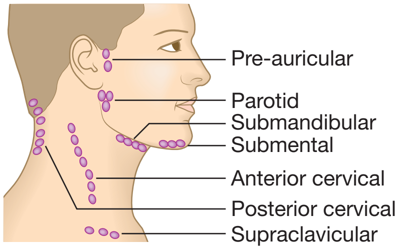
Insets (Glossitis) From Hoffbrand VA, John E, Pettit JE, Vyas P. Color atlas of clinical hematology, 4th edn. Philadelphia: Mosby, Elsevier Inc.; 2010; (Petechiae) Young NS, Gerson SL, High KA (eds). Clinical hematology. St Louis: Mosby, Elsevier Inc.; 2006.

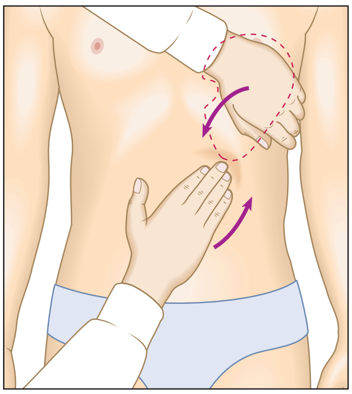
Abnormalities detected in the blood are caused not only by primary diseases of the blood and lymphoreticular systems but also by diseases affecting other systems of the body. The clinical assessment of patients with haematological abnormalities must include a general history and examination, as well as a search for symptoms and signs of abnormalities of red cells, white cells, platelets, haemostatic systems, lymph nodes and lymphoreticular tissues.

6 Lymphadenopathy



Lymphadenopathy can be caused by benign or malignant disease. The clinical points to clarify are shown in the box.

i Lymphadenopathy



History
- Speed of onset, rate of enlargement
- Painful or painless
- Associated symptoms: weight loss, night sweats, itch

Examination
- Sites: localised, generalised
- Size (cm)
- Character: hard, soft, rubbery
- Fixed, mobile
- Search area that node drains for abnormalities (e.g. dental abscess)
- Other general examination (e.g. joints, rashes, finger clubbing)

8 Examination of the spleen

- Move your hand up from the right iliac fossa, towards the left upper quadrant on expiration.
- Keep your hand still and ask the patient to take a deep breath through the mouth to feel the spleen edge being displaced downwards.
- Place your left hand around the patient's lower ribs and approach the costal margin to pull the spleen forwards.
- To help palpate small spleens, roll the patient on to the right side and examine as before.

i Characteristics of the spleen
- Notch
- Superficial
- Dull to percussion
- Cannot get examining hand between ribs and spleen
- Moves well with respiration

Anaemia

Symptoms and signs help to indicate the clinical severity of anaemia. A full history and examination is needed to identify the underlying cause.

i Anaemia

Non-specific symptoms
- Tiredness
- Lightheadedness
- Breathlessness
- Development/worsening of ischaemic symptoms, e.g. angina or claudication

Non-specific signs
- Mucous membrane pallor
- Tachypnoea
- Raised jugular venous pressure
- Tachycardia
- Flow murmurs
- Ankle oedema
- Postural hypotension

Bleeding

Bleeding can be due to congenital or acquired abnormalities in the clotting system. History and examination help to clarify the severity and the underlying cause of the bleeding problem.

i Bleeding

History
- Site of bleed
- Duration of bleed
- Precipitating causes, including previous surgery or trauma
- Family history
- Drug history
- Age at presentation
- Other medical conditions, e.g. liver disease

Examination

There are two main patterns of bleeding:

1. Mucosal bleeding
   Reduced number or function of platelets (e.g. bone marrow failure or aspirin) or von Willebrand factor (e.g. von Willebrand disease)
      Skin: petechiae, bruises
      Gum and mucous membrane bleeding
      Fundal haemorrhage
      Post-surgical bleeding
2. Coagulation factor deficiency
   (e.g. haemophilia or warfarin/anticoagulant)
      Bleeding into joints (haemarthrosis) or muscles
      Bleeding into soft tissues
      Retroperitoneal haemorrhage
      Intracranial haemorrhage
      Post-surgical bleeding

Disorders of the blood cover a wide spectrum of illnesses, ranging from some of the most common disorders affecting humans (anaemias) to relatively rare conditions such as leukaemias and congenital coagulation disorders. Although the latter are uncommon, advances in cellular and molecular biology have had major impacts on their diagnosis, treatment and prognosis. Haematological changes occur as a consequence of diseases affecting any system and give important information in the diagnosis and monitoring of many conditions.

Functional anatomy and physiology

Blood flows throughout the body in the vascular system, and consists of:

- red cells, which transport oxygen from the lungs to the tissues
- white cells, which defend against infection
- platelets, which interact with blood vessels and clotting factors to maintain vascular integrity and prevent bleeding
- plasma, which contains proteins with many functions, including antibodies and coagulation factors.

Haematopoiesis

Haematopoiesis describes the formation of blood cells, an active process that must maintain normal numbers of circulating cells and be able to respond rapidly to increased demands such as bleeding or infection. During development, haematopoiesis occurs in the yolk sac, liver and spleen, and subsequently in red bone marrow in the medullary cavity of all bones. In childhood, red marrow is progressively replaced by fat (yellow marrow) so that, in adults, normal haematopoiesis is restricted to the vertebrae, pelvis, sternum, ribs, clavicles, skull, upper humeri and proximal femora. However, red marrow can expand in response to increased demands for blood cells.

Bone marrow contains a range of immature haematopoietic precursor cells and a storage pool of mature cells for release at times of increased demand. Haematopoietic cells interact closely with surrounding connective tissue stroma, made up of reticular cells, macrophages, fat cells, blood vessels and nerve fibres (Fig. 23.1). In normal marrow, nests of red cell precursors cluster around a central macrophage, which provides iron and also phagocytoses nuclei from red cells prior to their release into the circulation. Megakaryocytes are large cells that produce and release platelets into vascular sinuses. White cell precursors are clustered next to the bone trabeculae; maturing cells migrate into the marrow spaces towards the vascular sinuses. Plasma cells are antibody-secreting mature B cells that normally represent less than 5% of the marrow population and are scattered throughout the intertrabecular spaces.

Stem cells

All blood cells are derived from pluripotent haematopoietic stem cells. These comprise only 0.01% of the total marrow cells, but they can self-renew (i.e. make more stem cells) or differentiate to produce a hierarchy of lineage-committed progenitor cells. The resulting primitive progenitor cells cannot be identified morphologically, so they are named according to the types of cell (or colony) they form during cell culture experiments. CFU–GM (colony-forming unit – granulocyte, monocyte) is a progenitor cell that produces granulocytic and monocytic lines, CFU–E produce erythroid cells, and CFU–Meg produce megakaryocytes and ultimately platelets (Fig. 23.2).

Growth factors, produced in bone marrow stromal cells and elsewhere, control the survival, proliferation, differentiation and function of stem cells and their progeny. Some, such as, interleukin-3 (IL-3), stem cell factor (SCF) and granulocyte, macrophage–colony-stimulating factor (GM–CSF), act on a wide number of cell types at various stages of differentiation. Others, such as erythropoietin, granulocyte–colony-stimulating factor (G–CSF) and thrombopoietin (Tpo), are lineage-specific. Many of these growth factors are now synthesised by recombinant DNA technology and used as treatments: for example, erythropoietin to correct renal anaemia and G–CSF to hasten neutrophil recovery after chemotherapy.

The bone marrow also contains stem cells that can differentiate into non-haematological cells. Mesenchymal stem cells differentiate

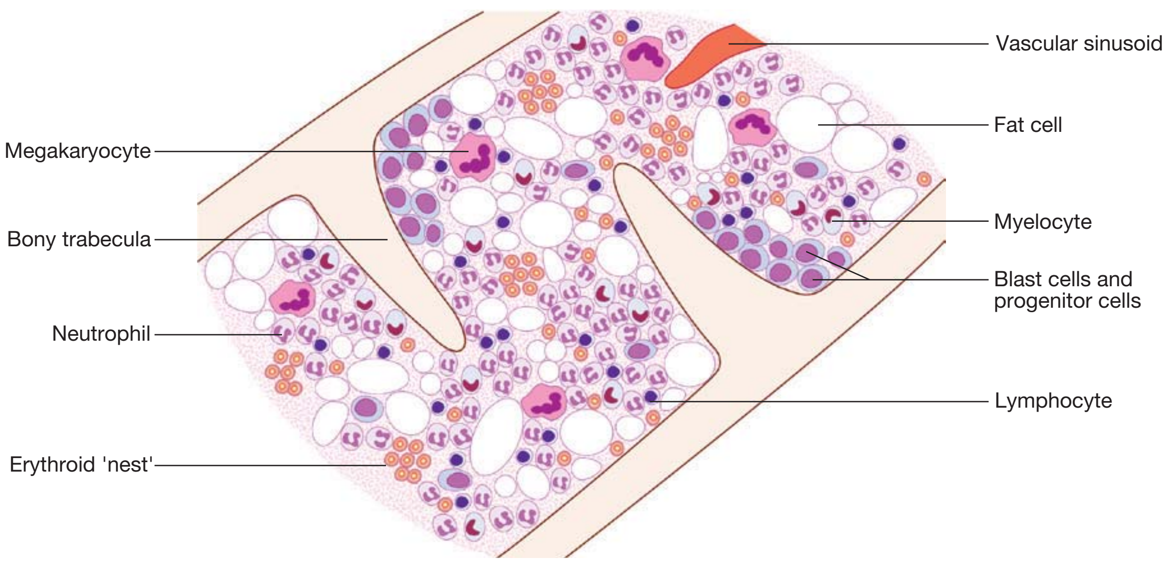


Fig. 23.1 Structural organisation of normal bone marrow.

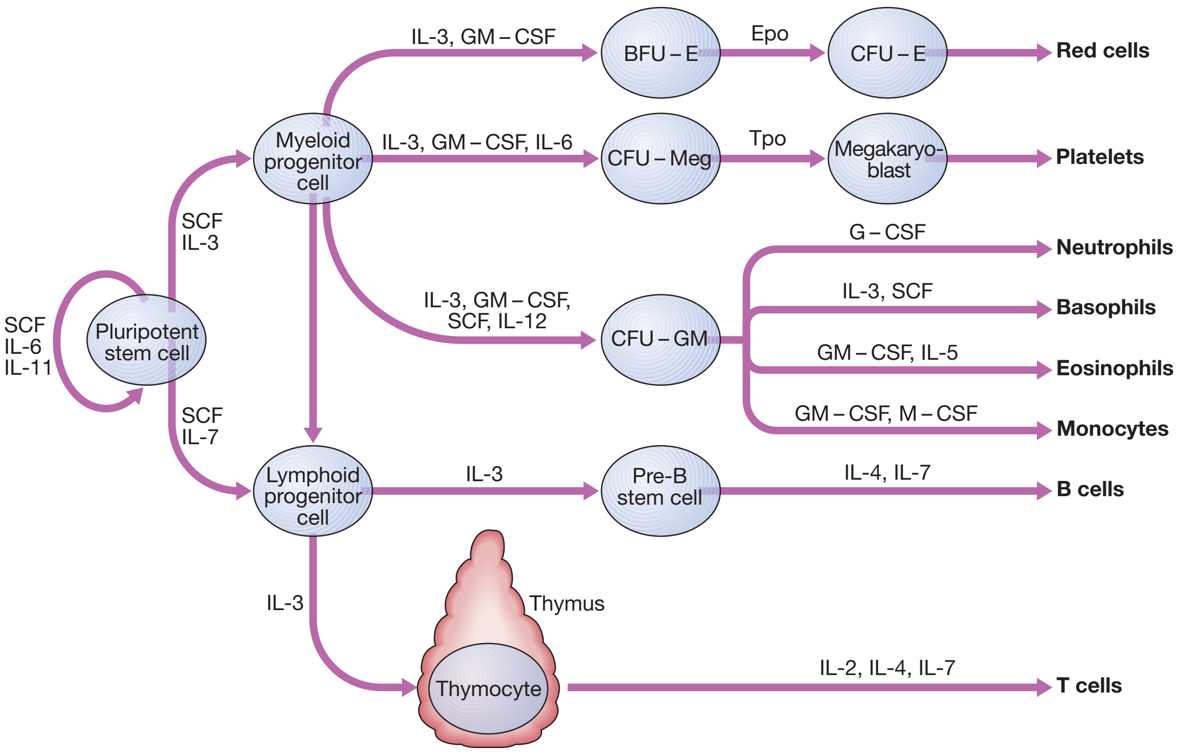

Fig. 23.2 Stem cells and growth factors in haematopoietic cell development. (BFU–E = burst-forming unit – erythroid; CFU–E = colony-forming unit – erythroid; CFU–GM = colony-forming unit – granulocyte, monocyte; CFU–Meg = colony-forming unit – megakaryocyte; Epo = erythropoietin; G–CSF = granulocyte–colony-stimulating factor; GM–CSF = granulocyte, macrophage–colony-stimulating factor; IL = interleukin; M–CSF = macrophage–colony-stimulating factor; SCF = stem cell factor; Tpo = thrombopoietin)

into skeletal muscle, cartilage, cardiac muscle, and fat cells while others differentiate into nerves, liver and blood vessel endothelium. This is termed stem cell plasticity and may have exciting clinical applications in the future (Ch. 3).

Blood cells and their functions

Red cells

Red cell precursors formed in the bone marrow from the erythroid (CFU–E) progenitor cells are called erythroblasts or normoblasts (Fig. 23.3). These divide and acquire haemoglobin, which turns the cytoplasm pink; the nucleus condenses and is extruded from the cell. The first non-nucleated red cell is a reticulocyte, which still contains ribosomal material in the cytoplasm, giving these large cells a faint blue tinge ('polychromasia'). Reticulocytes lose their ribosomal material and mature over 3 days, during which time they are released into the circulation. Increased numbers of circulating reticulocytes (reticulocytosis) reflect increased erythropoiesis. Proliferation and differentiation of red cell precursors is stimulated by erythropoietin, a polypeptide hormone produced by renal interstitial peritubular cells in response to hypoxia. Failure of erythropoietin production in patients with renal failure (p. 384) causes anaemia, which can be treated with exogenous recombinant erythropoietin or similar pharmacological agents called erythropoiesis-stimulating agents, e.g. darbepoetin.

Normal mature red cells circulate for about 120 days. They are 8 μm biconcave discs lacking a nucleus but filled with haemoglobin, which delivers oxygen to the tissues. In order to pass through the smallest capillaries, the red cell membrane is deformable, with a lipid bilayer to which a 'skeleton' of filamentous proteins is attached via special linkage proteins (Fig. 23.4). Inherited abnormalities of any of these proteins result in loss of membrane as cells pass through the spleen, and the formation of abnormally shaped red cells called spherocytes or elliptocytes (see Fig. 23.8D). Red cells are exposed to osmotic stress in the pulmonary and renal circulation; in order to maintain homeostasis, the membrane contains ion pumps, which control intracellular levels of sodium, potassium, chloride and bicarbonate. In the absence of mitochondria, the energy for these functions is provided by anaerobic glycolysis and the pentose phosphate pathway in the cytosol. Membrane glycoproteins inserted into the lipid bilayer also form the antigens recognised by blood grouping (see Fig. 23.4). The ABO and Rhesus systems are the most commonly recognised (p. 931) but over 400 blood group antigens have been described.

Haemoglobin

Haemoglobin is a protein specially adapted for oxygen transport. It is composed of four globin chains, each surrounding an iron-containing porphyrin pigment molecule termed haem. Globin chains are a combination of two alpha and two non-alpha chains; haemoglobin A (αα/ββ) represents over 90% of adult haemoglobin, whereas haemoglobin F (αα/γγ) is the predominant type in the fetus. Each haem molecule contains a ferrous ion (Fe^{2+}), to which oxygen reversibly binds; the affinity for oxygen increases as successive oxygen molecules bind. When oxygen is bound, the beta chains 'swing' closer together; they move apart as oxygen is lost. In the 'open' deoxygenated state, 2,3-bisphosphoglycerate (2,3-BPG), a product of red cell

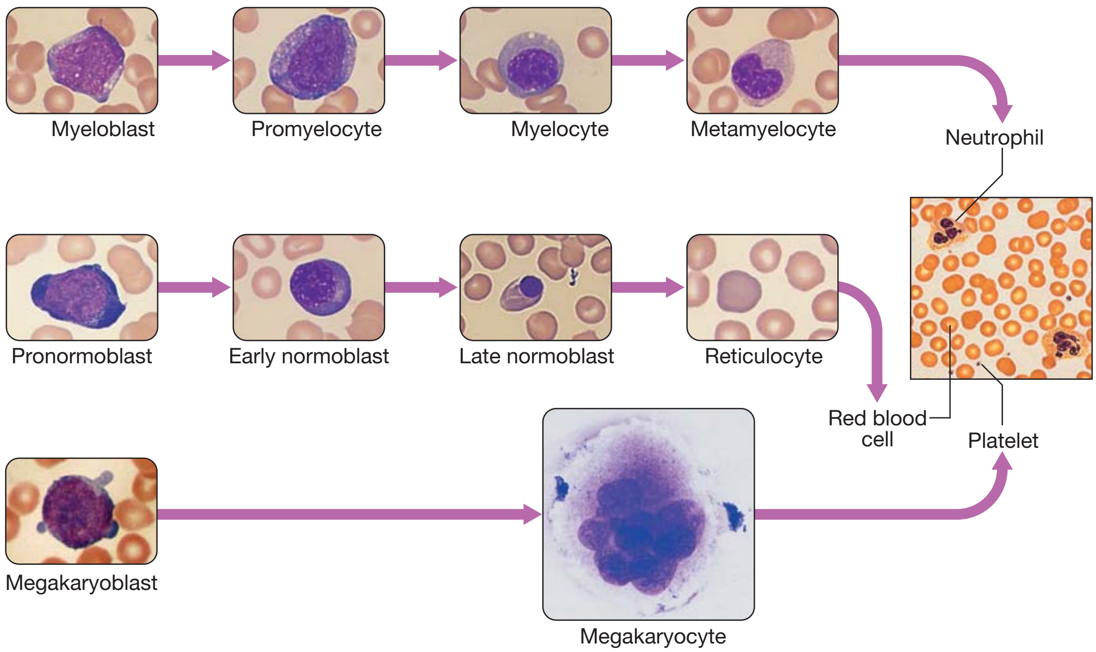

Fig. 23.3 Maturation pathway of red cells, granulocytes and platelets. The image on the right is a normal blood film.

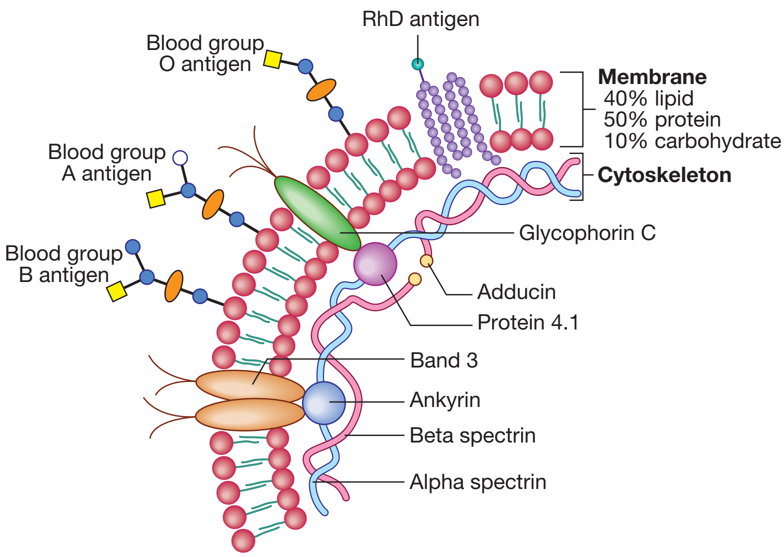

Fig. 23.4 Normal structure of red cell membrane. Red cell membrane flexibility is conferred by attachment of cytoskeletal proteins. Important transmembrane proteins include band 3 (an ion transport channel) and glycophorin C (involved in cytoskeletal attachment and gas exchange, and a receptor for *Plasmodium falciparum* in malaria). Antigens on the red blood cell determine an individual's blood group. There are about 22 blood group systems (groups of carbohydrate or protein antigens controlled by a single gene or by multiple closely linked loci); the most important clinically are the ABO and Rhesus (Rh) systems (p. 931). The ABO genetic locus has three main allelic forms: A, B and O. The A and B alleles encode glycosyltransferases that introduce *N*-acetylgalactosamine (open circle) and *D*-galactose (blue circle), respectively, on to antigenic carbohydrate molecules on the membrane surface. People with the O allele produce an O antigen, which lacks either of these added sugar groups. Rh antigens are transmembrane proteins.

metabolism, binds to the haemoglobin molecule and lowers its oxygen affinity. These complex interactions produce the sigmoid shape of the oxygen dissociation curve (Fig. 23.5). The position of this curve depends on the concentrations of 2,3-BPG, H^+ ions and CO_2; increased levels shift the curve to the right and cause oxygen to be released more readily, e.g. when red cells reach hypoxic tissues. Haemoglobin F is unable to bind 2,3-BPG and has a left-shifted oxygen dissociation curve, which, together with the low pH of fetal blood, ensures fetal oxygenation. Strong oxidising agents, such as dapsone, can convert ferrous iron in haemoglobin to its ferric state (Fe^{3+}). The resultant methaemoglobin also has a left-shifted oxygen dissociation curve, which can result in tissue hypoxia (p. 135).

Genetic mutations affecting the haem-binding pockets of globin chains or the 'hinge' interactions between globin chains result in haemoglobinopathies or unstable haemoglobins. Alpha globin chains are produced by two genes on chromosome 16, and beta globin chains by a single gene on chromosome 11; imbalance in the production of globin chains results in the thalassaemias (p. 951). Defects in haem synthesis cause the porphyrias (p. 378).

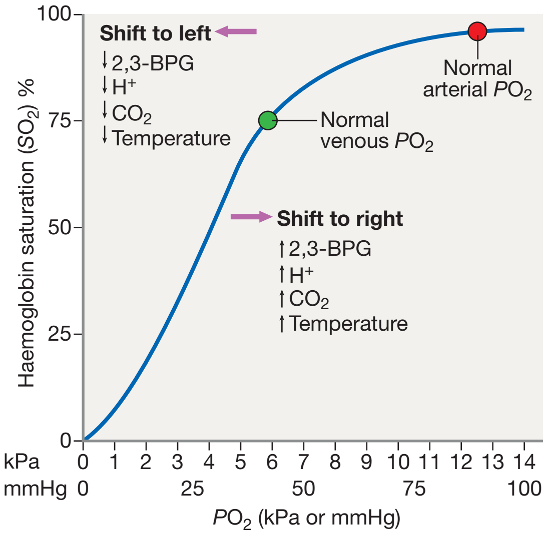

Fig. 23.5 The haemoglobin–oxygen dissociation curve. Factors are listed that shift the curve to the right (more oxygen released from blood) and to the left (less oxygen released) at given PO_2. To convert kPa to mmHg, multiply by 7.5. (2,3-BPG = 2,3-bisphosphoglycerate)

Destruction

Red cells at the end of their lifespan of approximately 120 days are phagocytosed by the reticulo-endothelial system. Amino acids from globin chains are recycled and iron is removed from haem for reuse in haemoglobin synthesis. The remnant haem structure is degraded to bilirubin and conjugated with glucuronic acid before being excreted in bile. In the small bowel, bilirubin is converted to stercobilin; most of this is excreted, but a small amount is reabsorbed and excreted by the kidney as urobilinogen. Increased red cell destruction due to haemolysis or ineffective haematopoiesis results in jaundice and increased urinary urobilinogen. Free intravascular haemoglobin is toxic and is normally bound by haptoglobins, which are plasma proteins produced by the liver.

White cells

White cells or leucocytes in the blood consist of granulocytes (neutrophils, eosinophils and basophils), monocytes and lymphocytes (see Fig. 23.12). Granulocytes and monocytes are formed from bone marrow CFU–GM progenitor cells during myelopoiesis. The first recognisable granulocyte in the marrow is the myeloblast, a large cell with a small amount of basophilic cytoplasm and a primitive nucleus with open chromatin and nucleoli. As the cells divide and mature, the nucleus segments and the cytoplasm acquires specific neutrophilic, eosinophilic or basophilic granules (see Fig. 23.3). This takes about 14 days. The cytokines G–CSF, GM–CSF and M–CSF are involved in the production of myeloid cells, and G–CSF can be used clinically to hasten recovery of blood neutrophil counts after chemotherapy.

Myelocytes or metamyelocytes are normally found only in the marrow but may appear in the circulation in infection or toxic states. The appearance of more primitive myeloid precursors in the blood is often associated with the presence of nucleated red cells and is termed a 'leucoerythroblastic' picture; this indicates a serious disturbance of marrow function.

Neutrophils

Neutrophils, the most common white blood cells in the blood of adults, are 10–14 μm in diameter, with a multilobular nucleus containing 2–5 segments and granules in their cytoplasm. Their main function is to recognise, ingest and destroy foreign particles and microorganisms (p. 64). A large storage pool of mature neutrophils exists in the bone marrow. Every day, some 10^{11} neutrophils enter the circulation, where cells may be circulating freely or attached to endothelium in the marginating pool. These two pools are equal in size; factors such as exercise or catecholamines increase the number of cells flowing in the blood. Neutrophils spend 6–10 hours in the circulation before being removed, principally by the spleen. Alternatively, they pass into the tissues and either are consumed in the inflammatory process or undergo apoptotic cell death and phagocytosis by macrophages.

Eosinophils

Eosinophils represent 1–6% of the circulating white cells. They are a similar size to neutrophils but have a bilobed nucleus and prominent orange granules on Romanowsky staining. Eosinophils are phagocytic and their granules contain a peroxidase capable of generating reactive oxygen species and proteins involved in the intracellular killing of protozoa and helminths (p. 233). They are also involved in allergic reactions (e.g. atopic asthma, p. 567; see also p. 84).

Basophils

These cells are less common than eosinophils, representing less than 1% of circulating white cells. They contain dense black granules that obscure the nucleus. Mast cells resemble basophils but are found only in the tissues. These cells are involved in hypersensitivity reactions (p. 66).

Monocytes

Monocytes are the largest of the white cells, with a diameter of 12–20 μm and an irregular nucleus in abundant pale blue cytoplasm containing occasional cytoplasmic vacuoles. These cells circulate for a few hours and then migrate into tissue, where they become macrophages, Kupffer cells or antigen-presenting dendritic cells. The former phagocytose debris, apoptotic cells and microorganisms (see Box 4.1, p. 64).

Lymphocytes

Lymphocytes are derived from pluripotent haematopoietic stem cells in the bone marrow. There are two main types: T cells (which mediate cellular immunity) and B cells (which mediate humoral immunity) (p. 68). Lymphoid cells that migrate to the thymus develop into T cells, whereas B cells develop in the bone marrow.

The majority (about 80%) of lymphocytes in the circulation are T cells. Lymphocytes are heterogeneous, the smallest being the size of red cells and the largest the size of neutrophils. Small lymphocytes are circular with scanty cytoplasm but the larger cells are more irregular with abundant blue cytoplasm. Lymphocyte subpopulations have specific functions and lifespan can vary from a few days to many years. Cell surface antigens ('cluster of differentiation' (CD) antigens), which appear at different points of lymphocyte maturation and indicate the lineage and maturity of the cell, are used to classify lymphomas and lymphoid leukaemias.

Haemostasis

Blood must be maintained in a fluid state in order to function as a transport system, but must be able to solidify to form a clot following vascular injury in order to prevent excessive bleeding, a process known as haemostasis. Successful haemostasis

is localised to the area of tissue damage and is followed by removal of the clot and tissue repair. This is achieved by complex interactions between the vascular endothelium, platelets, von Willebrand factor, coagulation factors, natural anticoagulants and fibrinolytic enzymes (Fig. 23.6). Dysfunction of any of these components may result in haemorrhage or thrombosis.

Platelets

Platelets are formed in the bone marrow from megakaryocytes. Megakaryocytic progenitor cells (CFU–Meg) divide to form megakaryoblasts, which undergo a process called 'endomitotic reduplication', in which there is division of the nucleus but not the cell. This creates mature megakaryocytes, large cells with several nuclei and cytoplasm containing platelet granules. Large numbers of platelets then fragment off from each megakaryocyte into the circulation. The formation and maturation of megakaryocytes is stimulated by thrombopoietin produced in the liver. Platelets circulate for 8–10 days before they are destroyed in the reticulo-endothelial system. Some 30% of peripheral platelets are normally pooled in the spleen and do not circulate.

Under normal conditions, platelets are discoid, with a diameter of 2–4 μm (Fig. 23.7). The surface membrane invaginates to form a tubular network, the canalicular system, which provides a conduit for the discharge of the granule content following platelet activation. Drugs that inhibit platelet function and thrombosis include aspirin (cyclo-oxygenase inhibitor), clopidogrel, prasugrel and ticagrelor (adenosine diphosphate (ADP)-mediated activation inhibitors), dipyridamole (phosphodiesterase inhibitor), and the glycoprotein IIb/IIIa inhibitors abciximab, tirofiban and eptifibatide (which prevent fibrinogen binding; p. 500).

Clotting factors

The coagulation system consists of a cascade of soluble inactive zymogen proteins designated by Roman numerals.

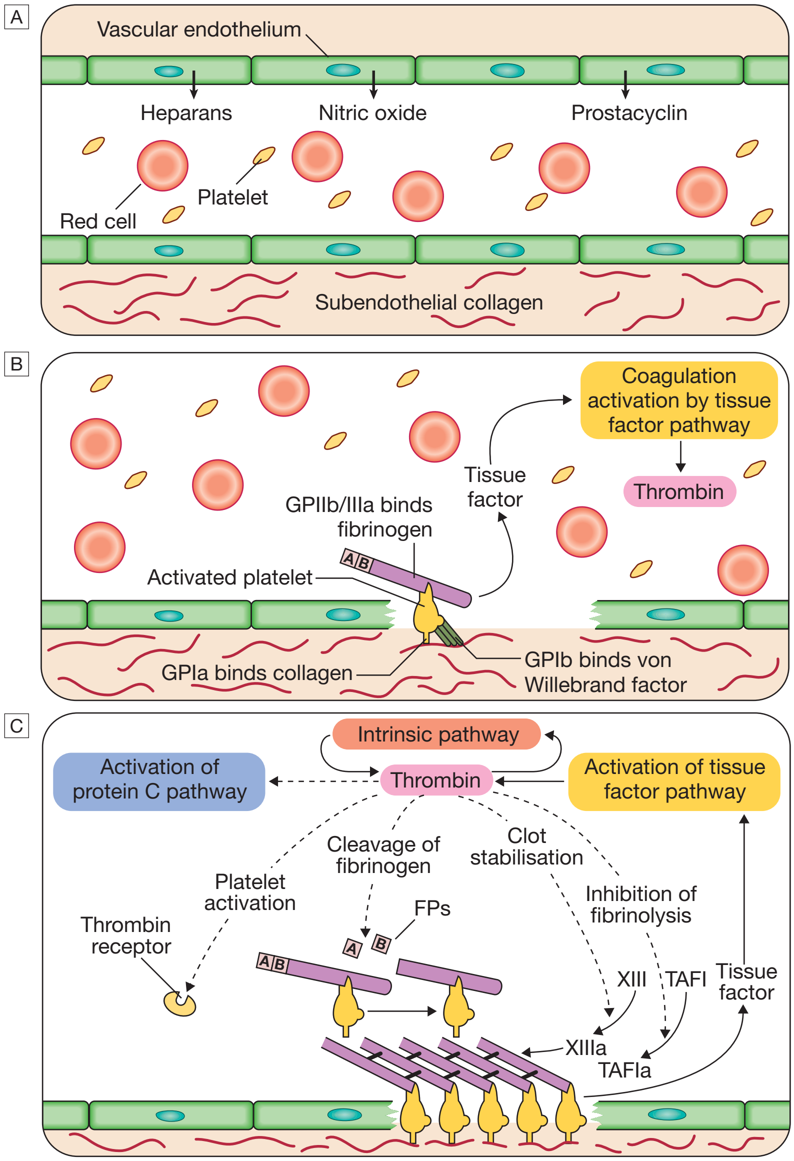

Fig. 23.6 The stages of normal haemostasis. A *Stage 1. Pre-injury conditions encourage flow.* The vascular endothelium produces substances (including nitric oxide, prostacyclin and heparans) to prevent adhesion of platelets and white cells to the vessel wall. Platelets and coagulation factors circulate in a non-activated state.

B *Stage 2. Early haemostatic response: platelets adhere; coagulation is activated.* At the site of injury, the endothelium is breached, exposing subendothelial collagen. Small amounts of tissue factor (TF) are released. Platelets bind to collagen via a specific receptor, glycoprotein Ia (GPIa), causing a change in platelet shape and its adhesion to the area of damage by the binding of other receptors (GPIb and GPIIb/IIIa) to von Willebrand factor and fibrinogen, respectively. Coagulation is activated by the tissue factor (extrinsic) pathway, generating small amounts of thrombin.

C and D *Stage 3. Fibrin clot formation: platelets become activated and aggregate; fibrin formation is supported by the platelet membrane; stable fibrin clot forms.* The adherent platelets are activated by many pathways, including binding of adenosine diphosphate (ADP), collagen, thrombin and adrenaline (epinephrine) to surface receptors. The cyclo-oxygenase pathway converts arachidonic acid from the platelet membrane into thromboxane A_2, which causes aggregation of platelets. Activation of the platelets results in release of the platelet granule contents, enhancing coagulation further (see Fig. 23.7). Thrombin plays a key role in the control of coagulation: the small amount generated via the TF pathway massively amplifies its own production; the 'intrinsic' pathway becomes activated and large amounts of thrombin are generated. Thrombin directly causes clot formation by cleaving fibrinopeptides (FPs) from

When proteolytically cleaved and activated, each is capable of activating one or more components of the cascade. Activated factors are designated by the suffix 'a'. Some of these reactions require phospholipid and calcium. Coagulation occurs by two pathways: it is initiated by the extrinsic (or tissue factor) pathway and amplified by the 'intrinsic pathway' (see Fig. 23.6D).

Clotting factors are synthesised by the liver, although factor V is also produced by platelets and endothelial cells. Factors II, VII, IX and X require post-translational carboxylation to allow them to participate in coagulation. The carboxylase enzyme responsible for this in the liver is vitamin K-dependent. Vitamin K is converted to an epoxide in this reaction and must be reduced to its active form by a reductase enzyme. This reductase is inhibited by warfarin, and this is the basis of the anticoagulant effect of coumarins (p. 939). Congenital (e.g. haemophilia) and acquired (e.g. liver failure) causes of coagulation factor deficiency are associated with bleeding.

Investigation of diseases of the blood

The full blood count

To obtain a full blood count (FBC), anticoagulated blood is processed through automated blood analysers that use a variety of technologies (particle-sizing, radiofrequency and laser instrumentation) to measure the haematological parameters. These include numbers of circulating cells, the proportion of whole blood volume occupied by red cells (the haematocrit, Hct), and the red cell indices that give information about the size of red cells (mean cell volume, MCV) and the amount of haemoglobin present in the red cells (mean cell haemoglobin, MCH). Blood analysers can differentiate types of white blood cell and give automated counts of neutrophils, lymphocytes, monocytes, eosinophils and basophils. It is important to appreciate, however, that a

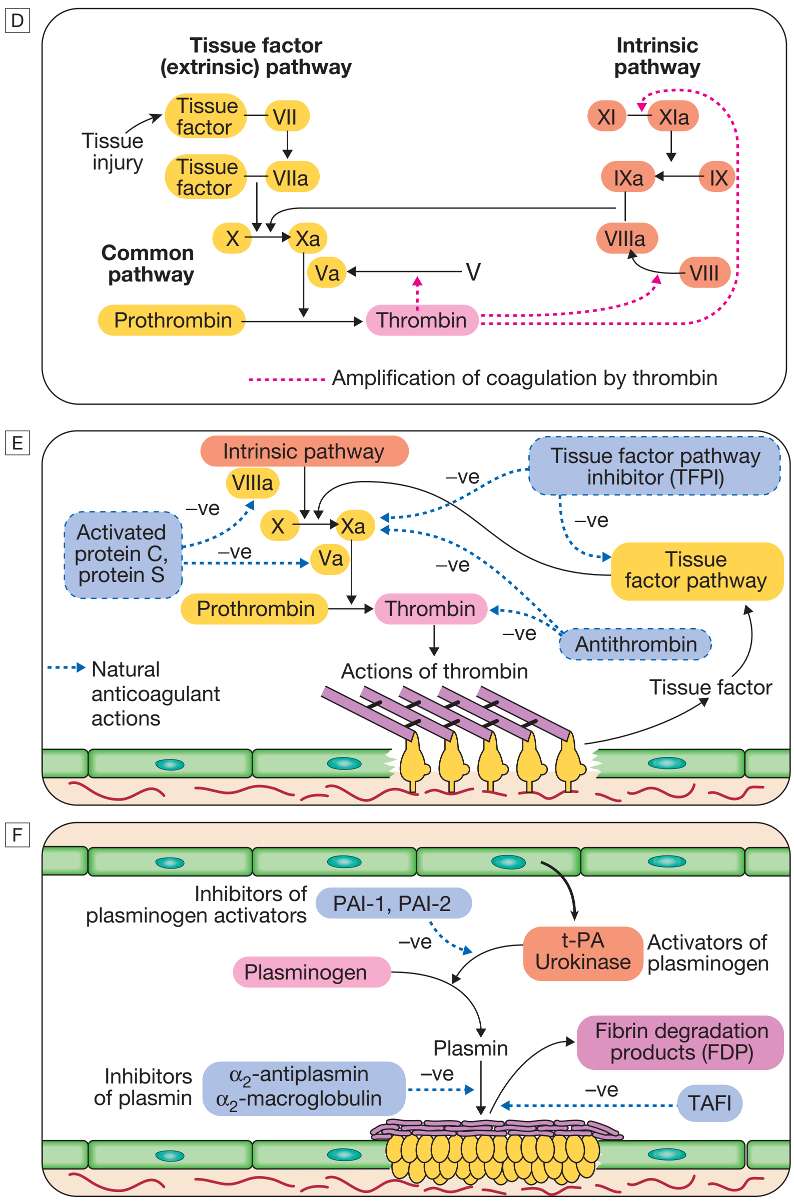

Fig. 23.6, cont'd fibrinogen to produce fibrin. Fibrin monomers are cross-linked by factor XIII, which is also activated by thrombin. Having had a key role in clot formation and stabilisation, thrombin then starts to regulate clot formation in two main ways: (a) activation of the protein C (PC) pathway (a natural anticoagulant), which reduces further coagulation; (b) activation of thrombin-activatable fibrinolysis inhibitor (TAFI), which inhibits fibrinolysis (see E and F).

E *Stage 4. Limiting clot formation: natural anticoagulants reverse activation of coagulation factors.* Once haemostasis has been secured, the propagation of clot is curtailed by anticoagulants. Antithrombin is a serine protease inhibitor synthesised by the liver, which destroys activated factors such as XIa, Xa and thrombin (IIa). Its major activity against thrombin and Xa is enhanced by heparin and fondaparinux, explaining their anticoagulant effect. Tissue factor pathway inhibitor (TFPI) binds to and inactivates VIIa and Xa. Activation of PC occurs following binding of thrombin to membrane-bound thrombomodulin; activated protein C (aPC) binds to its co-factor, protein S (PS), and cleaves Va and VIIIa. PC and PS are vitamin K-dependent and are depleted by coumarin anticoagulants such as warfarin.

F *Stage 5. Fibrinolysis: plasmin degrades fibrin to allow vessel recanalisation and tissue repair.* The insoluble clot needs to be broken down for vessel recanalisation. Plasmin, the main fibrinolytic enzyme, is produced when plasminogen is activated, e.g. by tissue plasminogen activator (t-PA) or urokinase in the clot. Plasmin hydrolyses the fibrin clot, producing fibrin degradation products, including the D-dimer. This process is highly regulated; the plasminogen activators are controlled by an inhibitor called plasminogen activator inhibitor (PAI), the activity of plasmin is inhibited by α_2-antiplasmin and α_2-macroglobulin, and fibrinolysis is further inhibited by the thrombin-activated TAFI.

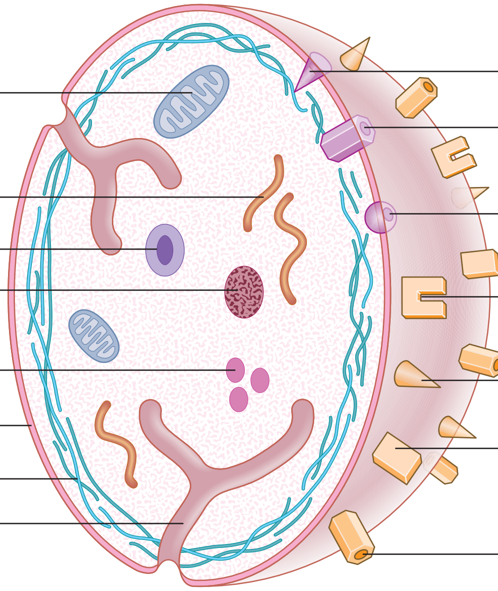

Fig. 23.7 Normal platelet structure. The platelet surface is populated by glycoproteins, which bind to key structures including fibrinogen, collagen and von Willebrand factor and cell surface receptors for thrombin, ADP and adrenaline (epinephrine). Through internal signalling pathways, platelet activation causes degranulation of alpha and dense granules, which ultimately results in platelet aggregation. Blockade of these pathways by drugs such as aspirin, clopidogrel, ticagrelor, tirofiban and abciximab forms the basis of antiplatelet therapy. (ADP = adenosine diphosphate; GP = glycoprotein)

i 23.1 Spurious full blood count results from autoanalysers

Result	Explanation
Increased haemoglobin	Lipaemia, jaundice, very high white cell count
Reduced haemoglobin	Improper sample mixing, blood taken from vein into which an infusion is flowing
Increased red cell volume (mean cell volume, MCV)	Cold agglutinins, non-ketotic hyperosmolarity
Increased white cell count	Nucleated red cells present
Reduced platelet count	Clot in sample, platelet clumping

number of conditions can lead to spurious results (Box 23.1). The reference ranges for a number of common haematological parameters in adults are given in Chapter 35.

Blood film examination

Although technical advances in full blood count analysers have resulted in fewer blood samples requiring manual examination, scrutiny of blood components prepared on a microscope slide (the ‘blood film’) can often yield valuable information (Box 23.2 and Fig. 23.8). Analysers cannot identify abnormalities of red cell shape and content (e.g. Howell–Jolly bodies, basophilic stippling, malaria parasites) or fully define abnormal white cells such as blasts.

Bone marrow examination

In adults, bone marrow for examination is usually obtained from the posterior iliac crest. After a local anaesthetic, marrow can be sucked out from the medullary space, stained and examined under the microscope (bone marrow aspirate). In addition, a core of bone may be removed (trephine biopsy), fixed and decalcified before sections are cut for staining (Fig. 23.9). A bone marrow aspirate is used to assess the composition and morphology of haematopoietic cells or abnormal infiltrates. Further investigations may be performed, such as cell surface marker analysis (immunophenotyping), chromosome and molecular studies to assess malignant disease, or marrow culture for suspected tuberculosis. A trephine biopsy is superior for assessing marrow cellularity, marrow fibrosis, and infiltration by abnormal cells such as metastatic carcinoma.

Investigation of coagulation

Bleeding disorders

In patients with clinical evidence of a bleeding disorder (p. 913), there are recommended screening tests (Box 23.3). Physiological activation of coagulation is predominantly by tissue factor, with amplification of the process by the small amounts of thrombin formed as a result. For ease of description, the terms extrinsic, intrinsic and common pathways are still used (see Fig. 23.6D).

Coagulation tests measure the time to clot formation in vitro in a plasma sample after the clotting process is initiated by activators and calcium. The result of the test sample is compared with normal controls. The tissue factor (‘extrinsic’) pathway (see Fig. 23.6D) is assessed by the prothrombin time (PT), and the ‘intrinsic’ pathway by the activated partial thromboplastin time (APTT), sometimes known as the partial thromboplastin time with kaolin (PTTK). Coagulation is delayed by deficiencies of coagulation factors and by the presence of inhibitors of coagulation, such as heparin. The approximate reference ranges and causes of abnormalities are shown in Box 23.3. If both the PT and APTT are prolonged, this indicates either deficiency or inhibition of the

23.2 How to interpret red cell appearances

Microcytosis (reduced average cell size, MCV <76 fL) A

- Iron deficiency
- Thalassaemia
- Sideroblastic anaemia

Macrocytosis (increased average cell size, MCV >100 fL) B

- Vitamin B_{12} or folate deficiency
- Liver disease, alcohol
- Hypothyroidism
- Myelodysplastic syndromes
- Drugs (e.g. zidovudine, trimethoprim, phenytoin, methotrexate, hydroxycarbamide)

Target cells (central area of haemoglobinisation) C

- Liver disease
- Thalassaemia
- Post-splenectomy
- Haemoglobin C disease

Spherocytes (dense cells, no area of central pallor) D

- Autoimmune haemolytic anaemia
- Post-splenectomy
- Hereditary spherocytosis

Red cell fragments (intravascular haemolysis) E

- Microangiopathic haemolysis, e.g. haemolytic uraemic syndrome (HUS), thrombotic thrombocytopenic purpura (TTP)
- Disseminated intravascular coagulation (DIC)

Nucleated red blood cells (normoblasts) F

- Marrow infiltration
- Severe haemolysis
- Myelofibrosis
- Acute haemorrhage

Howell–Jolly bodies (small round nuclear remnants) G

- Hyposplenism
- Post-splenectomy
- Dyshaematopoiesis

Polychromasia (young red cells – reticulocytes present) H

- Haemolysis, acute haemorrhage
- Increased red cell turnover

Basophilic stippling (abnormal ribosomal RNA appears as blue dots) I

- Dyshaematopoiesis
- Lead poisoning

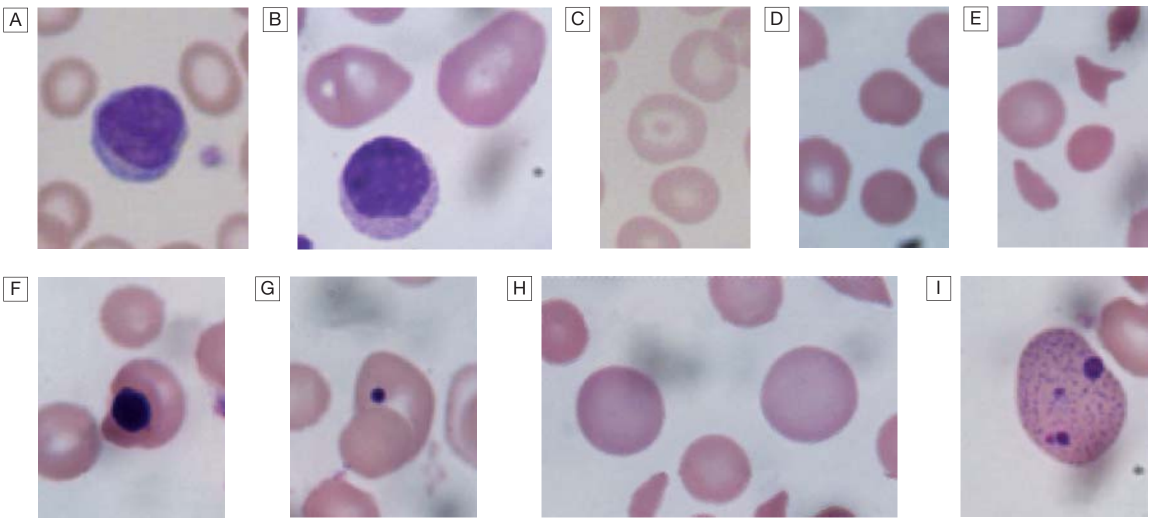

Fig. 23.8 Appearance of red blood cells. A Microcytosis. B Macrocytosis. C Target cells. D Spherocytes. E Red cell fragments. F Nucleated red blood cells. G Howell–Jolly bodies. H Polychromasia. I Basophilic stippling.

final common pathway (which includes factors X, V, prothrombin and fibrinogen) or global coagulation factor deficiency involving more than one factor, as occurs in disseminated intravascular coagulation (DIC, pp. 196 and 978). Further specific tests may be performed based on interpretation of the clinical scenario and results of these screening tests. A mixing test with normal plasma allows differentiation between a coagulation factor deficiency (the prolonged time corrects) and the presence of an inhibitor of coagulation (the prolonged time does not correct); the latter may be a chemical (heparins) or an antibody (most often a lupus anticoagulant but occasionally a specific inhibitor of one of the coagulation factors, typically factor VIII). Von Willebrand disease may present with a normal APTT; further investigation of suspected cases is detailed on page 974.

Platelet function has historically been assessed by the bleeding time, measured as the time to stop bleeding after a standardised incision. However, most centres have abandoned the use of this test. Platelet function can be assessed in vitro by measuring aggregation in response to various agonists, such as adrenaline (epinephrine), collagen, thrombin, arachidonic acid and ADP, agglutination in response to ristocetin or by measuring the constituents of the intracellular granules, e.g. adenosine triphosphate, adenosine diphosphate and their ratio to each other (ATP/ADP).

Coagulation screening tests are also performed in patients with suspected DIC, when clotting factors and platelets are consumed, resulting in thrombocytopenia and prolonged PT and APTT. In addition, there is evidence of active coagulation with

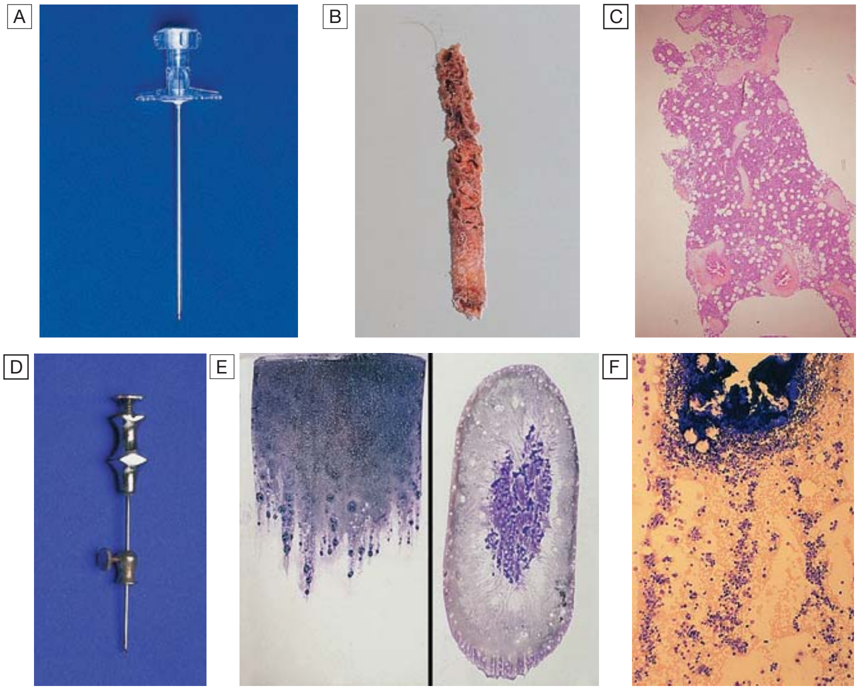

Fig. 23.9 Bone marrow aspirate and trephine. A Trephine biopsy needle. B Macroscopic appearance of a trephine biopsy. C Microscopic appearance of stained section of trephine. D Bone marrow aspirate needle. E Stained macroscopic appearance of marrow aspirate: smear (left) and squash (right). F Microscopic appearance of stained marrow particles and trails of haematopoietic cells.

i 23.3 Coagulation screening tests[1]

Investigation	Reference range[2]	Situations in which tests may be abnormal
Platelet count	150–400×10^9/L	Thrombocytopenia
Prothrombin time (PT)	9–12 secs	Deficiencies of factors II, V, VII or X Severe fibrinogen deficiency
Activated partial thromboplastin time (APTT)	26–36 secs	Deficiencies of factors II, V, VIII, IX, X, XI, XII Severe fibrinogen deficiency Unfractionated heparin therapy Antibodies against clotting factors Lupus anticoagulant Multiple factor deficiency (e.g. DIC)
Fibrinogen concentration	1.5–4.0 g/L	Hypofibrinogenaemia, e.g. liver failure, DIC

[1]**N.B.** International normalised ratio (INR) is used only to monitor coumarin therapy and is not a coagulation screening test. [2]Ranges are approximate and may vary between laboratories.
(DIC = disseminated intravascular coagulation)

consumption of fibrinogen and generation of fibrin degradation products (D-dimers). Note, however, that fibrinogen is an acute phase protein that may also be elevated in inflammatory disease (p. 70).

Monitoring anticoagulant therapy

The international normalised ratio (INR) is validated only to assess the therapeutic effect of coumarin anticoagulants, including warfarin. INR is the ratio of the patient's PT to that of a normal control, raised to the power of the international sensitivity index of the thromboplastin used in the test (ISI, derived by comparison with an international reference standard material). Concentrations of the direct oral anticoagulants (DOACs) cannot be accurately assessed from the PT or the APTT, with which they have a variable and generally poor correlation.

Monitoring of heparin therapy is, on the whole, required only with unfractionated heparins. Therapeutic anticoagulation prolongs the APTT relative to a control sample by a ratio of approximately 1.5–2.5. Low-molecular-weight heparins have such a predictable dose response that monitoring of the anticoagulant effect is not required, except in patients with renal impairment (glomerular filtration rate less than 30 mL/min). When monitoring is indicated, an anti-Xa activity assay rather than APTT should be used.

Thrombotic disorders

Measurement of plasma levels of D-dimers derived from fibrin degradation is useful in excluding the diagnosis of active venous thrombosis in some patients (see Fig. 10.6, p. 187).

A variety of tests exist that may help to explain an underlying propensity to thrombosis, especially venous thromboembolism (thrombophilia) (Box 23.4). Examples of possible indications for testing are given in Box 23.5. In most patients, the results do not affect clinical management (p. 975) but they may influence the duration of anticoagulation (e.g. antiphospholipid antibodies, p. 977), justify family screening in inherited thrombophilias (p. 975), or suggest additional management strategies to reduce thrombosis risk (e.g. in myeloproliferative disease and paroxysmal nocturnal haemoglobinuria; p. 950). Anticoagulants can interfere with some of these assays; for example, warfarin reduces protein C and S levels and affects measurement of lupus anticoagulant, while heparin interferes with antithrombin and lupus anticoagulant

23.4 Investigation of possible thrombophilia

Full blood count

Plasma levels
- Antithrombin
- Protein C
- Protein S (free)
- Antiphospholipid antibodies, lupus anticoagulant, anticardiolipin antibody/anti-β_2GP1

Thrombin/reptilase time (for dysfibrinogenaemia)

Genetic testing
- Factor V Leiden
- Prothrombin G20210A
- *JAK-2 V617F* mutation
- *CALR* mutations

Flow cytometry
- Screen for GPI-linked cell surface proteins (CD14, 16, 55, 59), deficient in paroxysmal nocturnal haemoglobinuria

(CD = cluster of differentiation; GP1 = glycoprotein 1; GPI = glycerol phosphatidyl inositol)

23.5 Possible indications for thrombophilia testing*

- Venous thrombosis <45 years
- Recurrent venous thrombosis
- Family history of unprovoked or recurrent thrombosis
- Combined arterial and venous thrombosis
- Venous thrombosis at an unusual site:
  - Cerebral venous thrombosis
  - Hepatic vein (Budd–Chiari syndrome)
  - Portal vein, mesenteric vein

*Antiphospholipid antibodies should be sought where clinical criteria for antiphospholipid syndrome (APS) are fulfilled (p. 977). Thrombophilia testing may explain the diagnosis without necessarily affecting management and this limits the clinical value of such an approach.

23.6 Haematological investigations in old age

- **Blood cell counts and film components**: not altered in general by ageing alone, although haemoglobin concentrations fall with increasing age.
- **Ratio of bone marrow cells to marrow fat**: falls.
- **Neutrophils**: maintained throughout life, although leucocytes may be less readily mobilised by bacterial invasion in old age.
- **Lymphocytes**: functionally compromised by age due to a T-cell-related defect in cell-mediated immunity.
- **Clotting factors**: no major changes, although mild congenital deficiencies may be first noticed in old age.
- **Erythrocyte sedimentation rate (ESR)**: raised above the reference range but usually in association with chronic or subacute disease. In truly healthy older people, the ESR range is very similar to that in younger people.

assays. Therefore these tests, when required, should be performed when the patient is not taking anticoagulants.

Presenting problems in blood disease

Anaemia

Anaemia refers to a state in which the level of haemoglobin in the blood is below the reference range appropriate for age and sex. Other factors, including pregnancy and altitude, also affect haemoglobin levels and must be taken into account when considering whether an individual is anaemic. The clinical features of anaemia reflect diminished oxygen supply to the tissues (p. 912). A rapid onset of anaemia (e.g. due to blood loss) causes more profound symptoms than a gradually developing anaemia. Individuals with cardiorespiratory disease are more susceptible to symptoms of anaemia.

23.7 Causes of anaemia

Decreased or ineffective marrow production
- Lack of iron, vitamin B_{12} or folate
- Hypoplasia/myelodysplasia
- Invasion by malignant cells
- Renal failure
- Anaemia of chronic disease

Normal marrow production but increased removal of cells
- Blood loss
- Haemolysis
- Hypersplenism

The clinical assessment and investigation of anaemia should gauge its severity and define the underlying cause (Box 23.7).

Clinical assessment

- *Iron deficiency anaemia* (p. 940) is the most common type of anaemia worldwide. A thorough gastrointestinal history is important, looking in particular for symptoms of blood loss. Menorrhagia is a common cause of anaemia in pre-menopausal females, so women should always be asked about their periods.
- *A dietary history* should assess the intake of iron and folate, which may become deficient in comparison to needs (e.g. in pregnancy or during periods of rapid growth; pp. 712, 945 and 1284).
- *Past medical history* may reveal a disease that is known to be associated with anaemia, such as rheumatoid arthritis (anaemia of chronic disease), or previous surgery (e.g. resection of the stomach or small bowel, which may lead to malabsorption of iron and/or vitamin B_{12}).
- *Family history and ethnic background* may raise suspicion of haemolytic anaemias, such as the haemoglobinopathies and hereditary spherocytosis. Pernicious anaemia may also run in families but is not associated with a clear Mendelian pattern of inheritance.
- *A drug history* may reveal the ingestion of drugs that cause blood loss (e.g. aspirin and anti-inflammatory drugs), haemolysis (e.g. sulphonamides) or aplasia (e.g. chloramphenicol).

On examination, as well as the general physical findings of anaemia shown on page 912, there may be specific findings related to the aetiology of the anaemia; for example, a patient may be found to have a right iliac fossa mass due to an underlying caecal carcinoma. Haemolytic anaemias can cause jaundice. Vitamin B_{12} deficiency may be associated with neurological signs, including peripheral neuropathy, dementia and signs of subacute combined degeneration of the cord (p. 1138). Sickle-cell anaemia (p. 951) may result in leg ulcers, stroke or features of pulmonary hypertension. Anaemia may be multifactorial and the lack of specific symptoms and signs does not rule out silent pathology.

Investigations

Schemes for the investigation of anaemias are often based on the size of the red cells, which is most accurately indicated by the MCV in the FBC. Commonly, in the presence of anaemia:

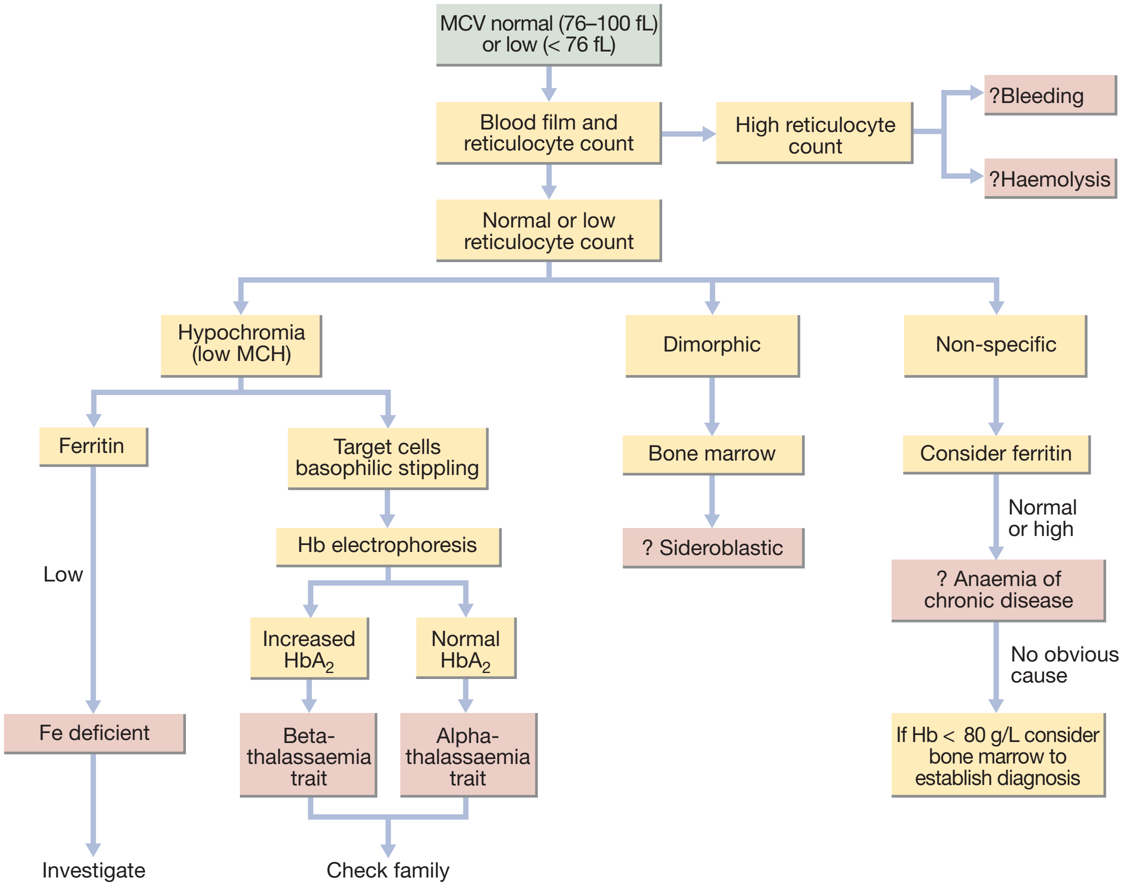

Fig. 23.10 Investigation of anaemia with normal or low mean cell volume (MCV). (Hb = haemoglobin; MCH = mean cell haemoglobin)

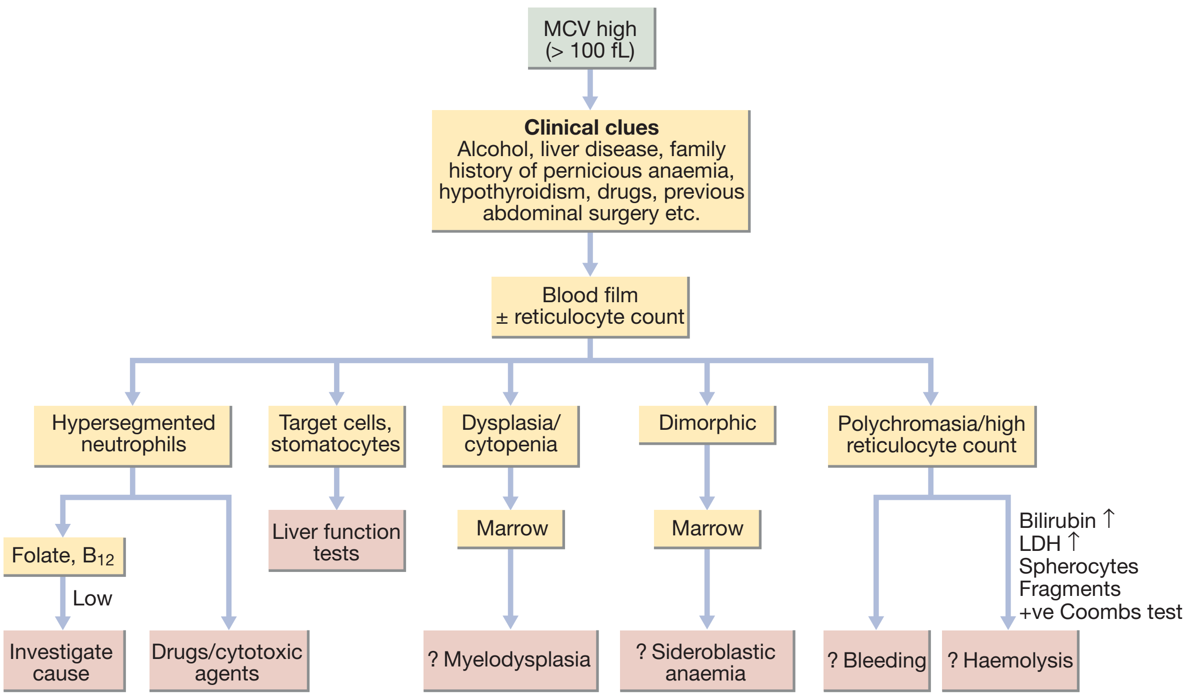

Fig. 23.11 Investigation of anaemia with high mean cell volume (MCV). (LDH = lactate dehydrogenase)

- A normal MCV (normocytic anaemia) suggests either acute blood loss or the anaemia of chronic disease, also known as the anaemia of inflammation (ACD/AI) (Fig. 23.10).
- A low MCV (microcytic anaemia) suggests iron deficiency or thalassaemia or sometimes ACD/AI (Fig. 23.10).
- A high MCV (macrocytic anaemia) suggests vitamin B_{12} or folate deficiency or myelodysplasia (Fig. 23.11).

Specific types of anaemia and their management are described later in this chapter (p. 940).

High haemoglobin

Patients with a persistently raised haematocrit (Hct) (>0.52 males, >0.48 females) for more than 2 months should be investigated. 'True' polycythaemia (or absolute erythrocytosis) indicates an excess of red cells, while 'relative', 'apparent' or 'low-volume' polycythaemia is due to a decreased plasma volume. Causes of polycythaemia are shown in Box 23.8. These involve increased erythropoiesis in the bone marrow, either due to a primary increase in marrow activity, or in response to increased erythropoietin (Epo) levels in chronic hypoxaemia, or due to inappropriate secretion of Epo. Athletes who seek to benefit from increased oxygen-carrying capacity have been known to use Epo to achieve this.

Apparent erythrocytosis with a raised Hct, normal red cell mass (RCM) and reduced plasma volume may be associated with hypertension, smoking, alcohol and diuretic use (Gaisböck's syndrome).

Clinical assessment and investigations

Males and females with Hct values of over 0.60 and over 0.56, respectively, can be assumed to have an absolute erythrocytosis. A clinical history and examination will identify most patients with polycythaemia secondary to hypoxia. The presence of hypertension, smoking, excess alcohol consumption and/or diuretic use is consistent with low-volume polycythaemia (Gaisböck's syndrome). In polycythaemia rubra vera (PRV), a mutation in a kinase, *JAK-2 V617F*, is found in over 90% of cases (p. 970). Patients with PRV have an increased risk of arterial thromboses, particularly stroke, and venous thromboembolism. They may also have aquagenic pruritus (itching after exposure to water), hepatosplenomegaly and gout (due to high red cell turnover).

If the *JAK-2* mutation is absent and there is no obvious secondary cause, a measurement of red cell mass is required to confirm an absolute erythrocytosis, followed by further investigations to exclude hypoxia, and causes of inappropriate erythropoietin secretion.

Leucopenia (low white cell count)

A reduction in the total numbers of circulating white cells is called leucopenia. This may be due to a reduction in all types of white cell or in individual cell types (usually neutrophils or lymphocytes). Leucopenia may occur in isolation or as part of a reduction in all three haematological lineages (pancytopenia; p. 930).

Neutropenia

A reduction in neutrophil count (usually $<1.5\times10^9$/L but dependent on age and race) is called neutropenia. The main causes are listed in Box 23.9 and Figure 23.12. Drug-induced neutropenia is not uncommon (Box 23.10). Clinical manifestations range from no symptoms to overwhelming sepsis. The risk of bacterial infection is related to the degree of neutropenia, with counts lower than 0.5×10^9/L considered to be critically low. Fever is the first and often only manifestation of infection. A sore throat, perianal pain or skin inflammation may be present. The lack of neutrophils allows the patient to become septicaemic and shocked within hours if immediate antibiotic therapy is not commenced. Management is discussed on page 224.

Lymphopenia

This is an absolute lymphocyte count of less than 1×10^9/L. The causes are shown in Box 23.9. Although minor reductions may be asymptomatic, deficiencies in cell-mediated immunity may result in infections (with organisms such as fungi, viruses and mycobacteria) and a propensity to lymphoid and other malignancies (particularly those associated with viral infections such as Epstein–Barr virus (EBV), human papillomavirus (HPV)

23.8 Classification and causes of erythrocytosis

	Absolute erythrocytosis	Relative (low-volume) erythrocytosis
Haematocrit	High	High
Red cell mass	High	Normal
Plasma volume	Normal	Low
Causes	*Primary* Myeloproliferative disorder Polycythaemia rubra vera (primary proliferative polycythaemia) *Secondary* High erythropoietin due to tissue hypoxia: High altitude Cardiorespiratory disease High-affinity haemoglobins Inappropriately increased erythropoietin: Renal disease (hydronephrosis, cysts, carcinoma) Other tumours (hepatoma, bronchogenic carcinoma, uterine fibroids, phaeochromocytoma, cerebellar haemangioblastoma) Exogenous testosterone therapy Exogenous erythropoietin administration: Performance-enhancing drug-taking in athletes	Diuretics Smoking Obesity Alcohol excess Gaisböck's syndrome

23.9 How to interpret white blood cell results

Neutrophils A

Neutrophilia
- Infection: bacterial, fungal
- Trauma: surgery, burns
- Infarction: myocardial infarct, pulmonary embolus, sickle-cell crisis
- Inflammation: gout, rheumatoid arthritis, ulcerative colitis, Crohn's disease
- Malignancy: solid tumours, Hodgkin lymphoma
- Myeloproliferative disease: polycythaemia, chronic myeloid leukaemia
- Physiological: exercise, pregnancy

Neutropenia
- Infection: viral, bacterial (e.g. *Salmonella*), protozoal (e.g. malaria)
- Drugs: see Box 23.10
- Autoimmune: connective tissue disease
- Alcohol
- Bone marrow infiltration: leukaemia, myelodysplasia
- Congenital: Kostmann's syndrome
- Constitutional: Afro-Caribbean and Middle Eastern descent

Eosinophils B

Eosinophilia
- Allergy: hay fever, asthma, eczema
- Infection: parasitic
- Drug hypersensitivity: e.g. gold, sulphonamides
- Vasculitis: e.g. eosinophilic granulomatosis with polyangiitis (Churg–Strauss), granulomatosis with polyangiitis (Wegener's)
- Connective tissue disease: polyarteritis nodosa
- Malignancy: solid tumours, lymphomas
- Primary bone marrow disorders: myeloproliferative disorders, hypereosinophilic syndrome (HES), acute myeloid leukaemia

Basophils C

Basophilia
- Myeloproliferative disease: polycythaemia, chronic myeloid leukaemia
- Inflammation: acute hypersensitivity, ulcerative colitis, Crohn's disease
- Iron deficiency

Monocytes D

Monocytosis
- Infection: bacterial (e.g. tuberculosis)
- Inflammation: connective tissue disease, ulcerative colitis, Crohn's disease
- Malignancy: solid tumours, chronic myelomonocytic leukaemia

Lymphocytes E

Lymphocytosis
- Infection: viral, bacterial (e.g. *Bordetella pertussis*)
- Lymphoproliferative disease: chronic lymphocytic leukaemia, lymphoma
- Post-splenectomy

Lymphopenia
- Inflammation: connective tissue disease
- Lymphoma
- Renal failure
- Sarcoidosis
- Drugs: glucocorticoids, cytotoxics
- Congenital: severe combined immunodeficiency
- HIV infection

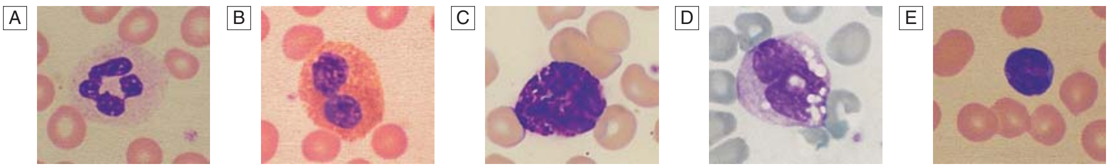

Fig. 23.12 Appearance of white blood cells. A Neutrophil. B Eosinophil. C Basophil. D Monocyte. E Lymphocyte.

23.10 Drugs that can induce neutropenia*

Group	Examples
Analgesics/anti-inflammatory agents	Gold, penicillamine, naproxen
Antithyroid drugs	Carbimazole, propylthiouracil
Anti-arrhythmics	Quinidine, procainamide
Antihypertensives	Captopril, enalapril, nifedipine
Antidepressants/psychotropics	Amitriptyline, dosulepin, mianserin
Antimalarials	Pyrimethamine, dapsone, sulfadoxine, chloroquine
Anticonvulsants	Phenytoin, sodium valproate, carbamazepine
Antibiotics	Sulphonamides, penicillins, cephalosporins
Miscellaneous	Cimetidine, ranitidine, chlorpropamide, zidovudine

*Many drugs can induce cytopenias. In suspected cases check drug summary of product characteristics.

and human herpesvirus 8 (HHV-8)). Lymphopenia without any obvious cause is common with advancing age.

Leucocytosis (high white cell count)

An increase in the total numbers of circulating white cells is called leucocytosis. This is usually due to an increase in a specific type of cell (see Box 23.9). It is important to realise that an increase in a single type of white cell (e.g. eosinophils or monocytes) may not increase the total white cell count (WCC) above the upper limit of normal and will be apparent only if the 'differential' of the white count is examined.

Neutrophilia

An increase in the number of circulating neutrophils is called a neutrophilia or a neutrophil leucocytosis. It can result from an increased production of cells from the bone marrow or redistribution from the marginated pool. The normal neutrophil count depends on age, race and certain physiological parameters. During pregnancy, not only is there an increase in neutrophils but also earlier forms, such as metamyelocytes, can be found in the blood. The causes of a neutrophilia are shown in Box 23.9.

Eosinophilia

A high eosinophil count of more than 0.5×10^9/L is usually secondary to infection (especially parasites; p. 233), allergy (e.g. eczema, asthma, reactions to drugs; p. 84), immunological disorders (e.g. polyarteritis, sarcoidosis) or malignancy (e.g. lymphomas) (see Box 23.9). Usually, such eosinophilia is short-lived.

In the rarer primary disorders, there is a persistently raised, often clonal, eosinophilia, e.g. in myeloproliferative disorders, subtypes of acute myeloid leukaemia and idiopathic hypereosinophilic syndrome (HES). Recently, specific mutations in receptor tyrosine kinase genes have been found in some primary eosinophilias (e.g. causing rearrangements of platelet-derived growth factor receptors α and β or c-kit), which allow diagnosis and, in some cases, specific therapy with tyrosine kinase inhibitors such as imatinib.

Eosinophil infiltration can damage many organs (e.g. heart, lungs, gastrointestinal tract, skin, musculoskeletal system); evaluation of eosinophilia therefore includes not only the identification of any underlying cause and its appropriate treatment but also assessment of any related organ damage.

Lymphocytosis

A lymphocytosis is an increase in circulating lymphocytes above that expected for the patient's age. In adults, this is greater than 3.5×10^9/L. Infants and children have higher counts; age-related reference ranges should be consulted. Causes are shown in Box 23.9; the most common is viral infection.

Lymphadenopathy

Enlarged lymph glands may be an important indicator of haematological disease but they are not uncommon in reaction to infection or inflammation (Box 23.11). The sites of lymph node groups, and symptoms and signs that may help elucidate the underlying cause are shown on page 913. Nodes that enlarge in response to local infection or inflammation ('reactive nodes') usually expand rapidly and are painful, whereas those due to haematological disease are more frequently painless. Localised lymphadenopathy should elicit a search for a source of inflammation or primary malignancy in the appropriate drainage area:

- the scalp, ear, mouth and throat, face, teeth or thyroid for neck nodes
- the breast for axillary nodes
- the perineum or external genitalia for inguinal nodes.

Generalised lymphadenopathy may be secondary to infection, often viral, connective tissue disease or extensive skin disease (dermatopathic lymphadenopathy) but is more likely to signify underlying haematological malignancy. Weight loss and drenching night sweats that may require a change of nightclothes are associated with haematological malignancies, particularly lymphoma.

Initial investigations in lymphadenopathy include an FBC (to detect neutrophilia in infection or evidence of haematological disease), measurement of erythrocyte sedimentation rate (ESR) and a chest X-ray (to detect mediastinal lymphadenopathy). If the findings suggest malignancy, a formal cutting needle or excision biopsy of a representative node is indicated to obtain a histological diagnosis.

i 23.11 Causes of lymphadenopathy

Infective
- Bacterial: streptococcal, tuberculosis, brucellosis
- Viral: Epstein–Barr virus (EBV), human immunodeficiency virus (HIV)
- Protozoal: toxoplasmosis
- Fungal: histoplasmosis, coccidioidomycosis

Neoplastic
- Primary: lymphomas, leukaemias
- Secondary: lung, breast, thyroid, stomach, melanoma

Connective tissue disorders
- Rheumatoid arthritis
- Systemic lupus erythematosus (SLE)

Sarcoidosis

Amyloidosis

Drugs
- Phenytoin

Splenomegaly

The spleen may be enlarged due to involvement by lymphoproliferative disease, the resumption of extramedullary haematopoiesis in myeloproliferative disease, enhanced reticulo-endothelial activity in autoimmune haemolysis, expansion of the lymphoid tissue in response to infections, or vascular congestion as a result of portal hypertension (Box 23.12). Hepatosplenomegaly is suggestive of lympho- or myeloproliferative disease, liver disease or infiltration (e.g. with amyloid). Associated lymphadenopathy is suggestive of lymphoproliferative disease. An enlarged spleen may cause abdominal discomfort, accompanied by back pain and abdominal bloating and early satiety due to stomach compression. Splenic infarction produces severe abdominal pain radiating to the left shoulder tip, associated with a splenic rub on auscultation. Rarely, spontaneous or traumatic rupture and bleeding may occur.

Investigation should focus on the suspected cause. Imaging of the spleen by ultrasound or computed tomography (CT) will detect variations in density in the spleen, which may be a feature of lymphoproliferative disease; it also allows imaging of the liver and abdominal lymph nodes. Biopsy of enlarged abdominal or superficial lymph nodes may provide the diagnosis, as might a bone marrow biopsy in splenic lymphomas. A chest X-ray or CT of the thorax will detect mediastinal lymphadenopathy. An FBC may show pancytopenia secondary to hypersplenism, when the enlarged spleen has become overactive, destroying blood cells prematurely. If other abnormalities are present, such as abnormal lymphocytes or a leucoerythroblastic blood film, a bone marrow examination is indicated. Screening for infectious or liver disease (p. 852) may be appropriate. If all investigations are unhelpful, splenectomy may be diagnostic but is rarely carried out in these circumstances.

Bleeding

Normal bleeding is seen following surgery and trauma. Pathological bleeding occurs when structurally abnormal vessels rupture or when a vessel is breached in the presence of a defect in haemostasis. This may be due to a deficiency or dysfunction of platelets, the coagulation factors or von Willebrand factor, or

23.12 Causes of splenomegaly

Congestive	
Portal hypertension	
• Cirrhosis • Hepatic vein occlusion • Portal vein thrombosis	• Stenosis or malformation of portal or splenic vein
Cardiac	
• Chronic congestive cardiac failure	• Constrictive pericarditis
Infective	
Bacterial	
• Endocarditis • Sepsis • Tuberculosis	• Brucellosis • *Salmonella*
Viral	
• Hepatitis • Epstein–Barr	• Cytomegalovirus
Protozoal	
• Malaria* • Leishmaniasis (kala-azar)*	• Trypanosomiasis
Fungal	
• Histoplasmosis	
Inflammatory/granulomatous disorders	
• Felty's syndrome in rheumatoid arthritis	• Sarcoidosis • Systemic lupus erythematosus
Haematological	
Red cell disorders	
• Megaloblastic anaemia • Haemoglobinopathies	• Hereditary spherocytosis
Autoimmune haemolytic anaemias	
Myeloproliferative disorders	
• Chronic myeloid leukaemia* • Myelofibrosis*	• Polycythaemia rubra vera • Essential thrombocythaemia
Neoplastic	
• Leukaemias, including chronic myeloid leukaemia*	• Lymphomas
Other malignancies	
• Metastatic cancer – rare	
Lysosomal storage diseases	
• Gaucher's disease	• Niemann–Pick disease
Miscellaneous	
• Cysts, amyloid, thyrotoxicosis, haemophagocytic syndromes	

*Causes of massive splenomegaly.

occasionally to excessive fibrinolysis, which is most commonly observed following therapeutic thrombolysis (p. 500).

Clinical assessment

'Screening' blood tests (see Box 23.3) do not reliably detect all causes of pathological bleeding (e.g. von Willebrand disease, scurvy, certain anticoagulant drugs and the causes of purpura listed in Box 23.13) and should not be used indiscriminately. A careful clinical evaluation is the key to diagnosis of bleeding disorders (p. 970). It is important to consider the following:

- *Site of bleeding.* Bleeding into muscle and joints, along with retroperitoneal and intracranial haemorrhage, indicates a likely defect in coagulation factors. Purpura, prolonged bleeding from superficial cuts, epistaxis, gastrointestinal haemorrhage or menorrhagia is more likely to be due to thrombocytopenia, a platelet function disorder or von Willebrand disease. Recurrent bleeds at a single site suggest a local structural abnormality rather than coagulopathic bleeding.
- *Duration of history.* It may be possible to assess whether the disorder is congenital or acquired.
- *Precipitating causes.* Bleeding arising spontaneously indicates a more severe defect than bleeding that occurs only after trauma.
- *Surgery.* Ask about operations. Dental extractions, tonsillectomy and circumcision are stressful tests of the haemostatic system. Immediate post-surgical bleeding suggests defective platelet plug formation and primary haemostasis; delayed haemorrhage is more suggestive of a coagulation defect. However, in post-surgical patients, persistent bleeding from a single site is more likely to indicate surgical bleeding than a bleeding disorder.
- *Family history.* While a positive family history may be present in patients with inherited disorders, the absence of affected relatives does not exclude a hereditary bleeding diathesis; about one-third of cases of haemophilia arise in individuals without a family history, and deficiencies of factor VII, X and XIII are recessively inherited. Recessive disorders are more common in cultures where there is consanguineous marriage.
- *Drugs.* Use of antithrombotic, anticoagulant and fibrinolytic drugs must be elicited. Drug interactions with warfarin and drug-induced thrombocytopenia should be considered. Some 'herbal' remedies may result in a bleeding diathesis.

Clinical examination may reveal different patterns of skin bleeding. Petechial purpura is minor bleeding into the dermis that is flat and non-blanching (Fig. 23.13). Petechiae are typically found in patients with thrombocytopenia or platelet dysfunction.

23.13 Causes of non-thrombocytopenic purpura

- Senile purpura
- Factitious purpura
- Henoch–Schönlein purpura (p. 1043)
- Vasculitis (p. 1040)
- Paraproteinaemias
- Purpura fulminans, e.g. in disseminated intravascular coagulation secondary to sepsis

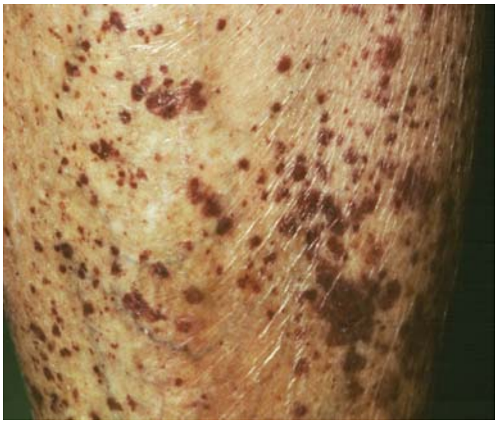

Fig. 23.13 Petechial purpura.

Palpable purpura occurs in vasculitis. Ecchymosis, or bruising, is more extensive bleeding into deeper layers of the skin. The lesions are initially dark red or purple but become yellow as haemoglobin is degraded. Retroperitoneal bleeding presents with a flank or peri-umbilical haematoma. Telangiectasia of lips and tongue points to hereditary haemorrhagic telangiectasia (p. 970). Joints should be examined for evidence of haemarthroses. A full examination is important, as it may give clues to an underlying associated systemic illness such as a haematological or other malignancy, liver disease, renal failure, connective tissue disease and possible causes of splenomegaly.

Investigations

Screening investigations and their interpretation are described on page 920. If the patient has a history that is strongly suggestive of a bleeding disorder and all the preliminary screening tests give normal results, further investigations, such as measurement of von Willebrand factor and assessment of platelet function, should be performed (p. 921).

Thrombocytopenia (low platelet count)

A reduced platelet count may arise by one of two mechanisms:

- decreased or abnormal production (bone marrow failure and hereditary thrombocytopathies)
- increased consumption following release into the circulation (immune-mediated, DIC or sequestration).

Spontaneous bleeding does not usually occur until the platelet count falls below 20×10^9/L, unless their function is also compromised. Purpura and spontaneous bruising are characteristic but there may also be oral, nasal, gastrointestinal or genitourinary bleeding. Severe thrombocytopenia ($<10 \times 10^9$/L) may result in retinal haemorrhage and potentially fatal intracranial bleeding, but this is rare.

Investigations are directed at the possible causes listed in Box 23.14. A blood film is the single most useful initial investigation. Examination of the bone marrow may reveal increased megakaryocytes in consumptive causes of thrombocytopenia, or the underlying cause of bone marrow failure in leukaemia, hypoplastic anaemia or myelodysplasia.

Treatment (if required) depends on the underlying cause. Platelet transfusion is rarely required and is usually confined to patients with bone marrow failure and platelet counts below 10×10^9/L, or to clinical situations with actual or predicted serious haemorrhage.

Thrombocytosis (high platelet count)

The most common reason for a raised platelet count is that it is reactive to another process, such as infection, inflammation, connective tissue disease, malignancy, iron deficiency, acute haemolysis or gastrointestinal bleeding (Box 23.15). The presenting clinical features are usually those of the underlying disorder and haemostasis is rarely affected. Reactive thrombocytosis is distinguished from the myeloproliferative disorders by the presence of uniform small platelets, lack of splenomegaly, and the presence of an associated disorder. The key to diagnosis is the clinical history and examination, combined with observation of the platelet count over time (reactive thrombocytosis gets better with resolution of the underlying cause).

The platelets are a product of an abnormally expanding clone of cells in the myeloproliferative disorders, chronic myeloid leukaemia

23.14 Causes of thrombocytopenia

Decreased production

Marrow hypoplasia
- Childhood bone marrow failure syndromes, e.g. Fanconi's anaemia, dyskeratosis congenita, amegakaryocytic thrombocytopenia
- Idiopathic aplastic anaemia
- Drug-induced: cytotoxics, antimetabolites
- Transfusion-associated graft-versus-host disease

Marrow infiltration
- Leukaemia
- Myeloma
- Carcinoma (rare)
- Myelofibrosis
- Osteopetrosis
- Lysosomal storage disorders, e.g. Gaucher's disease

Haematinic deficiency
- Vitamin B_{12} and/or folate deficiency

Familial (macro-)thrombocytopathies
- Myosin heavy chain abnormalities, e.g. Alport's syndrome, Fechtner's syndrome, May–Hegglin anomaly
- Bernard–Soulier syndrome
- Montreal platelet syndrome
- Wiskott–Aldrich syndrome (small platelets)
- Mediterranean macrothrombocytopathy

Increased consumption

Immune mechanisms
- Idiopathic thrombocytopenic purpura*
- Neonatal alloimmune thrombocytopenia
- Post-transfusion purpura
- Drug-associated, especially quinine, vancomycin and heparin

Coagulation activation
- Disseminated intravascular coagulation (see Box 23.68, p. 978)

Mechanical pooling
- Hypersplenism

Thrombotic microangiopathies
- Haemolytic uraemic syndrome (HUS) and atypical HUS
- Liver disease
- Thrombotic thrombocytopenic purpura
- Pre-eclampsia

Others
- Gestational thrombocytopenia
- Type 2B von Willebrand disease

*Associated conditions include collagen vascular diseases (particularly systemic lupus erythematosus), B-cell malignancy, HIV infection and antiphospholipid syndrome.

23

23.15 Causes of a raised platelet count

Reactive thrombocytosis
- Acute and chronic inflammatory disorders
- Infection
- Malignant disease
- Tissue damage
- Haemolytic anaemias
- Post-splenectomy
- Post-haemorrhage

Clonal thrombocytosis
- Primary thrombocythaemia
- Polycythaemia rubra vera
- Chronic myeloid leukaemia
- Myelofibrosis
- Myelodysplastic syndromes (MDSs; refractory anaemia with ring sideroblasts and thrombocytosis (RARS-T), MDS with isolated deletion of 5q)

and some forms of myelodysplasia. As with PRV, patients with essential thrombocythaemia may present with thrombosis or, rarely, bleeding. Stroke, transient ischaemic attacks, amaurosis fugax, digital ischaemia or gangrene, aquagenic pruritus, splenomegaly and systemic upset are also features. Patients with myeloproliferative disorders may also present with features such as aquagenic pruritus, splenomegaly and systemic upset.

Pancytopenia

Pancytopenia refers to the combination of anaemia, leucopenia and thrombocytopenia. It may be due to reduced production of blood cells as a consequence of bone marrow suppression or infiltration, or there may be peripheral destruction or splenic pooling of mature cells. Causes are shown in Box 23.16. A bone marrow aspirate and trephine are usually required to establish the diagnosis.

23.16 Causes of pancytopenia

Bone marrow failure

- Hypoplastic/aplastic anaemia (p. 968): inherited, idiopathic, viral, drugs

Bone marrow infiltration

- Acute leukaemia
- Myeloma
- Lymphoma
- Carcinoma
- Haemophagocytic syndrome
- Myelodysplastic syndromes

Ineffective haematopoiesis

- Megaloblastic anaemia
- Acquired immunodeficiency syndrome (AIDS)

Peripheral pooling/destruction

- Hypersplenism: portal hypertension, Felty's syndrome, malaria, myelofibrosis
- Systemic lupus erythematosus

Infection

Infection is a major complication of haematological disorders. It relates to the immunological deficit caused by the disease itself, or its treatment with chemotherapy and/or immunotherapy (pp. 224 and 925).

Principles of management of haematological disease

Blood products and transfusion

Blood transfusion from an unrelated donor to a recipient inevitably carries some risk, including adverse immunological interactions between the host and infused blood (p. 931), and transmission of infectious agents. Although there are many compelling clinical indications for blood component transfusion, there are also many clinical circumstances in which transfusion is conventional but the evidence for its effectiveness is limited. In these settings, allogeneic transfusion may be avoided by following protocols that recommend the use of low haemoglobin thresholds for red cell transfusion, perioperative blood salvage and antifibrinolytic drugs.

Blood products

Blood components are prepared from whole blood or specific blood constituents collected from individual donors and include red cells, platelets, plasma and cryoprecipitate (Box 23.17).

Plasma derivatives are licensed pharmaceutical products produced on a factory scale from large volumes of human plasma obtained from many people and treated to remove transmissible infection. Examples include:

- *Coagulation factors.* Concentrates of factors VIII and IX are used for the treatment of conditions such as haemophilia A, haemophilia B and von Willebrand disease. Coagulation factors made by recombinant DNA technology are now preferred due to perceived lack of infection risk but plasma-derived products are still used in many countries.
- *Immunoglobulins.* Intravenous immunoglobulin G (IVIgG) is administered as regular replacement therapy to reduce infective complications in patients with primary and secondary immunodeficiency. A short, high-dose course of IVIgG may also be effective in some immunological disorders, including immune thrombocytopenia (p. 971) and Guillain–Barré syndrome (p. 1140). IVIgG can cause acute reactions and must be infused strictly according to the manufacturer's product information. There is a risk of renal dysfunction in susceptible patients and, in these circumstances, immunoglobulin products containing low or no sucrose are preferred. Anti-zoster immunoglobulin has a role in the prophylaxis of varicella zoster (p. 239). Anti-Rhesus D immunoglobulin is used in pregnancy to prevent haemolytic disease of the newborn (see Box 23.19 below).
- *Human albumin.* This is available in two strengths. The 5% solution can be used as a colloid resuscitation fluid but it is no more effective and is more expensive than crystalloid solutions. Human albumin 20% solution is used in the management of hypoproteinaemic oedema in nephrotic syndrome (p. 395) and ascites in chronic liver disease (p. 864). It is hyperoncotic and expands plasma volume by more than the amount infused.

Blood components and their use are summarised in Box 23.17.

Blood donation

A safe supply of blood components depends on a well-organised system with regular donation by healthy individuals who have no excess risk of infections transmissible in blood (Fig. 23.14). Blood donations are obtained by either venesection of a unit of whole blood or collection of a specific component, such as platelets, by apheresis. During apheresis, the donor's blood is drawn via a closed system into a machine that separates the components by centrifugation and collects the desired fraction into a bag, returning the rest of the blood to the donor. Each donation must be tested for hepatitis B virus (HBV), hepatitis C virus (HCV), HIV and human T-cell lymphotropic virus (HTLV) nucleic acid and/or antibodies. Platelet concentrates may be tested for bacterial contamination. The need for other microbiological tests depends on local epidemiology. For example, testing for *Trypanosoma cruzi* (Chagas' disease; p. 279) is necessary in areas of South America and the USA where infection is prevalent. Tests for West Nile virus have been required in the USA since this agent became

23.17 Blood components and their use

Component	Major haemorrhage	Other indications
Red cell concentrate[1] Most of the plasma is removed and replaced with a solution of glucose and adenine in saline to maintain viability of red cells ABO compatibility with recipient essential	Replace acute blood loss: increase circulating red cell mass to relieve clinical features caused by insufficient oxygen delivery. Order 4–6 U initially to allow high red cell to FFP transfusion ratios of (at least) 2 : 1	*Severe anaemia* If no cardiovascular disease, transfuse to maintain Hb at 70 g/L If known or likely to have cardiovascular disease, maintain Hb at 90 g/L
Platelet concentrate One adult dose is made from four donations of whole blood, or from a single platelet apheresis donation ABO compatibility with recipient preferable	Maintain platelet count $>50\times10^9$/L, or in multiple or central nervous system trauma $>100\times10^9$/L If ongoing bleeding, order when platelets $<100\times10^9$/L to allow for delivery time Each adult dose has a minimum of 2.4×10^{11} platelets, which raises platelet count by 40×10^9/L unless there is consumptive coagulopathy, e.g. disseminated intravascular coagulation	*Thrombocytopenia*, e.g. in acute leukaemia Maintain platelet count $>10\times10^9$/L if not bleeding Maintain platelet count $>20\times10^9$/L if minor bleeding or at risk (sepsis, concurrent use of antibiotics, abnormal coagulation) Increase platelet count $>50\times10^9$/L for minor invasive procedure (e.g. lumbar puncture, gastroscopy and biopsy, insertion of indwelling lines, liver biopsy, laparotomy) or in acute, major blood loss Increase platelet count $>100\times10^9$/L for operations in critical sites such as brain or eyes
Fresh frozen plasma[2] 150–300 mL plasma from one donation of whole blood ABO compatibility with recipient recommended	Dilutional coagulopathy with a PT prolonged >50% is likely after replacement of 1–1.5 blood volumes with red cell concentrate Give initially in (at least) a ratio of 1 FFP:2 red cell concentrate; order 15–20 mL/kg and allow for thawing time. Further doses only if bleeding continues and guided by PT and APTT	*Replacement of coagulation factor deficiency* If no virally inactivated or recombinant product is available *Thrombotic thrombocytopenic purpura* Plasma exchange (using virus-inactivated plasma if available) is frequently effective
Cryoprecipitate[2] Fibrinogen and coagulation factor concentrated from plasma by controlled thawing 10–20 mL pack contains: Fibrinogen 150–300 mg Factor VIII 80–120 U von Willebrand factor 80–120 U In UK supplied as pools of 5 U	Aim to keep fibrinogen >1.5 g/L. Pooled units (of 10 donations) will raise fibrinogen by 1 g/L	*von Willebrand disease and haemophilia* If virus-inactivated or recombinant products are not available

[1]Whole blood is an alternative to red cell concentrate. ABO compatibility with recipient essential. [2]Pooled plasma can be treated with solvent and detergent or single units treated with methylene blue as an additional viral inactivation step. Virus-inactivated plasma is indicated for large-volume exposure, as in treatment of thrombotic thrombocytopenic purpura, and for treatment of children in the UK born after 1995.
(APTT = activated partial thromboplastin time; FFP = fresh frozen plasma; Hb = haemoglobin; PT = prothrombin time)

prevalent. Components for use in specific patient groups are prepared from hepatitis E virus-negative donors in the UK, and plasma donated in the UK is not used at present for producing pooled plasma derivatives in view of concerns about transmission of variant Creutzfeldt–Jakob disease (vCJD; p. 1127).

Adverse effects of transfusion

Death directly attributable to transfusion is rare, at less than 0.3 per 100 000 transfusions. Relatively minor symptoms of transfusion reactions (fever, itch or urticaria) occur in up to 3% of transfusions, and usually in patients who have had repeated transfusions. Any symptoms or signs that arise during a transfusion must be taken seriously, as they may be the first warnings of a serious reaction. Figure 23.16 below outlines the symptoms and signs, management and investigation of acute reactions to blood components.

Red cell incompatibility

Red blood cell membranes contain numerous cell surface molecules that are potentially antigenic (see Fig. 23.4). The ABO and Rhesus D antigens are the most important in routine transfusion and antenatal practice.

ABO blood groups

The frequency of the ABO antigens varies among different populations. The ABO blood group antigens are oligosaccharide chains that project from the red cell surface. These chains are attached to proteins and lipids that lie in the red cell membrane. The *ABO* gene encodes a glycosyltransferase that catalyses the final step in the synthesis of the chain, which has three common alleles: A, B and O. The O allele encodes an inactive enzyme, leaving the ABO antigen precursor (called the H antigen) unmodified. The A and B alleles encode enzymes that differ by

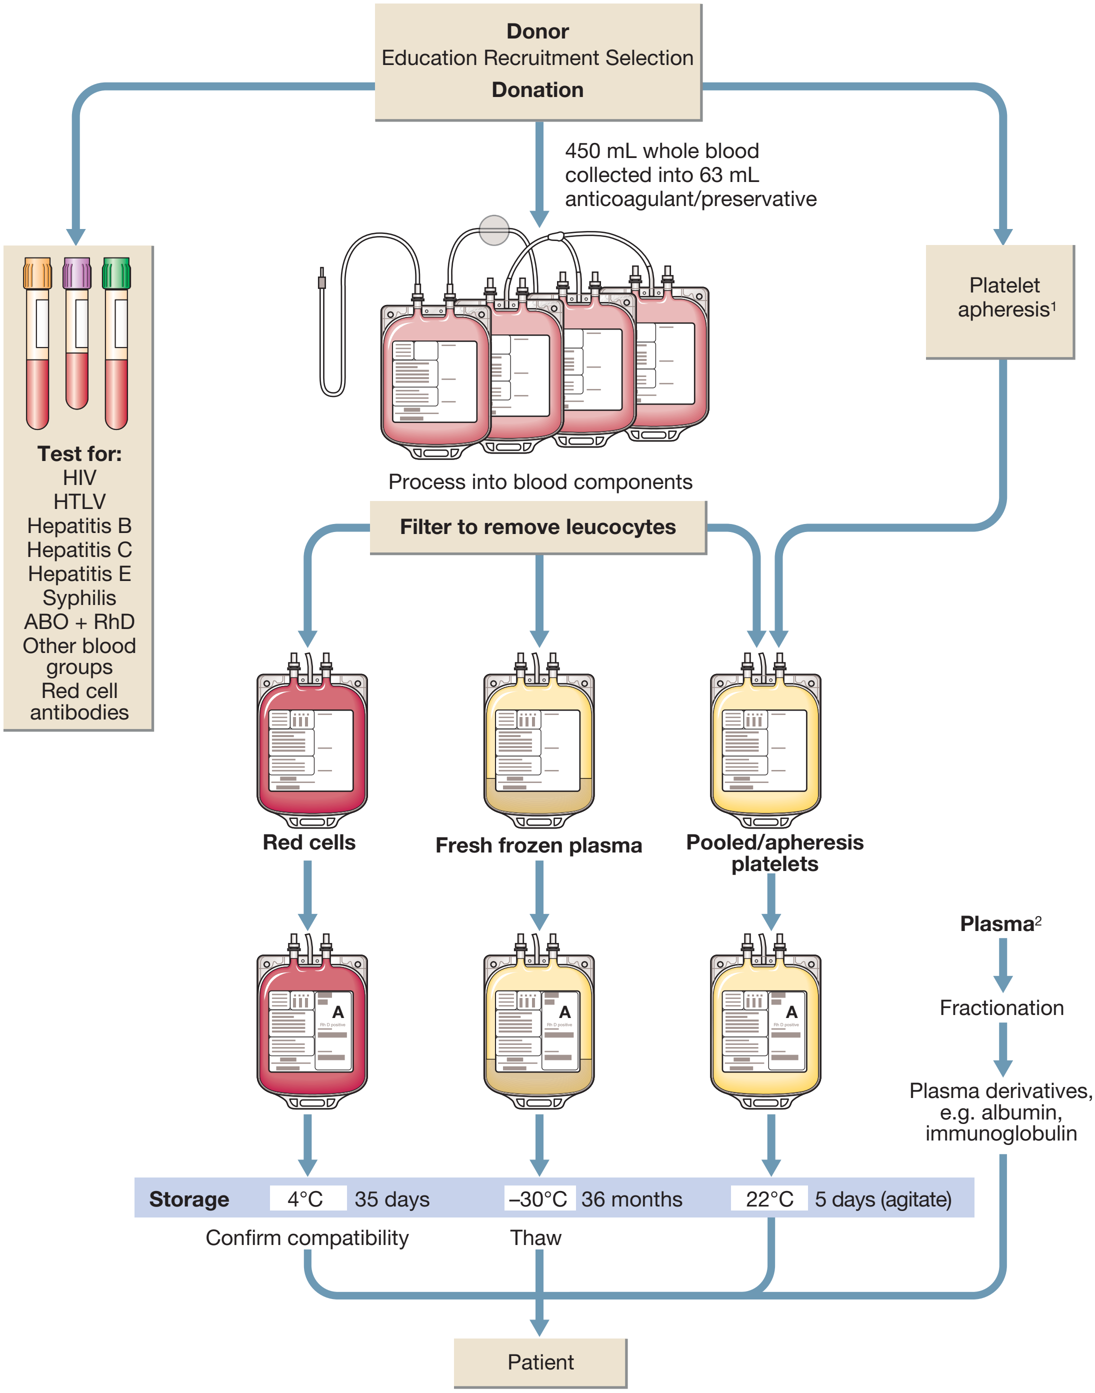

Fig. 23.14 Blood donation, processing and storage. [1]Platelet apheresis involves circulating the donor's blood through a cell separator to remove platelets before returning other blood components to the donor. [2]In the UK, plasma for fractionation is imported as a precautionary measure against vCJD. (vCJD = variant Creutzfeldt–Jakob disease; HIV = human immunodeficiency virus; HTLV = human T-cell lymphotropic virus)

four amino acids and hence attach different sugars to the end of the chain. Individuals are tolerant to their own ABO antigens, but do not suppress B-cell clones producing antibodies against ABO antigens that they do not carry themselves (Box 23.18). They are, therefore, capable of mounting a humoral immune response to these 'foreign' antigens.

ABO-incompatible red cell transfusion

If red cells of an incompatible ABO group are transfused (especially if a group O recipient is transfused with group A, B or AB red cells), the *recipient*'s IgM anti-A, anti-B or anti-AB binds to the *transfused* red cells. This activates the full complement pathway (p. 66), creating pores in the red cell membrane and destroying

23.18 ABO blood group antigens and antibodies

ABO blood group	Red cell A or B antigens	Antibodies in plasma	UK frequency (%)
0	None	Anti-A and anti-B	46
A	A	Anti-B	42
B	B	Anti-A	9
AB	A and B	None	3

the transfused red cells in the circulation (intravascular haemolysis). The anaphylatoxins C3a and C5a, released by complement activation, liberate cytokines such as tumour necrosis factor (TNF), interleukin 1 (IL-1) and IL-8, and stimulate degranulation of mast cells with release of vasoactive mediators. All these substances may lead to inflammation, increased vascular permeability and hypotension, which may, in turn, cause shock and renal failure. Inflammatory mediators can also cause platelet aggregation, lung peribronchial oedema and smooth muscle contraction. About 20–30% of ABO-incompatible transfusions cause some degree of morbidity, and 5–10% cause or contribute to a patient's death. The main reason for this relatively low morbidity is the lack of potency of ABO antibodies in group A or B subjects; even if the recipient is group O, those who are very young or very old usually have weaker antibodies that do not lead to the activation of large amounts of complement.

The Rhesus D blood group and haemolytic disease of the newborn

About 15% of Caucasians are Rhesus-negative: that is, they lack the Rhesus D (RhD) red cell surface antigen (see Fig. 23.4). In other populations (e.g. in Chinese and Bengalis), only 1–5% are Rhesus-negative. RhD-negative individuals do not normally produce substantial amounts of anti-RhD antibodies. However, if RhD-positive red cells enter the circulation of an RhD-negative individual, IgG antibodies are produced. This can occur during pregnancy if the mother is exposed to fetal cells via fetomaternal haemorrhage, or following transfusion. If a woman is so sensitised, during a subsequent pregnancy anti-RhD antibodies can cross the placenta; if the fetus is RhD-positive, haemolysis with severe fetal anaemia and hyperbilirubinaemia can result. This can cause severe neurological damage or death due to haemolytic disease of the newborn (HDN). Therefore, an RhD-negative female who may subsequently become pregnant should never be transfused with RhD-positive blood.

In RhD-negative women, administration of anti-RhD immunoglobulin (anti-D) perinatally can block the immune response to RhD antigen on fetal cells and is the only effective product for preventing the development of Rhesus antibodies (Box 23.19).

HDN can also be caused by other alloantibodies against red cell antigens, usually after previous pregnancies or transfusions. These antigens include Rhc, RhC, RhE, Rhe, and the Kell, Kidd and Duffy antigen systems. HDN can also occur if there is fetomaternal ABO incompatibility, most commonly seen in a group O mother with a group A fetus. The fetus is generally less severely affected by ABO incompatibility than by RhD, Rhc or Kell antigen mismatch, and the incompatibility is often picked up coincidentally after birth.

Other immunological complications of transfusion

Rare but serious complications include transfusion-associated lung injury (TRALI) and transfusion-associated graft-versus-host disease

23.19 Rhesus D blood groups in pregnancy

- **Haemolytic disease of the newborn (HDN)**: occurs when the mother has anti-red cell immunoglobulin G (IgG) antibodies that cross the placenta and haemolyse fetal red cells.
- **Screening for HDN in pregnancy**: at the time of booking (12–16 weeks) and again at 28–34 weeks' gestation, every pregnant woman should have a blood sample sent for determination of ABO and Rhesus D (RhD) group and testing for red cell alloantibodies that may be directed against paternal blood group antigens present on fetal red cells.
- **Anti-D immunoglobulin prophylaxis in a pregnant woman who is RhD-negative**: antenatal anti-D prophylaxis is offered at 28–34 weeks to RhD-negative pregnant women who have no evidence of immune anti-D. This prevents the formation of antibodies that could cause HDN. Following delivery of an RhD-positive baby, the mother is given further anti-D within 72 hours; a maternal sample is checked for remaining fetal red cells and additional anti-D is given if indicated. Additional anti-D is also given after potential sensitising events antenatally (e.g. early bleeding). Doses vary according to national recommendations.

(TA GVHD). The latter occurs when there is sharing of a human leucocyte antigen (HLA) haplotype between donor and recipient, which allows transfused lymphocytes to engraft, proliferate and recognise the recipient as foreign, resulting in acute GVHD (p. 937). Prevention is by gamma- or X-ray irradiation of blood components before their administration to prevent lymphocyte proliferation. Those at risk of TA GVHD, who must receive irradiated blood components, include patients with congenital T-cell immunodeficiencies or Hodgkin lymphoma, patients with aplastic anaemia receiving immunosuppressive therapy with antithymocyte globulin (ATG), recipients of haematopoietic stem cell transplants or of blood from a family member, neonates who have received an intrauterine transfusion, and patients taking T-lymphocyte-suppressing drugs, such as fludarabine and other purine analogues.

Transfusion-transmitted infection

Over the past 30 years, HBV, HIV-1 and HCV have been identified and effective tests introduced to detect and exclude infected donations. Where blood is from 'safe' donors and correctly tested, the current risk of a donated unit being infectious is very small. By 2013 in the UK, the estimated chance that a unit of blood from a 'safe' donor might transmit one of the viruses for which blood is tested was 1 in 6.6 million units for HIV-1, 1 in 51.5 million for HCV and 1 in 2.6 million for HBV. However, some patients who received transfusions before these tests were available suffered serious consequences from infection; this serves as a reminder to avoid non-essential transfusion, since it is impossible to exclude the emergence of new or currently unrecognised transfusion-transmissible infection. Licensed plasma derivatives that have been virus-inactivated do not transmit HIV, HTLV, HBV, HCV, cytomegalovirus or other lipid-enveloped viruses.

Variant CJD is a human prion disease linked to bovine spongiform encephalitis (BSE; p. 1127). The risk of a recipient acquiring the agent of vCJD from a transfusion is uncertain, but of 16 recipients of blood from donors who later developed the disease, 3 have died with clinical vCJD and 1 other had postmortem immunohistological features of infection.

Bacterial contamination of a blood component – usually platelets – is extremely rare (1 proven case in the UK in 2015) but can result in severe bacteraemia/sepsis in the recipient.

Safe transfusion procedures

The proposed transfusion and any alternatives should be discussed with the patient or, if that is not possible, with a relative, and this should be documented in the case record. Some patients, e.g. Jehovah's Witnesses, may refuse transfusion and require specialised management to survive profound anaemia following blood loss.

Pre-transfusion testing

To ensure that red cells supplied for transfusion are compatible with the intended recipient, the transfusion laboratory will perform either a 'group and screen' procedure or a 'cross-match'. In the group and screen procedure, the red cells from the patient's blood sample are tested to determine the ABO and RhD type, and the patient's serum is also tested against an array of red cells expressing the most important antigens to detect any red cell antibodies. Any antibody detected can be identified by further testing, so that red cell units that lack the corresponding antigen can be selected. The patient's sample can be held in the laboratory for up to a week, so that the hospital blood bank can quickly prepare compatible blood without the need for a further patient sample. Conventional cross-matching consists of the group and antibody screen, followed by direct confirmation of the compatibility of individual units of red cells with the patient's serum. Full cross-matching takes about 45 minutes if no red cell antibodies are present, but may require hours if a patient has multiple antibodies.

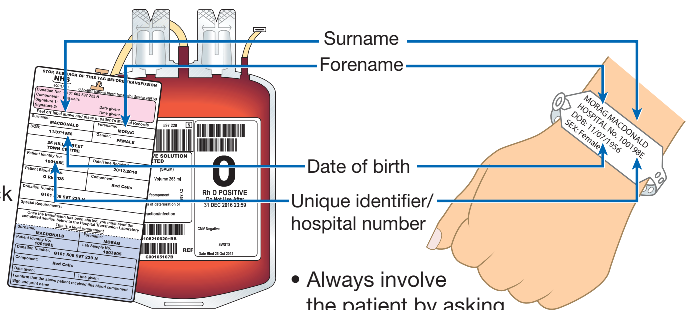
Blood can be supplied by 'electronic issue', without the need for compatibility cross-matching, if the laboratory's computer system shows that the patient's ABO and RhD groups have been identified and confirmed on two separate occasions and their antibody screen is negative. This allows group-specific units to be issued quickly and safely, for elective and emergency transfusion.

Bedside procedures for safe transfusion

Errors leading to patients receiving the wrong blood are an important avoidable cause of mortality and morbidity. Most incompatible transfusions result from failure to adhere to standard procedures for taking correctly labelled blood samples from the patient and ensuring that the correct pack of blood component is transfused into the intended patient. In the UK in 2015, there were 280 reports of transfusion of an incorrect blood component (11 per 100 000 units transfused). Every hospital where blood is transfused should have a written transfusion policy used by all staff who order, check or administer blood products (Fig. 23.15). Management of suspected transfusion reactions is shown in Figure 23.16.

Transfusion in major haemorrhage

The successful management of a patient with major haemorrhage requires frontline clinical staff to be trained to recognise significant blood loss early and to intervene before shock is established. Hospitals should have local major haemorrhage protocols and all clinical staff must be familiar with their content. Good team working and communication are essential to prevent poor clinical outcome, suboptimal or inappropriate transfusion practice and component wastage. Fresh frozen plasma (FFP) should be given as part of initial resuscitation in (at least) a 1:2 ratio with red cell concentrate (RCC) until coagulation results are available. If the patient is bleeding, a ratio of FFP to RCC of 1:1 should be given until laboratory results are available and use of cryoprecipitate should be considered. Once the bleeding is under control, further



Taking blood for pre-transfusion testing

- Positively identify the patient at the bedside
- Label the sample tube and complete the request form clearly and accurately after identifying the patient
- Do not write forms and labels in advance

Administering blood

- Positively identify the patient at the bedside
- Ensure that the identification of each blood pack matches the patient's identification
- Check that the ABO and RhD groups of each pack are compatible with the patient's
- Check each pack for evidence of damage
- If in doubt, do not use and return to the blood bank
- Complete the forms that document the transfusion of each pack

- Check the compatibility label on the pack against the patient's wristband

- Always involve the patient by asking them to state their name and date of birth, where possible

Record-keeping

- Record in the patient's notes, the reason for transfusion, the product given, dose, any adverse effects and the clinical respons

Observations

- Transfusions should only be given when the patient can be observed
- Blood pressure, pulse and temperature should be monitored before and 15 minutes after starting each pack
- In conscious patients, further observations are only needed if the patient has symptoms or signs of a reaction
- In unconscious patients, check pulse and temperature at intervals during transfusion
- Signs of abnormal bleeding during the transfusion could be due to disseminated intravascular coagulation resulting from an acute haemolytic reaction

Fig. 23.15 Bedside procedures for safe blood transfusion. The patient's safety depends on adherence to standard procedures for taking samples for compatibility testing, administering blood, record-keeping and observations.

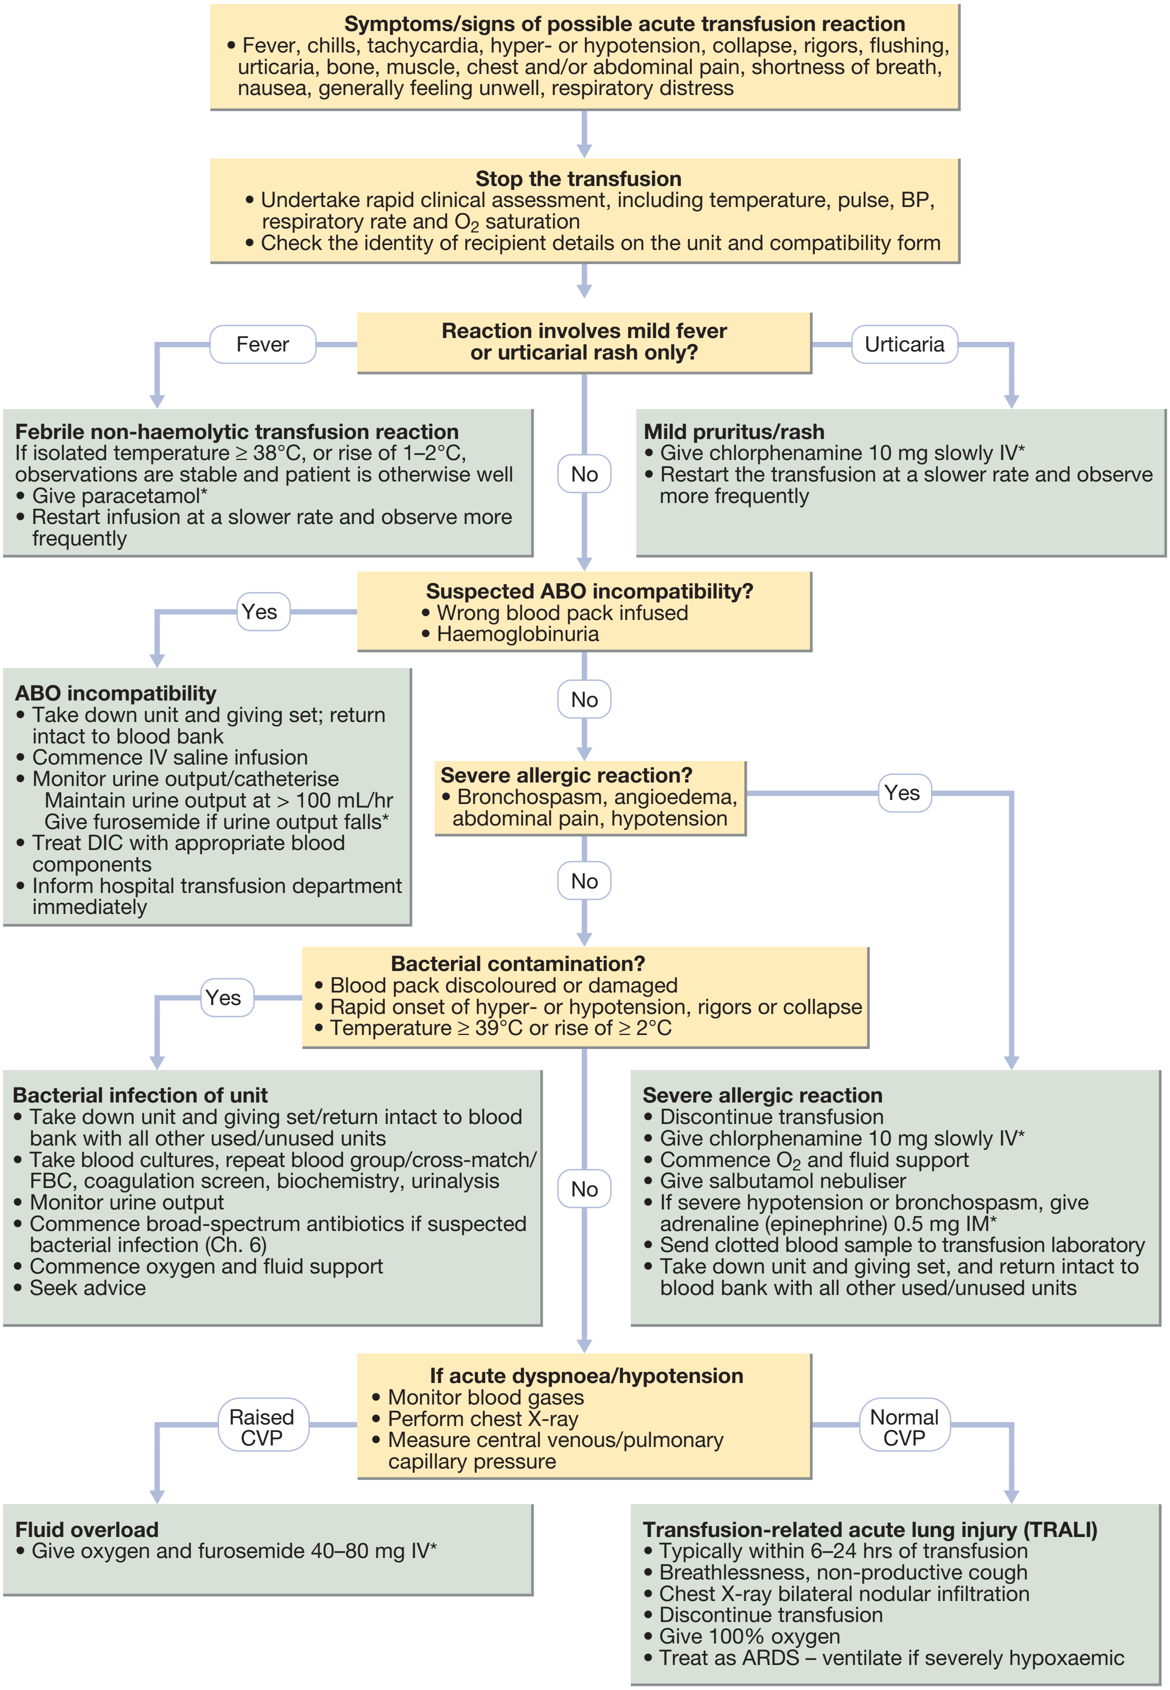


Fig. 23.16 Investigation and management of acute transfusion reactions. *Use size-appropriate dose in children. (ARDS = acute respiratory distress syndrome; BP = blood pressure; CVP = central venous pressure; DIC = disseminated intravascular coagulation; FBC = full blood count; IV = intravenous)

23

23.20 Key points in transfusion medicine

- A restrictive strategy for red cell transfusion (Hb <70 g/L) is at least as effective as a liberal strategy (<100 g/L).
- The majority of reports in haemovigilance schemes such as SHOT relate to errors in the process of transfusion.
- Although transfusion-transmitted infection is a major concern for patients receiving transfusion, it is rare.
- In patients with trauma or burns or those who have had surgery, there is no evidence that resuscitation with albumin or other colloid solutions reduces the risk of death compared to resuscitation with crystalloid solutions.
- It is recommended that transfusion should be carried out at night time only in unavoidable circumstances.

(SHOT = Serious Hazards of Transfusion)

FFP transfusion should be guided by laboratory results with transfusion triggers of PT and/or APTT above 1·5 times normal for a standard dose of FFP (15–20 mL/kg). Cryoprecipitate should be given if the fibrinogen level falls below 1.5 g/L. Platelets should be kept above 50×10^9/L; to allow for delivery time, platelets should be requested if there is ongoing bleeding and the platelet count has fallen below 100×10^9/L. Blood component use in major haemorrhage is summarised in Box 23.17 and key points in transfusion medicine in Box 23.20.

Chemotherapy

Chemotherapy refers to the use of drugs to treat cancer (Box 23.21; see also Fig. 33.2, p. 1317). Many haematological malignancies are sensitive to the effects of chemotherapy drugs and, as such, chemotherapy is the mainstay of treatment for most haematological cancers. There is a wide range of drugs available that work by damaging DNA or disrupting cellular metabolism, in such a way that natural apoptosis mechanisms, such as *TP53*, are activated and the cell dies. Despite cancer cells being more sensitive, chemotherapy is largely non-specific and kills some normal cells as well as cancer cells. This leads to common side-effects of treatment, such as transient bone marrow failure, mucositis and infertility. The supportive care of patients undergoing chemotherapy is critical in overcoming these side-effects. It is this supportive care, including blood product support, antibiotics, antifungal drugs, growth factors and antiemetics, that has allowed specialist haematology units to achieve the best possible results from intensive chemotherapy: for example, when treating acute leukaemia.

The basic principles of chemotherapy include combining several non-cross-reacting drugs in a regimen that kills a fixed proportion of cancer cells with a given dose. Several cycles of the combination are given to achieve gradual reduction of the tumour burden, to induce remission and, in some instances, to produce a cure (p. 1330).

In recent years, chemotherapy has been improved by the addition of treatments that are more targeted to the cancer cell, particularly monoclonal antibodies; for example, rituximab (anti-CD20) has been added to CHOP (cyclophosphamide doxorubicin, vincristine, prednisolone) and other regimens, significantly improving the outcome in a range of CD20-positive B-cell lymphomas, including diffuse large B-cell lymphoma, follicular lymphoma and mantle cell lymphoma. Chemotherapy drugs can also be linked to a monoclonal antibody to allow targeting of the chemotherapy drug to the specific cancer cell. Examples of such antibody–drug conjugates (ADCs) include the linking of the intercalating antibiotic calicheamicin to anti-CD33 (gemtuzumab ozogamicin) to treat acute myeloid leukaemia, and to anti-CD22 (inotuzumab ozogamicin) to treat acute lymphoblastic leukaemia. Small molecules targeted at the mechanisms causing cancer are replacing chemotherapy in some disease situations, such as tyrosine kinase inhibitors in chronic myeloid leukaemia and inhibitors of B-cell signalling in relapsed chronic lymphocytic leukaemia and lymphomas. More details of specific chemotherapies are given later in the chapter.

23.21 Examples of commonly used groups of cancer drugs in haematology

Alkylating agents

- Cross-link double-stranded DNA by adding an alkyl group, e.g. cyclophosphamide, melphalan, chlorambucil

Anthracyclines

- Intercalate between base pairs in the DNA molecule, e.g. daunorubicin, doxorubicin, idarubicin

Antimetabolites

- Inhibit DNA and RNA synthesis, e.g. cytosine arabinoside, fludarabine, methotrexate

Vinca alkaloids

- Cause disruption of tubulin, e.g. vincristine, vinblastine

Topoisomerase II inhibitors

- Prevent DNA repair, e.g. etoposide, daunorubicin, mitoxantrone

An example of a common combination regimen is CHOP, used in lymphoma: **c**yclophosphamide, **h**ydroxydaunorubicin (doxorubicin), **o**ncovin (vincristine) and **p**rednisolone, given every 21 days for six cycles

Haematopoietic stem cell transplantation

Transplantation of haematopoietic stem cells (HSCT) has offered the only hope of 'cure' in a variety of haematological and non-haematological disorders (Box 23.22). As standard treatment improves, the indications for HSCT are being refined and extended, although its use remains most common in haematological malignancies. The type of HSCT is defined according to the donor and source of stem cells:

- In *allogeneic* HSCT, the stem cells come from a *donor* – either a related donor (usually an HLA-identical sibling) or a closely HLA-matched volunteer unrelated donor (VUD).
- In an *autologous* transplant, the stem cells are harvested from the *patient* and stored in the vapour phase of liquid nitrogen until required. Stem cells can be harvested from the bone marrow or from the blood.

23.22 Indications for allogeneic haematopoietic stem cell transplantation

- Neoplastic disorders affecting stem cell compartments (e.g. leukaemias)
- Failure of haematopoiesis (e.g. aplastic anaemia)
- Major inherited defects in blood cell production (e.g. thalassaemia, immunodeficiency diseases)
- Inborn errors of metabolism with missing enzymes or cell lines

Allogeneic HSCT

Healthy bone marrow or blood stem cells from a donor are infused intravenously into the recipient, who has been suitably 'conditioned'. The conditioning treatment (chemotherapy with or without radiotherapy) is 'myeloablative' or, increasingly, 'non-myeloablative'. Myeloablative conditioning destroys malignant cells and immunosuppresses the recipient, as well as ablating the recipient's haematopoietic tissues. Reduced intensity conditioning (non-myeloablative) relies on intense immunosuppression to provide 'immunological space' for transplanted stem cells. The infused donor cells 'home' to the marrow, engraft and produce enough erythrocytes, granulocytes and platelets for the patient's needs after about 3–4 weeks. During this period of aplasia, patients are at risk of infection and bleeding, and require intensive supportive care as described on page 957. It may take several years to regain normal immunological function and patients remain at risk from opportunistic infections, particularly in the first year.

An advantage of receiving allogeneic donor stem cells is that the donor's immune system can recognise residual recipient malignant cells and destroy them. This immunological 'graft-versus-disease' effect is a powerful tool against many haematological tumours and can be boosted post-transplantation by the infusion of T cells taken from the donor: so-called donor lymphocyte infusion (DLI).

Considerable morbidity and mortality are associated with HSCT. The best results are obtained in patients with minimal residual disease, and in those under 20 years of age who have an HLA-identical sibling donor. Reduced-intensity conditioning has enabled treatment of older or less fit patients. In this form of transplantation, rather than using very intensive myeloablative conditioning, which causes morbidity from organ damage, relatively low doses of chemotherapy drugs, such as fludarabine and cyclophosphamide or busulfan, are used in combination with antibodies such as alemtuzumab (which targets CD52 on mature lymphoid cells) or anti-thymocyte globulin (ATG) to immunosuppress the recipient and allow donor stem cells to engraft. The emerging donor immune system then eliminates malignant cells via the 'graft-versus-disease' effect, which may be boosted by the elective use of donor T-cell infusions post-transplant. Such transplants have produced long-term remissions in some patients with acute leukaemia and myelodysplastic syndromes aged 40–65 years, who would not previously have been considered for a myeloablative allograft.

Complications

These are outlined in Boxes 23.23 and 23.24. The risks and outcomes of transplantation depend upon several patient- and disease-related factors. In general, 25% die from procedure-related complications, such as infection and GVHD, and there remains a significant risk of the haematological malignancy relapsing. The long-term survival for patients undergoing allogeneic HSCT in acute leukaemia is around 50%.

23.23 Complications of allogeneic haematopoietic stem cell transplantation

Early	
• Anaemia • Infections • Bleeding • Acute GVHD	• Mucositis – pain, nausea, diarrhoea • Liver veno-occlusive disease
Late	
• Chronic GVHD • Infertility	• Cataracts • Second malignancy

(GVHD = graft-versus-host disease)

23.24 Infections during recovery from haematopoietic stem cell transplantation (HSCT)

Infection	Time after HSCT	Management
Herpes simplex (p. 247)	0–4 weeks (aplastic phase)	Aciclovir prophylaxis and therapy
Bacterial, fungal	0–4 weeks (aplastic phase)	As for acute leukaemia (p. 956) – antibiotic and antifungal prophylaxis and therapy
Cytomegalovirus (p. 242)	5–21 weeks (cell-mediated immune deficiency)	Antigen screening in blood (PCR) and pre-emptive therapy (e.g. ganciclovir)
Varicella zoster (p. 238)	After 13 weeks	Aciclovir prophylaxis and therapy
Pneumocystis jirovecii (p. 318)	8–26 weeks	Co-trimoxazole
Encapsulated bacteria	8 weeks to years (immunoglobulin deficiency, prolonged with GVHD)	Prophylaxis and revaccination

(GVHD = graft-versus-host disease; PCR = polymerase chain reaction)

Graft-versus-host disease

GVHD is caused by the cytotoxic activity of donor T lymphocytes that become sensitised to their new host, regarding it as foreign. This may cause either an acute or a chronic form of GVHD.

Acute GVHD occurs in the first 100 days after transplant in about one-third of patients. It can affect the skin, causing rashes, the liver, causing jaundice, and the gut, causing diarrhoea, and may vary from mild to lethal. Prevention includes HLA-matching of the donor, immunosuppressant drugs, including methotrexate, ciclosporin, alemtuzumab or ATG. Severe presentations are very difficult to control and, despite high-dose glucocorticoids, may result in death.

Chronic GVHD may follow acute GVHD or arise independently; it occurs later than acute GVHD. It often resembles a connective tissue disorder, although in mild cases a rash may be the only manifestation. Chronic GVHD is usually treated with glucocorticoids and prolonged immunosuppression with, for example, ciclosporin. Chronic GVHD results in an increased infection risk. However, associated with chronic GVHD are the graft-versus-disease effect and a lower relapse rate of the underlying malignancy.

Autologous HSCT

This procedure can also be used in haematological malignancies. The patient's own stem cells from blood or marrow are first harvested and frozen. After conditioning myeloablative therapy, the autologous stem cells are reinfused into the blood stream in order to rescue the patient from the marrow damage and aplasia caused by chemotherapy. Autologous HSCT may be used for disorders that do not primarily involve the haematopoietic tissues, or for patients in whom very good remissions have been achieved. The most common indications are lymphomas and myeloma. The preferred source of stem cells for autologous transplants is peripheral blood (PBSCT). These stem cells engraft more

quickly, marrow recovery occurring within 2–3 weeks. There is no risk of GVHD and no immunosuppression is required. Thus autologous stem cell transplantation carries a lower procedure-related mortality rate than allogeneic HSCT at around 5%, but there is a higher rate of recurrence of malignancy because the anti-malignancy effect is solely dependent on the conditioning chemotherapy with no 'graft-versus-disease' effect.

Anticoagulant and antithrombotic therapy

There are numerous indications for anticoagulant and antithrombotic medications (Box 23.25). The guiding principles are outlined here but management in specific indications is discussed elsewhere in the book. Broadly speaking, antiplatelet medications are of greater efficacy in the prevention of arterial thrombosis and of less value in the prevention of venous thromboembolism (VTE). Thus, antiplatelet agents, such as aspirin, clopidogrel and, increasingly, ticagrelor, are the drugs of choice in acute coronary events (p. 498) and in ischaemic cerebrovascular disease, while warfarin and other anticoagulants are favoured in VTE (p. 975) and management of atrial fibrillation (p. 471). In some extremely prothrombotic situations, such as coronary artery stenting, a combination of anticoagulant and antiplatelet drugs is used (p. 491).

A wide range of anticoagulant and antithrombotic drugs is used in clinical practice. These drugs and their modes of action are given in Box 23.26. Newer agents allow predictable anticoagulation without the need for frequent monitoring and dose titration. Although warfarin remains the mainstay for oral anticoagulation, newer oral anticoagulants (dabigatran, rivaroxaban, edoxaban and apixaban), which can be given at fixed doses with predictable effects and no need for monitoring, have now been approved for the prevention of perioperative VTE, the treatment of established VTE and the prevention of cardioembolic stroke in patients with atrial fibrillation.

23.25 Indications for anticoagulation

Heparin/LMWH/Fondaparinux	
• Prevention and treatment of VTE • Percutaneous coronary intervention • Post-thrombolysis for MI • Unstable angina pectoris • Non-Q wave MI • Acute peripheral arterial occlusion • Cardiopulmonary bypass • Haemodialysis and haemofiltration	
Coumarins (warfarin etc.)	
• Prevention and treatment of VTE • Arterial embolism • Atrial fibrillation with specific risk factors for stroke (p. 472) • Mobile mural thrombus post-MI • Extensive anterior MI • Dilated cardiomyopathy • Cardioversion • Ischaemic stroke in antiphospholipid syndrome • Mitral stenosis and mitral regurgitation with atrial fibrillation	Therapeutic INR 2.5
• Recurrent venous thrombosis while on warfarin • Mechanical prosthetic cardiac valves	INR 3.5
Rivaroxaban	
• Prevention and treatment of VTE • Atrial fibrillation with risk factors for stroke	
Dabigatran etexilate	
• Prevention of VTE • Atrial fibrillation with risk factors for stroke	
Apixaban	
• Prevention of VTE • Atrial fibrillation with risk factors for stroke	
Edoxaban	
• Treatment of VTE • Atrial fibrillation with risk factors for stroke	

(INR = international normalised ratio; LMWH = low-molecular-weight heparin; MI = myocardial infarction; VTE = venous thromboembolism)

Heparins

Unfractionated heparin (UFH) and low-molecular-weight heparins (LMWHs) act by binding via a specific pentasaccharide in the heparin molecule to antithrombin. Fondaparinux is a synthetic pentasaccharide, which also binds antithrombin and has similar properties to LMWH. These agents enhance the natural anticoagulant activity of antithrombin (see Fig. 23.6E). Increased cleavage of activated proteases, particularly factor Xa and thrombin (IIa), accounts for the anticoagulant effect. LMWHs preferentially augment antithrombin activity against factor Xa. For the licensed indications, LMWHs are at least as efficacious as UFH but have several advantages:

- LMWHs are nearly 100% bioavailable and so produce reliable dose-dependent anticoagulation.
- LMWHs do not require monitoring of their anticoagulant effect (except possibly in patients with very low body

23.26 Modes of action of anticoagulant and antithrombotic drugs

Mode of action	Drug
Antiplatelet drugs	
Cyclo-oxygenase (COX) inhibition	Aspirin
Adenosine diphosphate (ADP) receptor inhibition	Clopidogrel Prasugrel Ticagrelor
Glycoprotein IIb/IIIa inhibition	Abciximab Tirofiban Eptifibatide
Phosphodiesterase inhibition	Dipyridamole
Oral anticoagulants	
Vitamin K antagonism	Warfarin/coumarins
Direct thrombin inhibition	Dabigatran
Direct Xa inhibition	Rivaroxaban Apixaban Edoxaban
Injectable anticoagulants	
Antithrombin-dependent inhibition of thrombin and Xa	Heparin LMWH
Antithrombin-dependent inhibition of Xa	Fondaparinux Danaparoid
Direct thrombin inhibition	Argatroban Bivalirudin

23.27 Treatments for emergencies in haematological practice

- Reversal of life- and limb-threatening haemorrhage in anticoagulated patients:
  - Warfarin: prothrombin complex concentrate and IV vitamin K_1
  - Unfractionated heparin: protamine sulphate
  - Dabigatran: idarucizumab
- Recognition of thrombotic thrombocytopenic purpura and treatment with plasma exchange
- Recognition of coagulopathy associated with acute promyelocytic leukaemia and treatment with all-trans-retinoic acid and fibrinogen replacement
- Recognition of chest syndrome and stroke in patients with sickle-cell anaemia and red cell transfusion or exchange transfusion
- Recognition of neutropenic sepsis in patients receiving chemotherapy and early treatment with empirical broad-spectrum antibiotics

weight and with a glomerular filtration rate below 30 mL/min).

- LMWHs have a half-life of around 4 hours when given subcutaneously, compared with 1 hour for UFH. This permits once-daily dosing by the subcutaneous route, rather than the therapeutic continuous intravenous infusion or twice-daily subcutaneous administration required for UFH.
- While rates of bleeding are similar between products, the risk of osteoporosis and heparin-induced thrombocytopenia is much lower for LMWH.

UFH is, however, more completely reversed by protamine sulphate in the event of bleeding and at the end of cardiopulmonary bypass, for which UFH remains the drug of choice (Box 23.27).

LMWHs are widely used for the prevention and treatment of VTE, the management of acute coronary syndromes and for most other scenarios listed in Box 23.25. In some situations, UFH is still favoured by some clinicians, though there is little evidence that it is advantageous, except when rapid reversibility is required. UFH is useful in patients with a high risk of bleeding, e.g. those who have peptic ulceration or who may require urgent surgery. It is also favoured in the treatment of life-threatening thromboembolism, e.g. major pulmonary embolism with significant hypoxaemia, hypotension and right-sided heart strain. In this situation, UFH is started with a loading intravenous dose of 80 U/kg, followed by a continuous infusion of 18 U/kg/hr initially. The level of anticoagulation should be assessed by the APTT after 6 hours and, if satisfactory, twice daily thereafter. It is usual to aim for a patient APTT that is 1.5–2.5 times the control time of the test. Monitoring of UFH treatment by APTT is not without difficulties and other assays, such as the specific anti-Xa assay, may provide more accurate guidance.

Heparin-induced thrombocytopenia

Heparin-induced thrombocytopenia (HIT) is a rare complication of heparin therapy, caused by induction of anti-heparin/PF4 antibodies that bind to and activate platelets via an Fc receptor. This results in platelet activation and a prothrombotic state, with a paradoxical thrombocytopenia. HIT is more common in surgical than medical patients (especially cardiac and orthopaedic patients), with use of UFH rather than LMWH, and with higher doses of heparin.

Clinical features

Patients present, typically 5–14 days after starting heparin treatment, with a fall in platelet count of more than 30% from baseline. The count may still be in the reference range. The patient may be asymptomatic, or develop venous or arterial thrombosis and skin lesions, including overt skin necrosis. Affected patients may complain of pain or itch at injection sites and of systemic symptoms, such as shivering, following heparin injections. Patients who have received heparin in the preceding 100 days and who have preformed antibodies may develop acute systemic symptoms and an abrupt fall in platelet count in the first 24 hours after re-exposure.

Investigations

The pre-test probability of the diagnosis is assessed using the 4Ts scoring system. This assigns a score based on:

- the **t**hrombocytopenia
- the **t**iming of the fall in platelet count
- the presence of new **t**hrombosis
- the likelihood of ano**t**her cause for the thrombocytopenia.

Individuals at low risk need no further test. Those with intermediate and high likelihood scores should have the diagnosis confirmed or refuted using an anti-PF4 enzyme-linked immunosorbent assay (ELISA).

Management

Heparin should be discontinued as soon as HIT is diagnosed and an alternative anticoagulant that does not cross-react with the antibody should be substituted. Argatroban (a direct thrombin inhibitor) and danaparoid (a heparin analogue) are licensed for use in the UK. In asymptomatic patients with HIT who do not receive an alternative anticoagulant, around 50% will sustain a thrombosis in the subsequent 30 days. Patients with established thrombosis have a poorer prognosis.

Coumarins

Although several coumarin anticoagulants are used around the world, warfarin is the most common.

Coumarins inhibit the vitamin K-dependent post-translational carboxylation of factors II (prothrombin), VII, IX and X in the liver (see Fig. 23.6D). This results in anticoagulation due to an effective deficiency of these factors. This is monitored by the INR, a standardised test based on measurement of the prothrombin time (p. 922). Recommended target INR values for specific indications are given in Box 23.25.

23

Warfarin anticoagulation typically takes more than 3–5 days to become established, even using loading doses. Patients who require rapid initiation of therapy may receive higher initiation doses of warfarin. A typical regime in this situation is to give 10 mg warfarin on the first and second days, with 5 mg on the third day; subsequent doses are titrated against the INR. Patients without an urgent need for anticoagulation (e.g. atrial fibrillation) can have warfarin introduced slowly using lower doses. Low-dose regimens are associated with a lower risk of the patient developing a supratherapeutic INR, and hence a lower bleeding risk. The duration of warfarin therapy depends on the clinical indication, and while treatment of deep vein thrombosis (DVT) or preparation for cardioversion may require a limited duration, anticoagulation to prevent cardioembolic stroke in atrial fibrillation or from heart valve disease is long-term.

The major problems with warfarin are:

- a narrow therapeutic window
- metabolism that is affected by many factors
- numerous drug interactions.

23.28 How to assess risks of anticoagulation

Contraindications

- Recent surgery, especially to eye or central nervous system
- Pre-existing haemorrhagic state, e.g. advanced liver disease, haemophilia, thrombocytopenia
- Pre-existing structural lesions, e.g. peptic ulcer
- Recent cerebral or gastrointestinal haemorrhage
- Uncontrolled hypertension
- Cognitive impairment
- Frequent falls

Bleeding risk score

- Several bleeding risk scores exist for different indications for anticoagulation
- The validation of most bleeding risk scores has been poor
- Many risk factors for thrombosis are also risk factors for bleeding
- Following anticoagulant-related bleeding, reassessment of bleeding and thrombosis risk is indicated
- In many cases, patients benefit from recommencing anticoagulants after bleeding

Drug interactions are common through protein binding and metabolism by the cytochrome P450 system. Inter-individual differences in warfarin doses required to achieve a therapeutic INR are mostly accounted for by naturally occurring polymorphisms in the *CYP2C9* and the *VKORC1* genes (which predict the metabolism and function of warfarin, respectively) and dietary intake of vitamin K.

Major bleeding is the most common serious side-effect of warfarin and occurs in 1–2% of patients each year. Fatal haemorrhage, which is most commonly intracranial, occurs in about 0.25% per annum. There are scoring systems that predict the annual bleeding risk and these can be used to help compare the risks and benefits of warfarin for an individual patient (Box 23.28). There are also some specific contraindications to anticoagulation (Box 23.28). Management of warfarin includes strategies for over-anticoagulation and for bleeding:

- If the INR is above the therapeutic level, warfarin should be withheld or the dose reduced. If the patient is not bleeding, it may be appropriate to give a small dose of vitamin K either orally or intravenously (1–2.5 mg), especially if the INR is greater than 8.
- In the event of bleeding, withhold further warfarin. Minor bleeding can be treated with 1–2.5 mg of vitamin K IV. Major haemorrhage should be treated as an emergency with vitamin K 5–10 mg slowly IV, combined with coagulation factor replacement (see Box 23.27). This should optimally be a prothrombin complex concentrate (30–50 U/kg) that contains factors II, VII, IX and X; if that is not available, fresh frozen plasma (15–30 mL/kg) should be given.

Direct oral anticoagulants

The direct oral anticoagulants (DOACs) offer an alternative to coumarins in the management of VTE and the prevention of stroke and systemic embolism in patients with atrial fibrillation. The DOACs are direct specific inhibitors of key proteases in the common pathway. Dabigatran inhibits thrombin while rivaroxaban, apixaban and edoxaban inhibit Xa. The key features of these drugs include the fact that they are efficacious in fixed oral doses, have a short half-life of around 10 hours, achieve peak plasma levels 2–4 hours after oral intake, have very few drug interactions and are all moderately dependent on renal function for their excretion. An initial perceived drawback was the lack of specific reversal agents for these drugs but idarucizumab is a monoclonal antibody now available for the reversal of dabigatran, and andexanet alfa, a site-inactivated Xa molecule, is close to licensing for the reversal of apixaban and rivaroxaban (see Box 23.27).

DOACs are now licensed for the prevention of VTE following high-risk orthopaedic surgery (except edoxaban), the acute management and prevention of recurrence of VTE, and the prevention of stroke and systemic embolism in patients with atrial fibrillation with risk factors. The general perception at present is that in these indications they are at least as efficacious as dose-adjusted coumarin and probably associated with less clinically significant bleeding.

Anaemias

Around 30% of the total world population is anaemic and half of these, some 600 million people, have iron deficiency. The classification of anaemia by the size of the red cells (MCV) indicates the likely cause (see Figs 23.10 and 23.11).

Red cells in the bone marrow must acquire a minimum level of haemoglobin before being released into the blood stream (Fig. 23.17). While in the marrow compartment, red cell precursors undergo cell division, driven by erythropoietin. If red cells cannot acquire haemoglobin at a normal rate, they will undergo more divisions than normal and will have a low MCV when finally released into the blood. The MCV is low because component parts of the haemoglobin molecule are not fully available: that is, iron in iron deficiency, globin chains in thalassaemia, haem ring in congenital sideroblastic anaemia and, occasionally, poor iron utilisation in the anaemia of chronic disease/anaemia of inflammation.

In megaloblastic anaemia, the biochemical consequence of vitamin B_{12} or folate deficiency is an inability to synthesise new bases to make DNA. A similar defect of cell division is seen in the presence of cytotoxic drugs or haematological disease in the marrow, such as myelodysplasia. In these states, cells haemoglobinise normally but undergo fewer cell divisions, resulting in circulating red cells with a raised MCV. The red cell membrane is composed of a lipid bilayer that will freely exchange with the plasma pool of lipid. Conditions such as liver disease, hypothyroidism, hyperlipidaemia and pregnancy are associated with raised lipids and may also cause a raised MCV. Reticulocytes are larger than mature red cells, so when the reticulocyte count is raised – e.g. in haemolysis – this may also increase the MCV.

Iron deficiency anaemia

This occurs when iron losses or physiological requirements exceed absorption.

Blood loss

The most common explanation in men and post-menopausal women is gastrointestinal blood loss (p. 780). This may result from occult gastric or colorectal malignancy, gastritis, peptic ulceration, inflammatory bowel disease, diverticulitis, polyps and angiodysplastic lesions. Worldwide, hookworm and schistosomiasis are the most common causes of gut blood loss (pp. 288 and 294). Gastrointestinal blood loss may be exacerbated

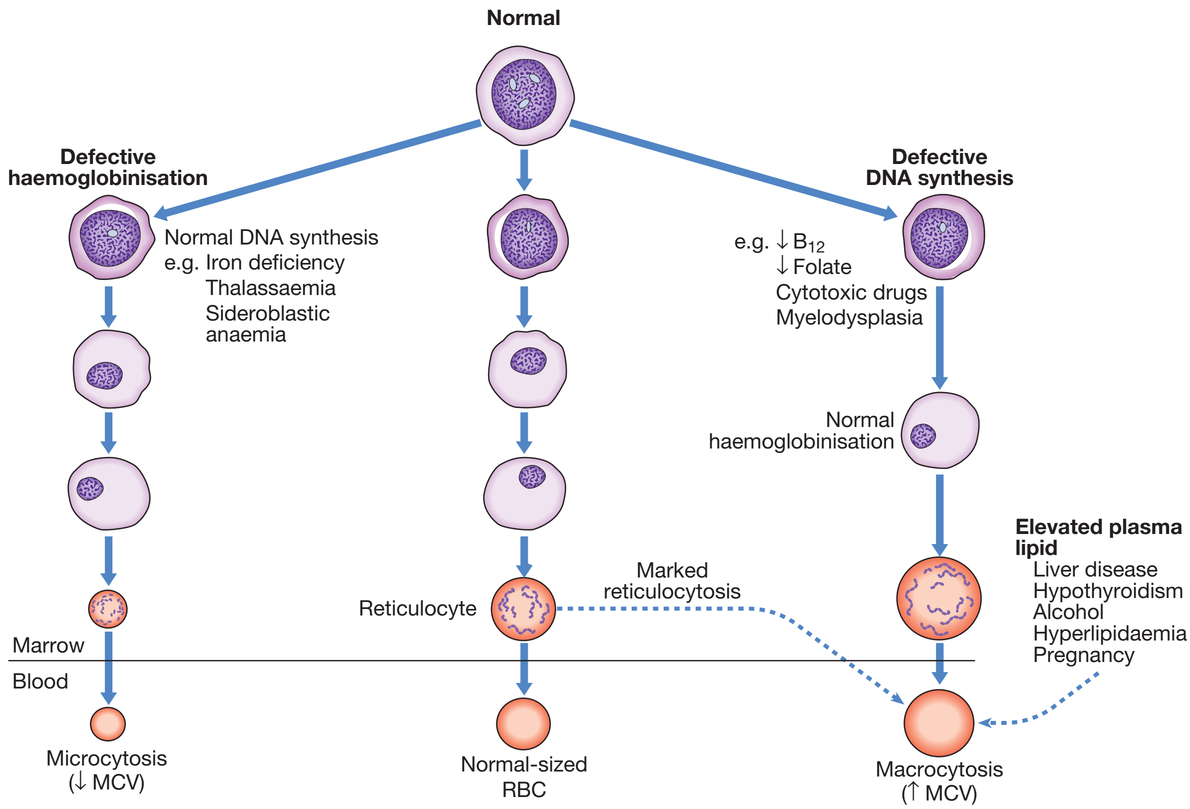

Fig. 23.17 Factors that influence the size of red cells in anaemia. In microcytosis, the MCV is <76 fL. In macrocytosis, the MCV is >100 fL. (MCV = mean cell volume; RBC = red blood cell)

by the chronic use of aspirin or non-steroidal anti-inflammatory drugs (NSAIDs), which cause intestinal erosions and impair platelet function. In women of child-bearing age, menstrual blood loss, pregnancy and breastfeeding contribute to iron deficiency by depleting iron stores; in developed countries, one-third of pre-menopausal women have low iron stores but only 3% display iron-deficient haematopoiesis. Very rarely, chronic haemoptysis or haematuria may cause iron deficiency.

Malabsorption

A dietary assessment should be made in all patients to ascertain their iron intake (p. 716). Gastric acid is required to release iron from food and helps to keep iron in the soluble ferrous state (Fig. 23.18). Achlorhydria in the elderly or that due to drugs such as proton pump inhibitors may contribute to the lack of iron availability from the diet, as may previous gastric surgery. Iron is absorbed actively in the upper small intestine and hence can be affected by coeliac disease (p. 805).

Physiological demands

At times of rapid growth, such as infancy and puberty, iron requirements increase and may outstrip absorption. In pregnancy, iron is diverted to the fetus, the placenta and the increased maternal red cell mass, and is lost with bleeding at parturition (Box 23.29).

Investigations

Confirmation of iron deficiency

Serum ferritin is a measure of iron stores in tissues and is the best single test to confirm iron deficiency (Box 23.30). It is a very specific test; a subnormal level is due to iron deficiency or, very rarely, hypothyroidism or vitamin C deficiency. Ferritin levels can be raised in liver disease and in the acute phase response; in these conditions, a ferritin level of up to 100 μg/L may still be compatible with low bone marrow iron stores.

23.29 Haematological physiology in pregnancy

- **Full blood count**: increased plasma volume (40%) lowers normal haemoglobin (reference range reduced to >105 g/L at 28 weeks). The mean cell volume (MCV) may increase by 5 fL. A progressive neutrophilia occurs. Gestational thrombocytopenia (rarely $<60\times10^9$/L) is a benign phenomenon.
- **Depletion of iron stores**: iron deficiency is a common cause of anaemia in pregnancy and, if present, should be treated with oral iron supplement.
- **Vitamin B_{12}**: serum levels are physiologically low in pregnancy but deficiency is uncommon.
- **Folate**: tissue stores may become depleted, and folate supplementation is recommended in all pregnancies (see Box 19.29, p. 712).
- **Coagulation factors**: from the second trimester, procoagulant factors increase approximately threefold, particularly fibrinogen, von Willebrand factor and factor VIII. This causes activated protein C resistance and a shortened activated partial thromboplastin time (APTT), and contributes to a prothrombotic state.
- **Anticoagulants**: levels of protein C increase from the second trimester, while levels of free protein S fall as C4b binding protein increases.

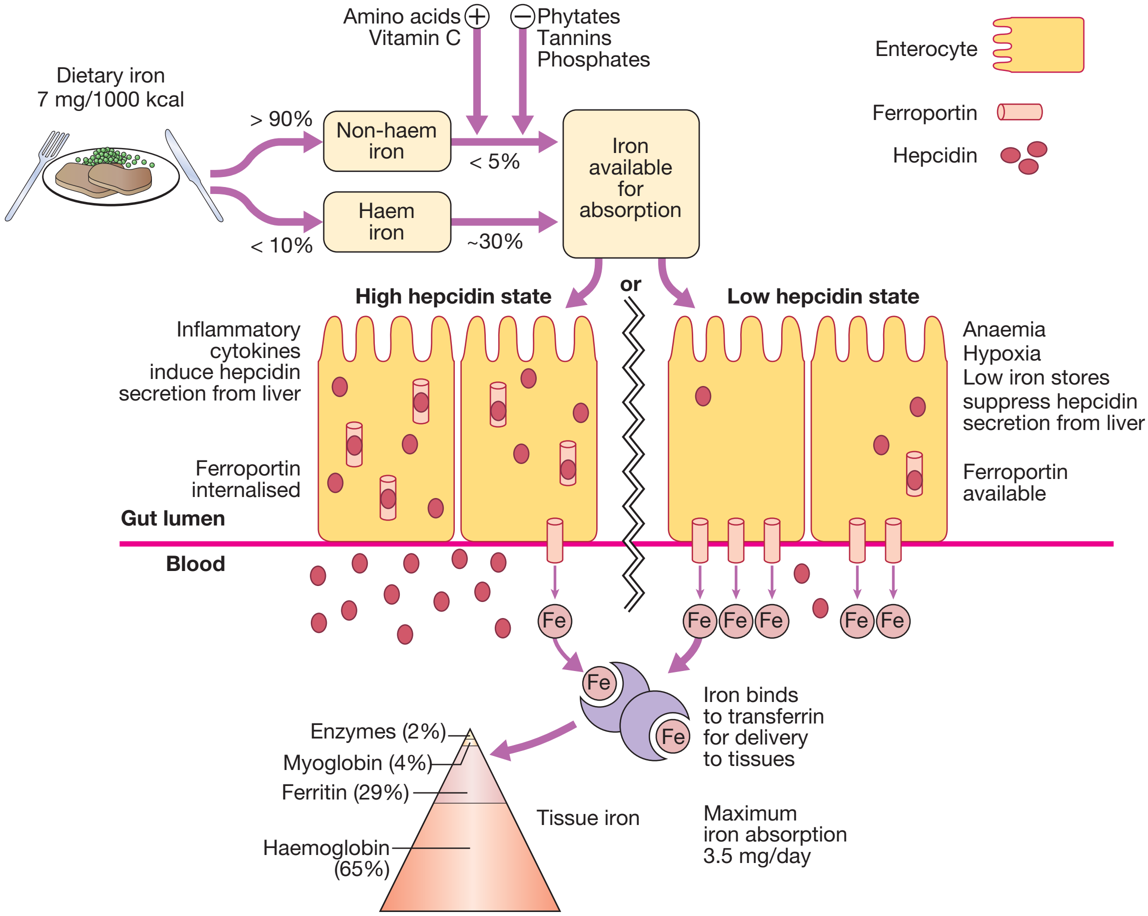

Fig. 23.18 The regulation of iron absorption, uptake and distribution in the body. The transport of iron is regulated in a similar fashion to enterocytes in other iron-transporting cells such as macrophages.

23.30 Investigations to differentiate anaemia of chronic disease from iron deficiency anaemia

	Ferritin	Iron	TIBC	Transferrin saturation	Soluble transferrin receptor
Iron deficiency anaemia	↓	↓	↑	↓	↑
Anaemia of chronic disease	↑/Normal	↓	↓	↓	↓/Normal

(TIBC = total iron binding capacity)

Plasma iron and total iron binding capacity (TIBC) are measures of iron availability; hence they are affected by many factors besides iron stores. Plasma iron has a marked diurnal and day-to-day variation and becomes very low during an acute phase response but is raised in liver disease and haemolysis. Levels of transferrin, the binding protein for iron, are lowered by malnutrition, liver disease, the acute phase response and nephrotic syndrome, but raised by pregnancy and the oral contraceptive pill. A transferrin saturation (i.e. iron/TIBC×100) of less than 16% is consistent with iron deficiency but is less specific than a ferritin measurement.

All proliferating cells express membrane transferrin receptors to acquire iron; a small amount of this receptor is shed into blood, where it can be detected in a free soluble form. At times of poor iron stores, cells up-regulate transferrin receptor expression and the levels of soluble plasma transferrin receptor increase. This can now be measured by immunoassay and used to distinguish storage iron depletion in the presence of an acute phase response or liver disease, when a raised level indicates iron deficiency. In difficult cases, it may still be necessary to examine a bone marrow aspirate for iron stores.

Investigation of the cause

This will depend on the age and sex of the patient, as well as the history and clinical findings. In men and in post-menopausal women with a normal diet, the upper and lower gastrointestinal tract should be investigated by endoscopy or radiological studies. Serum anti-transglutaminase antibodies and possibly a duodenal biopsy are indicated (p. 806) to detect coeliac disease. Current guidelines suggest exclusion of coeliac disease by antibody testing at an early stage of investigation. In the tropics, stool and urine should be examined for parasites (p. 233).

Management

Unless the patient has angina, heart failure or evidence of cerebral hypoxia, transfusion is not necessary and oral iron replacement is appropriate. Ferrous sulphate 200 mg 3 times daily (195 mg of elemental iron per day) is adequate and should be continued for 3–6 months to replete iron stores. Many patients suffer gastrointestinal side-effects with ferrous sulphate, including dyspepsia and altered bowel habit. When this occurs, reduction in dose to 200 mg twice daily or a switch to ferrous gluconate 300 mg twice daily (70 mg of elemental iron per day) or another alternative oral preparation should be tried. Delayed-release preparations are not useful, since they release iron beyond the upper small intestine, where it cannot be absorbed.

The haemoglobin should rise by around 10 g/L every 7–10 days and a reticulocyte response will be evident within a week. A failure to respond adequately may be due to non-adherence, continued blood loss, malabsorption or an incorrect diagnosis. Patients with malabsorption, chronic gut disease or inability to tolerate any oral preparation may need parenteral iron therapy. Previously, iron dextran or iron sucrose was used, but new preparations of iron isomaltose and iron carboxymaltose have fewer allergic effects and are preferred. Doses required can be calculated based on the patient's starting haemoglobin and body weight. Observation for anaphylaxis following an initial test dose is recommended.

Anaemia of chronic disease

Anaemia of chronic disease (ACD), also known as anaemia of inflammation (AI), is a common type of anaemia, particularly in hospital populations. It occurs in the setting of chronic infection, chronic inflammation or neoplasia. The anaemia is not related to bleeding, haemolysis or marrow infiltration, is mild, with haemoglobin in the range of 85–115 g/L, and is usually associated with a normal MCV (normocytic, normochromic), though this may be reduced in long-standing inflammation. The serum iron is low but iron stores are normal or increased, as indicated by the ferritin or stainable marrow iron.

Pathogenesis

It has recently become clear that the key regulatory protein that accounts for the findings characteristic of ACD/AI is hepcidin, which is produced by the liver (see Fig. 23.18). Hepcidin production is induced by pro-inflammatory cytokines, especially IL-6. Hepcidin binds to ferroportin on the membrane of iron-exporting cells, such as small intestinal enterocytes and macrophages, internalising the ferroportin and thereby inhibiting the export of iron from these cells into the blood. The iron remains trapped inside the cells in the form of ferritin, levels of which are therefore normal or high in the face of significant anaemia. Inhibition or blockade of hepcidin is a potential target for treatment of this form of anaemia.

Diagnosis and management

It is often difficult to distinguish ACD associated with a low MCV from iron deficiency. Box 23.30 summarises the investigations and results. Examination of the marrow may ultimately be required to assess iron stores directly. A trial of oral iron can be given in difficult situations. A positive response occurs in true iron deficiency but not in ACD. Measures that reduce the severity of the underlying disorder generally help to improve the ACD. Trials of higher-dose intravenous iron are under way to try to bypass the hepcidin-induced blockade.

Megaloblastic anaemia

This results from a deficiency of vitamin B_{12} or folic acid, or from disturbances in folic acid metabolism. Folate is an important substrate of, and vitamin B_{12} a co-factor for, the generation of the essential amino acid methionine from homocysteine. This reaction produces tetrahydrofolate, which is converted to thymidine monophosphate for incorporation into DNA. Deficiency of either vitamin B_{12} or folate will therefore produce high plasma levels of homocysteine and impaired DNA synthesis.

The end result is cells with arrested nuclear maturation but normal cytoplasmic development: so-called nucleocytoplasmic asynchrony. All proliferating cells will exhibit megaloblastosis; hence changes are evident in the buccal mucosa, tongue, small intestine, cervix, vagina and uterus. The high proliferation rate of bone marrow results in striking changes in the haematopoietic system in megaloblastic anaemia. Cells become arrested in development and die within the marrow; this ineffective erythropoiesis results in an expanded hypercellular marrow. The megaloblastic changes are most evident in the early nucleated red cell precursors, and haemolysis within the marrow results in a raised bilirubin and lactate dehydrogenase (LDH), but without the reticulocytosis characteristic of other forms of haemolysis (p. 945). Iron stores are usually raised. The mature red cells are large and oval, and sometimes contain nuclear remnants. Nuclear changes are seen in the immature granulocyte precursors and a characteristic appearance is that of 'giant' metamyelocytes with a large 'sausage-shaped' nucleus. The mature neutrophils show hypersegmentation of their nuclei, with cells having six or more nuclear lobes. If severe, a pancytopenia may be present in the peripheral blood.

Vitamin B_{12} deficiency, but not folate deficiency, is associated with neurological disease in up to 40% of cases, although advanced neurological disease due to B_{12} deficiency is now uncommon in the developed world. The main pathological finding is focal demyelination affecting the spinal cord, peripheral nerves, optic nerves and cerebrum. The most common manifestations are sensory, with peripheral paraesthesiae and ataxia of gait. The clinical and diagnostic features of megaloblastic anaemia are summarised in Boxes 23.31 and 23.32, and the neurological features of B_{12} deficiency in Box 23.33.

Vitamin B_{12}

Vitamin B_{12} absorption

The average daily diet contains 5–30 µg of vitamin B_{12}, mainly in meat, fish, eggs and milk – well in excess of the 1 µg daily

23.31 Clinical features of megaloblastic anaemia

Symptoms	
• Malaise (90%)	• Poor memory
• Breathlessness (50%)	• Depression
• Paraesthesiae (80%)	• Personality change
• Sore mouth (20%)	• Hallucinations
• Weight loss	• Visual disturbance
• Impotence	
Signs	
• Smooth tongue	• Skin pigmentation
• Angular cheilosis	• Heart failure
• Vitiligo	• Pyrexia

23.32 Investigations in megaloblastic anaemia

Investigation	Result
Haemoglobin	Often reduced, may be very low
Mean cell volume	Usually raised, commonly >120 fL
Erythrocyte count	Low for degree of anaemia
Blood film	Oval macrocytosis, poikilocytosis, red cell fragmentation, neutrophil hypersegmentation
Reticulocyte count	Low for degree of anaemia
Leucocyte count	Low or normal
Platelet count	Low or normal
Bone marrow	Increased cellularity, megaloblastic changes in erythroid series, giant metamyelocytes, dysplastic megakaryocytes, increased iron in stores, pathological non-ring sideroblasts
Serum ferritin	Elevated
Plasma lactate dehydrogenase	Elevated, often markedly

23.33 Neurological findings in B_{12} deficiency

Peripheral nerves
- Glove and stocking paraesthesiae
- Loss of ankle reflexes

Spinal cord
- Subacute combined degeneration of the cord
    - Posterior columns – diminished vibration sensation and proprioception
    - Corticospinal tracts – upper motor neuron signs

Cerebrum
- Dementia
- Optic atrophy

Autonomic neuropathy

requirement. In the stomach, gastric enzymes release vitamin B_{12} from food and at gastric pH it binds to a carrier protein termed R protein. The gastric parietal cells produce intrinsic factor, a vitamin B_{12}-binding protein that optimally binds vitamin B_{12} at pH 8. As gastric emptying occurs, pancreatic secretion raises the pH and vitamin B_{12} released from the diet switches from the R protein to intrinsic factor. Bile also contains vitamin B_{12} that is available for reabsorption in the intestine. The vitamin B_{12}–intrinsic factor complex binds to specific receptors in the terminal ileum, and vitamin B_{12} is actively transported by the enterocytes to plasma, where it binds to transcobalamin II, a transport protein produced by the liver, which carries it to the tissues for utilisation. The liver stores enough vitamin B_{12} for 3 years and this, together with the enterohepatic circulation, means that vitamin B_{12} deficiency takes years to become manifest, even if all dietary intake is stopped or severe B_{12} malabsorption supervenes.

Blood levels of vitamin B_{12} (cobalamin) provide a reasonable indication of tissue stores, are usually diagnostic of deficiency and remain the first-line tests for most laboratories. Additional tests have been evaluated, including measurement of methylmalonic acid, holotranscobalamin and plasma homocysteine levels, but do not add much in most clinical situations. Levels of cobalamins fall in normal pregnancy. Reference ranges vary between laboratories but levels below 150 ng/L are common and, in the last trimester, 5–10% of women have levels below 100 ng/L. Spuriously low B_{12} values occur in women using the oral contraceptive pill and in patients with myeloma, in whom paraproteins can interfere with vitamin B_{12} assays.

Causes of vitamin B_{12} deficiency

Dietary deficiency

This occurs only in strict vegans but the onset of clinical features can occur at any age between 10 and 80 years. Less strict vegetarians often have slightly low vitamin B_{12} levels but are not tissue vitamin B_{12}-deficient.

Gastric pathology

Release of vitamin B_{12} from food requires normal gastric acid and enzyme secretion, and this is impaired by hypochlorhydria in elderly patients or following gastric surgery. Total gastrectomy invariably results in vitamin B_{12} deficiency within 5 years, often combined with iron deficiency; these patients need life-long 3-monthly vitamin B_{12} injections. After partial gastrectomy, vitamin B_{12} deficiency only develops in 10–20% of patients by 5 years; an annual injection of vitamin B_{12} should prevent deficiency in this group.

Pernicious anaemia

This is an organ-specific autoimmune disorder in which the gastric mucosa is atrophic, with loss of parietal cells causing intrinsic factor deficiency. In the absence of intrinsic factor, less than 1% of dietary vitamin B_{12} is absorbed. Pernicious anaemia has an incidence of 25/100 000 population over the age of 40 years in developed countries, but an average age of onset of 60 years. It is more common in individuals with other autoimmune disease (Hashimoto's thyroiditis, Graves' disease, vitiligo or Addison's disease; Ch. 18) or a family history of these or pernicious anaemia. The finding of anti-intrinsic factor antibodies in the context of B_{12} deficiency is diagnostic of pernicious anaemia without further investigation. Antiparietal cell antibodies are present in over 90% of cases but are also present in 20% of normal females over the age of 60 years; a negative result makes pernicious anaemia less likely but a positive result is not diagnostic. The Schilling test, involving measurement of absorption of radio-labelled B_{12} after oral administration before and after replacement of intrinsic factor, has fallen out of favour with the availability of autoantibody tests, greater caution in the use of radioactive tracers, and limited availability of intrinsic factor.

Small bowel pathology

One-third of patients with pancreatic exocrine insufficiency fail to transfer dietary vitamin B_{12} from R protein to intrinsic factor. This usually results in slightly low vitamin B_{12} values but no tissue evidence of vitamin B_{12} deficiency.

Motility disorders or hypogammaglobulinaemia can result in bacterial overgrowth, and the ensuing competition for free vitamin B_{12} can lead to deficiency. This is corrected to some extent by appropriate antibiotics.

A small number of people heavily infected with the fish tapeworm (p. 297) develop vitamin B_{12} deficiency.

Inflammatory disease of the terminal ileum, such as Crohn's disease, may impair the absorption of vitamin B_{12}–intrinsic factor complex, as may surgery on that part of the bowel.

Folate

Folate absorption

Folates are produced by plants and bacteria; hence dietary leafy vegetables (spinach, broccoli, lettuce), fruits (bananas, melons) and animal protein (liver, kidney) are a rich source. An average Western diet contains more than the minimum daily intake of 50 μg but excess cooking destroys folates. Most dietary folate is present as polyglutamates; these are converted to monoglutamate in the upper small bowel and actively transported into plasma. Plasma folate is loosely bound to plasma proteins such as albumin and there is an enterohepatic circulation. Total body stores of folate are small and deficiency can occur in a matter of weeks.

Folate deficiency

The causes and diagnostic features of folate deficiency are shown in Boxes 23.34 and 23.35. The edentulous elderly or psychiatric patient is particularly susceptible to dietary deficiency and this is exacerbated in the presence of gut disease or malignancy. Pregnancy-induced folate deficiency is the most common cause of megaloblastosis worldwide and is more likely in the context of twin pregnancies, multiparity and hyperemesis gravidarum. Serum folate measurement is very sensitive to dietary intake; a single folate-rich meal can normalise it in a patient with true folate deficiency, whereas anorexia, alcohol and anticonvulsant therapy can reduce it in the absence of megaloblastosis. For this reason, red cell folate levels are a more accurate indicator of folate stores and tissue folate deficiency.

Management of megaloblastic anaemia

If a patient with a severe megaloblastic anaemia is very ill and treatment must be started before vitamin B_{12} and red cell folate results are available, that treatment should always include both folic acid and vitamin B_{12}. The use of folic acid alone in the presence of vitamin B_{12} deficiency may result in worsening of neurological features.

Rarely, if severe angina or heart failure is present, transfusion can be used in megaloblastic anaemia. The cardiovascular system is adapted to the chronic anaemia present in megaloblastosis, and the volume load imposed by transfusion may result in decompensation and severe cardiac failure. In such circumstances, exchange transfusion or slow administration of 1 U of red cells with diuretic cover may be given.

Vitamin B_{12} deficiency

Vitamin B_{12} deficiency is treated with hydroxycobalamin. In cases of uncomplicated deficiency, 1000 μg IM for 6 doses 2 or 3 days apart, followed by maintenance therapy of 1000 μg every 3 months for life, is recommended. In the presence of neurological involvement, a dose of 1000 μg on alternate days until there is no further improvement, followed by maintenance as above, is recommended. The reticulocyte count will peak by the 5th–10th day after starting replacement therapy. The haemoglobin will rise by 10 g/L every week until normalised. The response of the marrow is associated with a fall in plasma potassium levels and rapid depletion of iron stores. If an initial response is not maintained and the blood film is dimorphic (i.e. shows a mixture of microcytic and macrocytic cells), the patient may need additional iron therapy. A sensory neuropathy may take 6–12 months to correct; long-standing neurological damage may not improve.

Folate deficiency

Oral folic acid (5 mg daily for 3 weeks) will treat acute deficiency and 5 mg once weekly is adequate maintenance therapy. Prophylactic folic acid in pregnancy prevents megaloblastosis in women at risk, and reduces the risk of fetal neural tube defects (p. 712). Prophylactic supplementation is also given in chronic haematological disease associated with reduced red cell lifespan (e.g. haemolytic anaemias). There is some evidence that supraphysiological supplementation (400 μg/day) can reduce the risk of coronary and cerebrovascular disease by lowering plasma homocysteine levels. This has led the US Food and Drug Administration to introduce fortification of bread, flour and rice with folic acid.

23.34 Causes of folate deficiency

Diet
• Poor intake of vegetables
Malabsorption
• e.g. Coeliac disease, small bowel surgery
Increased demand
• Cell proliferation, e.g. haemolysis
• Pregnancy
Drugs*
• Certain anticonvulsants (e.g. phenytoin)
• Contraceptive pill
• Certain cytotoxic drugs (e.g. methotrexate)
*Usually only a problem in patients deficient in folate from another cause.

23.35 Investigation of folic acid deficiency

Diagnostic findings
• Serum folate levels may be low but are difficult to interpret
• Low red cell folate levels indicate prolonged folate deficiency and are probably the most relevant measure
Corroborative findings
• Macrocytic dysplastic blood picture
• Megaloblastic marrow

Haemolytic anaemia

Haemolysis indicates that there is shortening of the normal red cell lifespan of 120 days. There are many causes, as shown in Figure 23.19. To compensate, the bone marrow may increase its output of red cells six- to eightfold by increasing the proportion of red cells produced, expanding the volume of active marrow, and releasing reticulocytes prematurely. Anaemia occurs only if the rate of destruction exceeds this increased production rate.

There are some general features of haemolysis and other specific features that help to identify the reason for haemolysis. Results of investigations that establish the presence of haemolysis are shown in Box 23.36. Red cell destruction overloads pathways for haemoglobin breakdown in the liver (p. 850), causing a modest rise in unconjugated bilirubin in the blood and mild jaundice. Increased reabsorption of urobilinogen from the gut results in an increase in urinary urobilinogen (pp. 860 and 915). Red cell destruction releases LDH into the serum. The bone

marrow compensation results in a reticulocytosis, and sometimes nucleated red cell precursors appear in the blood. Increased proliferation of the bone marrow can result in a thrombocytosis, neutrophilia and, if marked, immature granulocytes in the blood, producing a leucoerythroblastic blood film. The appearances of the red cells may give an indication of the likely cause of the haemolysis:

- Spherocytes are small, dark red cells that suggest autoimmune haemolysis or hereditary spherocytosis.
- Sickle cells suggest sickle-cell disease.
- Red cell fragments indicate microangiopathic haemolysis.
- Bite cells (normal-sized red cells that look as if they have been partially eaten) suggest oxidative haemolysis.

The compensatory erythroid hyperplasia may give rise to folate deficiency, with megaloblastic blood features.

The differential diagnosis of haemolysis is determined by the clinical scenario in combination with the results of blood film examination and Coombs testing for antibodies directed against red cells (see below and Fig. 23.19).

Extravascular haemolysis

Physiological red cell destruction occurs in the reticulo-endothelial cells in the liver or spleen, so avoiding free haemoglobin in the

plasma. In most haemolytic states, haemolysis is predominantly extravascular.

To confirm the haemolysis, patients' red cells can be labelled with ^{51}chromium. When re-injected, they can be used to determine red cell survival; when combined with body surface radioactivity counting, this test may indicate whether the liver or the spleen is the main source of red cell destruction. However, it is seldom performed in clinical practice.

Intravascular haemolysis

Less commonly, red cell lysis occurs within the blood stream due to membrane damage by complement (ABO transfusion reactions, paroxysmal nocturnal haemoglobinuria), infections (malaria, *Clostridium perfringens*), mechanical trauma (heart valves, DIC) or oxidative damage (e.g. enzymopathies such as glucose-6-phosphate dehydrogenase deficiency, which may be triggered by drugs such as dapsone and maloprim). When intravascular red cell destruction occurs, free haemoglobin is released into the plasma. Free haemoglobin is toxic to cells and binding proteins have evolved to minimise this risk. Haptoglobin is an α_2-globulin produced by the liver, which binds free haemoglobin, resulting in a fall in its levels during active haemolysis. Once haptoglobins are saturated, free haemoglobin is oxidised to form methaemoglobin, which binds to albumin, in turn forming methaemalbumin, which can be detected spectrophotometrically in Schumm's test. Methaemoglobin is degraded and any free haem is bound to a second binding protein called haemopexin. If all the protective mechanisms are saturated, free haemoglobin may appear in the urine (haemoglobinuria). When fulminant, this gives rise to black urine, as in severe *falciparum* malaria infection (p. 274). In smaller amounts, renal tubular cells absorb the haemoglobin, degrade it and store the iron as haemosiderin. When the tubular cells are subsequently sloughed into the urine, they give rise to haemosiderinuria, which is always indicative of intravascular haemolysis (Box 23.36).

Causes of haemolytic anaemia

These can be classified as inherited or acquired (Fig. 23.19).

- *Inherited* red cell abnormalities resulting in chronic haemolytic anaemia may arise from pathologies of the red cell membrane (hereditary spherocytosis or elliptocytosis), haemoglobin (haemoglobinopathies), or protective enzymes that prevent cellular oxidative damage, such as glucose-6-phosphate dehydrogenase (G6PD).
- *Acquired* causes include auto- and alloantibody-mediated destruction of red blood cells and other mechanical, toxic and infective causes.

Red cell membrane defects

The structure of the red cell membrane is shown in Figure 23.4. The basic structure is a cytoskeleton 'stapled' on to the lipid bilayer by special protein complexes. This structure ensures great deformability and elasticity; the red cell diameter is 8 μm but the narrowest capillaries in the circulation are in the spleen, measuring just 2 μm in diameter. When the normal red cell structure is disturbed, usually by a quantitative or functional deficiency of one or more proteins in the cytoskeleton, cells lose their elasticity. Each time such cells pass through the spleen, they lose membrane relative to their cell volume. This results in an increase in mean cell haemoglobin concentration (MCHC), abnormal cell shape (see Box 23.2) and reduced red cell survival due to extravascular haemolysis.

Hereditary spherocytosis

This is usually inherited as an autosomal dominant condition, although 25% of cases have no family history and represent new mutations. The incidence is approximately 1 : 5000 in developed countries but this may be an under-estimate, since the disease may present de novo in patients aged over 65 years and is often discovered as a chance finding on a blood count. The most common abnormalities are deficiencies of beta spectrin or ankyrin (see Fig. 23.4). The severity of spontaneous haemolysis varies. Most cases are associated with an asymptomatic compensated chronic haemolytic state with spherocytes present on the blood film, a reticulocytosis and mild hyperbilirubinaemia. Pigment gallstones are present in up to 50% of patients and may cause symptomatic cholecystitis. Occasional cases are associated with more severe haemolysis; these may be due to coincidental polymorphisms in alpha spectrin or co-inheritance of a second defect involving a different protein. These cases tend to present earlier in life with symptomatic, sometimes transfusion-dependent anaemia.

The clinical course may be complicated by crises:

- *A haemolytic crisis* occurs when the severity of haemolysis increases; this is rare, and usually associated with infection.
- *A megaloblastic crisis* follows the development of folate deficiency; this may occur as a first presentation of the disease in pregnancy.
- *An aplastic crisis* occurs in association with parvovirus (erythrovirus) infection (p. 237). Parvovirus causes a common exanthem in children, but if individuals with chronic haemolysis become infected, the virus directly invades red cell precursors and temporarily switches off red cell production. Patients present with severe anaemia and a low reticulocyte count.

Investigations

The patient and other family members should be screened for features of compensated haemolysis (see Box 23.36). This may be all that is required to confirm the diagnosis. Haemoglobin levels are variable, depending on the degree of compensation. The blood film will show spherocytes but the direct Coombs test (Fig. 23.20) is negative, excluding immune haemolysis. An osmotic fragility test may show increased sensitivity to lysis in hypotonic saline solutions but is limited by lack of sensitivity and specificity. More specific flow cytometric tests, detecting binding of eosin-5-maleimide to red cells, are recommended in borderline cases.

Management

Folic acid prophylaxis, 5 mg daily, should be given for life. In severe cases, consideration may be given to splenectomy, which improves but does not normalise red cell survival. Potential indications for splenectomy include moderate to severe haemolysis with complications (anaemia and gallstones), although splenectomy should be delayed where possible until after 6 years of age in view of the risk of sepsis. Guidelines for the management of patients after splenectomy are presented in Box 23.37.

Acute, severe haemolytic crises require transfusion support, but blood must be cross-matched carefully and transfused slowly as haemolytic transfusion reactions may occur (p. 935).

Hereditary elliptocytosis

This term refers to a heterogeneous group of disorders that produce an increase in elliptocytic red cells on the blood film and a variable degree of haemolysis. This is due to a functional

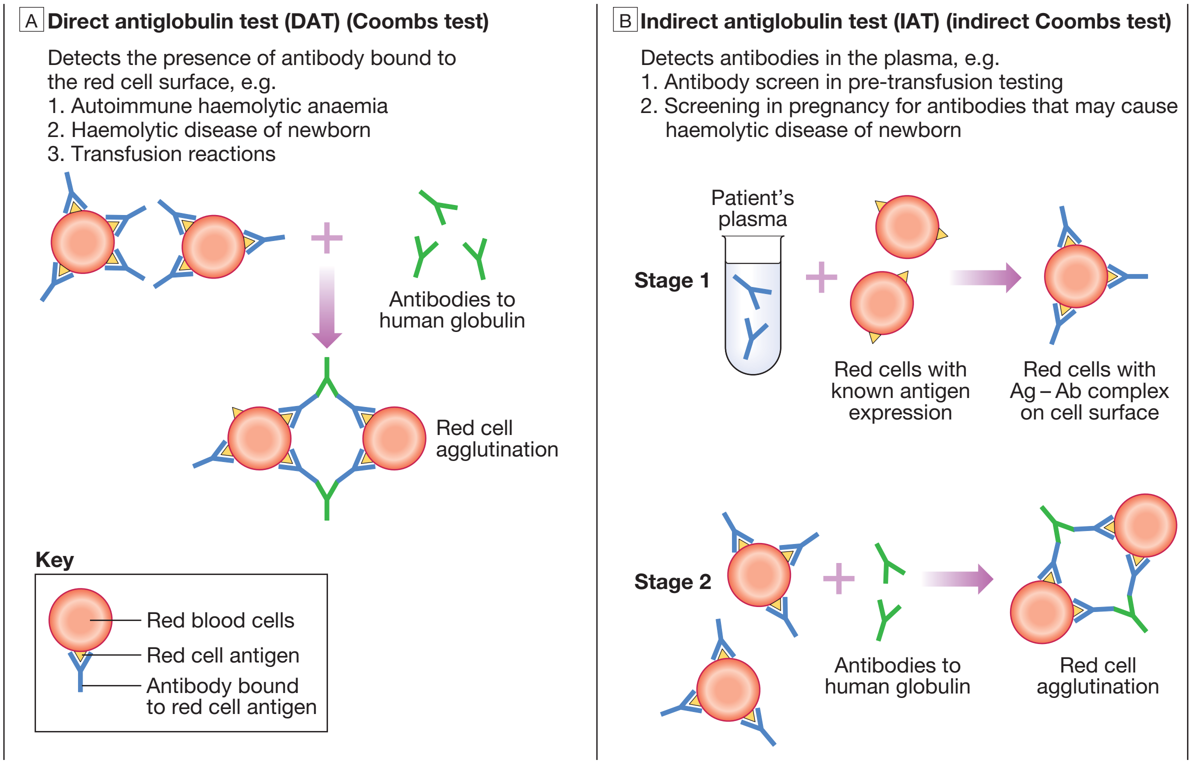

Fig. 23.20 Direct and indirect antiglobulin tests.

i 23.37 Management of the splenectomised patient

- Vaccinate with pneumococcal, *Haemophilus influenzae* type B, meningococcal group C and influenza vaccines at least 2–3 weeks before elective splenectomy. Vaccination should be given after emergency surgery but may be less effective
- Pneumococcal re-immunisation should be given at least 5-yearly and influenza annually. Vaccination status must be documented
- Life-long prophylactic penicillin V (500 mg twice daily) is recommended. In penicillin-allergic patients, consider a macrolide
- Patients should be educated regarding the risks of infection and methods of prophylaxis
- A card or bracelet should be carried to alert health professionals to the risk of overwhelming sepsis
- In sepsis, patients should be resuscitated and given IV antibiotics to cover pneumococcus, *Haemophilus* and meningococcus, according to local resistance patterns
- The risk of cerebral malaria is increased in the event of infection
- Animal bites should be promptly treated with local disinfection and antibiotics, to prevent serious soft tissue infection and sepsis

abnormality of one or more anchor proteins in the red cell membrane, e.g. alpha spectrin or protein 4.1 (see Fig. 23.4). Inheritance may be autosomal dominant or recessive. Hereditary elliptocytosis is less common than hereditary spherocytosis in Western countries, with an incidence of 1/10 000, but is more common in equatorial Africa and parts of South-east Asia. The clinical course is variable and depends on the degree of membrane dysfunction caused by the inherited molecular defect(s); most cases present as an asymptomatic blood film abnormality but occasional cases result in neonatal haemolysis or a chronic compensated haemolytic state. Management of the latter is the same as for hereditary spherocytosis.

A characteristic variant of hereditary elliptocytosis occurs in South-east Asia, particularly Malaysia and Papua New Guinea, with stomatocytes and ovalocytes in the blood. This has a prevalence of up to 30% in some communities because it offers relative protection from malaria and thus has sustained a high gene frequency. The blood film is often very abnormal and immediate differential diagnosis is broad.

Red cell enzymopathies

The mature red cell must produce energy via ATP to maintain a normal internal environment and cell volume while protecting itself from the oxidative stress presented by oxygen carriage. ATP is generated by glycolysis, while the hexose monophosphate shunt produces nicotinamide adenine dinucleotide phosphate (NADPH) and glutathione to protect against oxidative stress. The impact of functional or quantitative defects in the enzymes in these pathways depends on the importance of the steps affected and the presence of alternative pathways. In general, defects in the hexose monophosphate shunt pathway result in periodic haemolysis precipitated by episodic oxidative stress, while those in the glycolysis pathway result in shortened red cell survival and chronic haemolysis.

Glucose-6-phosphate dehydrogenase deficiency

The enzyme glucose-6-phosphate dehydrogenase (G6PD) is pivotal in the hexose monophosphate shunt pathway. Deficiencies result in the most common human enzymopathy, affecting 10% of the world's population, with a geographical distribution that parallels the malaria belt because heterozygotes are protected from malarial parasitisation. The enzyme is a heteromeric structure made of catalytic subunits that are encoded by a gene on the X chromosome. The deficiency therefore affects males and rare

i 23.38 Glucose-6-phosphate dehydrogenase deficiency

Clinical features

- Acute drug-induced haemolysis to (e.g.):
  Analgesics: aspirin, phenacetin
  Antimalarials: primaquine, quinine, chloroquine, pyrimethamine
  Antibiotics: sulphonamides, nitrofurantoin, ciprofloxacin
  Miscellaneous: quinidine, probenecid, vitamin K, dapsone
- Chronic compensated haemolysis
- Infection or acute illness
- Neonatal jaundice: may be a feature of the B⁻ enzyme
- Favism, i.e. acute haemolysis after ingestion of broad beans (*Vicia fava*)

Laboratory features

Non-spherocytic intravascular haemolysis during an attack

The blood film will show:

- Bite cells (red cells with a 'bite' of membrane missing)
- Blister cells (red cells with surface blistering of the membrane)
- Irregularly shaped small cells
- Polychromasia reflecting the reticulocytosis
- Denatured haemoglobin visible as Heinz bodies within the red cell cytoplasm with a supravital stain such as methyl violet

G6PD level

- Can be indirectly assessed by screening methods that usually depend on the decreased ability to reduce dyes
- Direct assessment of G6PD is made in those with low screening values
- Care must be taken close to an acute haemolytic episode because reticulocytes may have higher enzyme levels and give rise to a false normal result

homozygous females (p. 48), but it is carried by females. Carrier heterozygous females are usually only affected in the neonatal period or in the presence of skewed X-inactivation (p. 49).

Over 400 subtypes of G6PD are described. The most common types associated with normal activity are the B+ enzyme present in most Caucasians and 70% of Afro-Caribbeans, and the A+ variant present in 20% of Afro-Caribbeans. The two common variants associated with reduced activity are the A⁻ variety in approximately 10% of Afro-Caribbeans, and the Mediterranean or B⁻ variety in Caucasians. In East and West Africa, up to 20% of males and 4% of females (homozygotes) are affected and have enzyme levels of about 15% of normal. The deficiency in Caucasian and East Asian populations is more severe, with enzyme levels as low as 1%.

Clinical features and investigation findings are shown in Box 23.38.

Management aims to stop the intake of any precipitant drugs or foods and treat any underlying infection. Favism due to the consumption of fava beans is the classically described precipitant of haemolysis in patients with G6PD deficiency. Acute transfusion support may be life-saving.

Pyruvate kinase deficiency

This is the second most common red cell enzyme defect. It results in deficiency of ATP production and a chronic haemolytic anaemia. It is inherited as an autosomal recessive trait. The extent of anaemia is variable; the blood film shows characteristic 'prickle cells' that resemble holly leaves. Enzyme activity is only 5–20% of normal. Transfusion support may be necessary during periods of haemolysis.

Pyrimidine 5′ nucleotidase deficiency

The pyrimidine 5′ nucleotidase enzyme catalyses the dephosphorylation of nucleoside monophosphates and is important during the degradation of RNA in reticulocytes. It is inherited as an autosomal recessive trait and is as common as pyruvate kinase deficiency in Mediterranean, African and Jewish populations. The accumulation of excess ribonucleoprotein results in coarse basophilic stippling (see Box 23.2), associated with a chronic haemolytic state. The enzyme is very sensitive to inhibition by lead and this is the reason why basophilic stippling is a feature of lead poisoning.

Autoimmune haemolytic anaemia

This results from increased red cell destruction due to red cell autoantibodies. The antibodies may be IgG or IgM, or more rarely IgE or IgA. If an antibody avidly fixes complement, it will cause intravascular haemolysis, but if complement activation is weak, the haemolysis will be extravascular (in the reticulo-endothelial system). Antibody-coated red cells lose membrane to macrophages in the spleen and hence spherocytes are present in the blood. The optimum temperature at which the antibody is active (thermal specificity) is used to classify immune haemolysis:

- *Warm antibodies* bind best at 37°C and account for 80% of cases. The majority are IgG and often react against Rhesus antigens.
- *Cold antibodies* bind best at 4°C but can bind up to 37°C in some cases. They are usually IgM and bind complement. To be clinically relevant, they must act within the range of normal body temperatures. They account for the other 20% of cases.

Warm autoimmune haemolysis

The incidence of warm autoimmune haemolysis is approximately 1/100 000 population per annum; it occurs at all ages but is more common in middle age and in females. No underlying cause is identified in up to 50% of cases. The remainder are secondary to a wide variety of other conditions (see Fig. 23.19B).

Investigations

There is evidence of haemolysis, spherocytes and polychromasia on the blood film. The diagnosis is confirmed by the direct Coombs or antiglobulin test (see Fig. 23.20). The patient's red cells are mixed with Coombs reagent, which contains antibodies against human IgG/IgM/complement. If the red cells have been coated by antibody in vivo, the Coombs reagent will induce their agglutination and this can be detected visually. The relevant antibody can be eluted from the red cell surface and tested against a panel of typed red cells to determine against which red cell antigen it is directed. The most common specificity is for Rhesus antigens and most often anti-e; this is helpful when choosing blood to cross-match. The direct Coombs test can be negative in the presence of brisk haemolysis. A positive test requires about 200 antibody molecules to attach to each red cell; with a very avid complement-fixing antibody, haemolysis may occur at lower levels of antibody-binding. The standard Coombs reagent will miss IgA or IgE antibodies. Around 10% of all warm autoimmune haemolytic anaemias are Coombs test-negative.

Management

If the haemolysis is secondary to an underlying cause, this must be treated and any implicated drugs stopped.

It is usual to treat patients initially with prednisolone (1 mg/kg orally). A response is seen in 70–80% of cases but may take up to 3 weeks; a rise in haemoglobin will be matched by a fall in bilirubin, LDH and reticulocyte levels. Once the haemoglobin has normalised and the reticulocytosis resolved, the glucocorticoid dose can be reduced slowly over several weeks. Glucocorticoids probably work by decreasing macrophage destruction of antibody-coated red cells and reducing antibody production.

Transfusion support may be required for life-threatening problems, such as the development of heart failure or rapid unabated falls in haemoglobin. The least incompatible blood should be used but this may still give rise to transfusion reactions or the development of alloantibodies.

If the haemolysis fails to respond to glucocorticoids or can only be stabilised by large doses, then second-line therapies should be considered. These include immunomodulation/suppression and splenectomy. Currently, there are fewer splenectomies than previously and the second-line drug of choice in current UK guidance is the anti-CD20 monoclonal antibody rituximab. Splenectomy is associated with a good response in 50–60% of cases. The operation can be performed laparoscopically with reduced morbidity. If splenectomy is not appropriate, alternative immunosuppressive therapy with azathioprine, ciclosporin, mycophenolate or cyclophosphamide may be considered. There are concerns about all modes of second-line therapy, as long-term immunosuppression carries a risk of malignancy, while splenectomy is associated with an excess of severe infection due to the capsulate organisms pneumococcus and meningococcus (see Box 23.40).

Cold agglutinin disease

This is mediated by antibodies, usually IgM, which bind to the red cells at low temperatures and cause them to agglutinate. It may cause intravascular haemolysis if complement fixation occurs. This can be chronic when the antibody is monoclonal, or acute or transient when the antibody is polyclonal.

Chronic cold agglutinin disease

This typically affects elderly patients and may be associated with an underlying low-grade B-cell lymphoma. It causes a low-grade intravascular haemolysis with cold, painful and often blue fingers, toes, ears or nose (so-called acrocyanosis). The latter is due to red cell agglutination in the small vessels in these colder, exposed areas. The blood film shows red cell agglutination and the MCV may be spuriously high because the automated analysers detect red cell aggregates as single cells. Monoclonal IgM usually has anti-I or, less often, anti-i specificity. Treatment is primarily by transfusion support but may also be directed at any underlying lymphoma. Patients must keep extremities warm, especially in winter. Some patients respond to glucocorticoid therapy and rituximab. Two considerations for patients requiring blood transfusion is that the cross-match sample must be placed in a transport flask at a temperature of 37°C and blood administered via a blood-warmer. All patients should receive folic acid supplementation.

Other causes of cold agglutination

Cold agglutination can occur in association with *Mycoplasma pneumoniae* or with infectious mononucleosis. Paroxysmal cold haemoglobinuria is a very rare cause seen in children, in association with viral or bacterial infection. An IgG antibody binds to red cells in the peripheral circulation but lysis occurs in the central circulation when complement fixation takes place. This antibody is termed the Donath–Landsteiner antibody and has specificity against the P antigen on the red cells.

Alloimmune haemolytic anaemia

Alloimmune haemolytic anaemia is caused by antibodies against non-self red cells. It has two main causes, occurring after:

- unmatched blood transfusion (p. 935)
- maternal sensitisation to paternal antigens on fetal cells (haemolytic disease of the newborn, p. 933).

Non-immune haemolytic anaemia

Endothelial damage

Disruption of red cell membrane may occur in a number of conditions and is characterised by the presence of red cell fragments on the blood film and markers of intravascular haemolysis:

- *Mechanical heart valves.* High flow through incompetent valves or periprosthetic leaks through the suture ring holding a valve in place result in shear stress damage.
- *March haemoglobinuria.* Vigorous exercise, such as prolonged marching or marathon running, can cause red cell damage in the capillaries in the feet.
- *Thermal injury.* Severe burns cause thermal damage to red cells, characterised by fragmentation and the presence of microspherocytes in the blood.
- *Microangiopathic haemolytic anaemia.* Fibrin deposition in capillaries can cause severe red cell disruption. It may occur in a wide variety of conditions: disseminated carcinomatosis, malignant or pregnancy-induced hypertension, haemolytic uraemic syndrome (p. 408), thrombotic thrombocytopenic purpura (p. 979) and disseminated intravascular coagulation (p. 978).

Infection

Plasmodium falciparum malaria (p. 274) may be associated with intravascular haemolysis; when severe, this is termed blackwater fever because of the associated haemoglobinuria. *Clostridium perfringens* sepsis (p. 227), usually in the context of ascending cholangitis or necrotising fasciitis, may cause severe intravascular haemolysis with marked spherocytosis due to bacterial production of a lecithinase that destroys the red cell membrane.

Chemicals or drugs

Dapsone and sulfasalazine cause haemolysis by oxidative denaturation of haemoglobin. Denatured haemoglobin forms Heinz bodies in the red cells, visible on supravital staining with brilliant cresyl blue. Arsenic gas, copper, chlorates, nitrites and nitrobenzene derivatives may all cause haemolysis.

Paroxysmal nocturnal haemoglobinuria

Paroxysmal nocturnal haemoglobinuria (PNH) is a rare acquired, non-malignant clonal expansion of haematopoietic stem cells deficient in glycosylphosphatidylinositol (GPI) anchor protein. GPI anchors several key molecules to cells and its absence results in clinical outcomes that reflect this, causing intravascular haemolysis and anaemia because of increased sensitivity of red cells to lysis by complement. This happens because key defence mechanisms that protect cells from complement-mediated lysis (CD55 and CD59) are GPI-anchored to red cells under normal circumstances. Episodes of intravascular haemolysis result in haemoglobinuria, most noticeable in early morning urine, which

has a characteristic red–brown colour. The disease is associated with an increased risk of venous and arterial thrombosis in unusual sites, such as the liver or abdomen. PNH clones are also associated with hypoplastic bone marrow failure, aplastic anaemia and myelodysplastic syndrome (pp. 960 and 969). Management is supportive with transfusion and folate supplements and prophylaxis or treatment of thrombosis. Standard care now includes the anti-complement C5 monoclonal antibody eculizimab. This has been shown to be effective in reducing haemolysis, transfusion requirements and thrombotic risk. Eculizumab carries a risk of infection, particularly for *Neisseria meningitidis*, and all treated patients must be vaccinated against this organism.

Haemoglobinopathies

These diseases are caused by mutations affecting the genes encoding the globin chains of the haemoglobin molecule. Normal haemoglobin is composed of two alpha and two non-alpha globin chains. Alpha globin chains are produced throughout life, including in the fetus, so severe mutations may cause intrauterine death. Production of non-alpha chains varies with age; fetal haemoglobin (HbF-$\alpha\alpha/\gamma\gamma$) has two gamma chains, while the predominant adult haemoglobin (HbA-$\alpha\alpha/\beta\beta$) has two beta chains. Thus, disorders affecting the beta chains do not present until after 6 months of age. A constant small amount of haemoglobin A_2 (HbA_2-$\alpha\alpha/\delta\delta$, usually less than 2%) is made from birth.

The geographical distribution of the common haemoglobinopathies is shown in Figure 23.21. The haemoglobinopathies can be classified into qualitative or quantitative abnormalities.

Qualitative abnormalities – abnormal haemoglobins

In qualitative abnormalities (called the abnormal haemoglobins), there is a functionally important alteration in the amino acid structure of the polypeptide chains of the globin chains. Several hundred such variants are known; they were originally designated by letters of the alphabet, e.g. S, C, D or E, but the more recently described ones are known by names that usually taken from the town or district in which they were first described. The best-known example is haemoglobin S, found in sickle-cell anaemia. Mutations around the haem-binding pocket cause the haem ring to fall out of the structure and produce an unstable haemoglobin. These substitutions often change the charge of the globin chains, producing different electrophoretic mobility, and this forms the basis for the diagnostic use of haemoglobin electrophoresis to identify haemoglobinopathies.

Quantitative abnormalities – thalassaemias

In quantitative abnormalities (the thalassaemias), there are mutations causing a reduced rate of production of one or other of the globin chains, altering the ratio of alpha to non-alpha chains. In alpha-thalassaemia excess beta chains are present, while in beta-thalassaemia excess alpha chains are present. The excess chains precipitate, causing red cell membrane damage and reduced red cell survival due to haemolysis.

Sickle-cell anaemia

Sickle-cell disease results from a single glutamic acid to valine substitution at position 6 of the beta globin polypeptide chain. It is inherited as an autosomal recessive trait (p. 48). Homozygotes only produce abnormal beta chains that make haemoglobin S (HbS, termed SS), and this results in the clinical syndrome of sickle-cell disease. Heterozygotes produce a mixture of normal and abnormal beta chains that make normal HbA and HbS (termed AS), and this results in sickle-cell trait; although this was previously thought of as asymptomatic, it may be associated with an increased risk of sudden and cardiovascular death.

Epidemiology

The heterozygote frequency is over 20% in tropical Africa (see Fig. 23.21). In black American populations, sickle-cell trait has a frequency of 8%. Individuals with sickle-cell trait are relatively resistant to the lethal effects of *falciparum* malaria in early childhood; the high prevalence in equatorial Africa can be explained by the survival advantage it confers in areas where *falciparum* malaria is endemic. However, homozygous patients with sickle-cell anaemia do not have correspondingly greater resistance to *falciparum* malaria.

Pathogenesis

When haemoglobin S is deoxygenated, the molecules of haemoglobin polymerise to form pseudocrystalline structures known as 'tactoids'. These distort the red cell membrane and

23

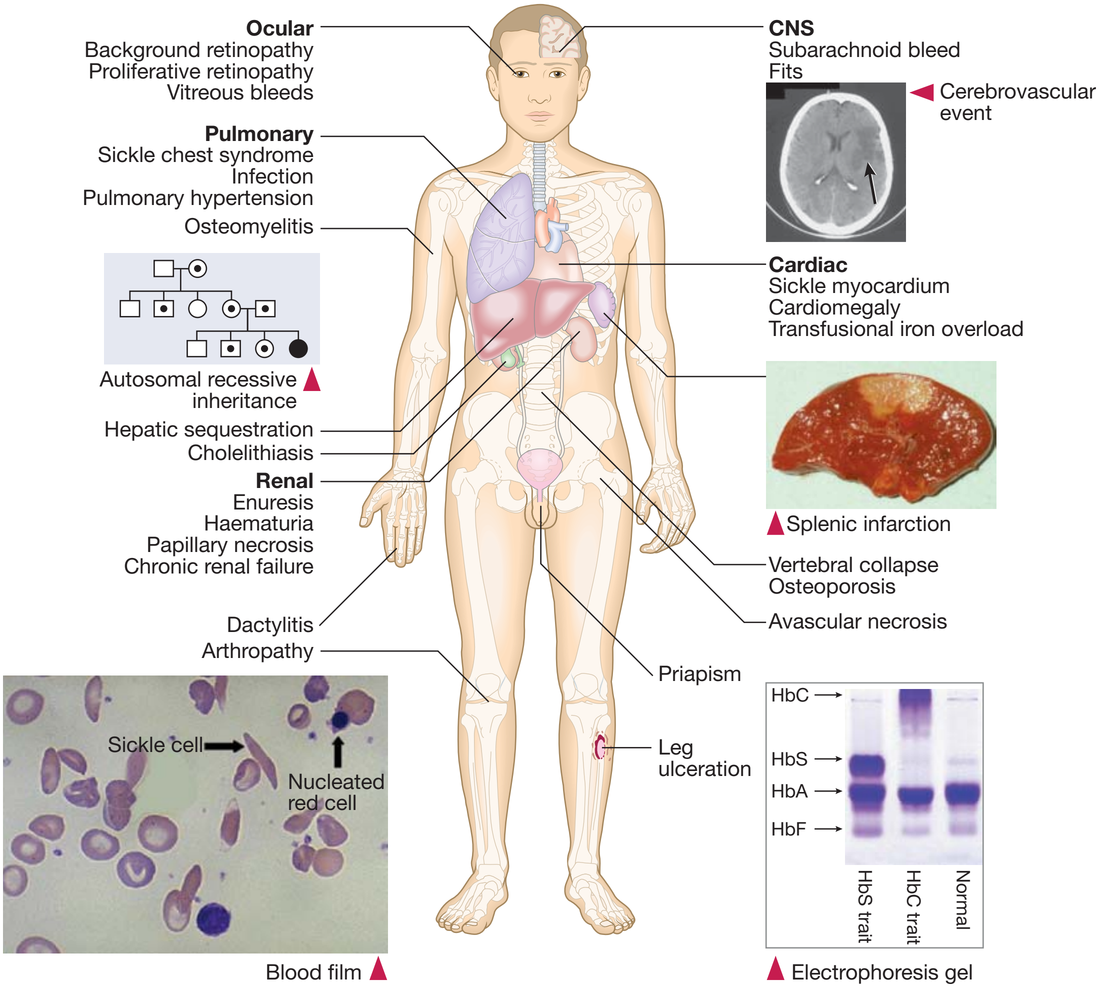

Fig. 23.22 Clinical and laboratory features of sickle-cell disease.

produce characteristic sickle-shaped cells (Fig. 23.22). The polymerisation is reversible when re-oxygenation occurs. The distortion of the red cell membrane, however, may become permanent and the red cell 'irreversibly sickled'. The greater the concentration of sickle-cell haemoglobin in the individual cell, the more easily tactoids are formed, but this process may be enhanced or retarded by the presence of other haemoglobins. Thus the abnormal haemoglobin C variant participates in polymerisation more readily than haemoglobin A, whereas haemoglobin F strongly inhibits polymerisation.

Clinical features

Sickling is precipitated by hypoxia, acidosis, dehydration and infection. Irreversibly sickled cells have a shortened survival and plug vessels in the microcirculation. This results in a number of acute syndromes, termed 'crises', and chronic organ damage (Fig. 23.22):

- *Painful vaso-occlusive crisis*. Plugging of small vessels in the bone produces acute severe bone pain. This affects areas of active marrow: the hands and feet in children (so-called dactylitis) or the femora, humeri, ribs, pelvis and vertebrae in adults. Patients usually have a systemic response with tachycardia, sweating and a fever. This is the most common form of crisis.
- *Stroke.* The single most devastating consequence of sickle-cell disease is stroke. Stroke or silent stroke occurs in 10–15% of children with sickle-cell disease. Children at risk of stroke can be identified by screening with transcranial Doppler ultrasound, with fast flow associated with increased stroke risk. These children may be offered strategies such as transfusion or treatment with hydroxycarbamide to reduce the risk of stroke.
- *Sickle chest syndrome*. This may follow a vaso-occlusive crisis and is the most common cause of death in adult sickle-cell disease. Bone marrow infarction results in fat emboli to the lungs, which cause further sickling and infarction, leading to ventilatory failure if not treated.
- *Sequestration crisis*. Thrombosis of the venous outflow from an organ causes loss of function and acute painful enlargement. In children, the spleen is the most common site. Massive splenic enlargement may result in severe anaemia, circulatory collapse and death. Recurrent sickling in the spleen in childhood results in infarction and adults may have no functional spleen. In adults, the liver may undergo sequestration with severe pain due to capsular stretching. Priapism is a complication seen in affected men.
- *Aplastic crisis*. Infection of adult sicklers with human parvovirus B19 (erythrovirus) may result in a severe but

23.39 Sickle-cell disease in pregnancy

- **Pre-conceptual counselling**: advice on the effect of sickle-cell disease on pregnancy, and vice versa, should be offered.
- **Vaccination status**: should be updated before conception.
- **Testing of partner**: testing for haemoglobinopathy status is advised.
- **Folic acid**: should be taken in high dose (5 mg daily) prior to and throughout pregnancy.
- **Hydroxycarbamide**: should be discontinued 3 months prior to conception.
- **Angiotensin-converting enzyme (ACE) inhibitors**: should be discontinued prior to conception.
- **Pulmonary hypertension**: should be excluded prior to conception.
- **Placental failure**: women with sickle-cell disease have increased rates, resulting in pre-eclampsia and intrauterine growth retardation.
- **Aspirin 75 mg**: should be given throughout pregnancy.
- **Thromboprophylaxis after delivery**: all women with sickle-cell disease should receive thromboprophylaxis with low-molecular-weight heparin for at least 10 days post vaginal delivery and for 6 weeks post caesarean section. Antenatal thromboprophylaxis should be considered for women with additional risk factors for venous thromboembolism (see Box 23.65).
- **Transfusion**: extended cross-matched blood for Rhesus and Kell status should be provided. Blood should be cytomegalovirus-negative.

self-limiting red cell aplasia. This results in profound anaemia, which may cause heart failure. Unlike in all other sickle crises, the reticulocyte count is low.

- *Pregnancy*. Pregnancy in sickle-cell disease requires planning and multidisciplinary management. Women with sickle-cell disease have increased pregnancy-related morbidity, which includes painful crisis, placental failure and thrombosis (Box 23.39).

Investigations

Patients with sickle-cell disease have a compensated anaemia, usually around 60–80 g/L. The blood film shows sickle cells, target cells and features of hyposplenism from a young age. A reticulocytosis is present. The presence of HbS can be demonstrated by exposing red cells to a reducing agent such as sodium dithionite; HbA gives a clear solution, whereas HbS polymerises to produce a turbid solution. This forms the basis of emergency screening tests before surgery in appropriate ethnic groups but cannot distinguish between sickle-cell trait and disease. The definitive diagnosis requires haemoglobin electrophoresis to demonstrate the absence of HbA, 2–20% HbF and the predominance of HbS. Both parents of the affected individual will have sickle-cell trait.

Management

All patients with sickle-cell disease should receive prophylaxis with daily folic acid, and appropriate management of the hyposplenic state that is uniformly found in these patients from an early age (see Box 23.37). Seasonal vaccination against influenza is also advised in these patients.

Vaso-occlusive crises are managed by aggressive rehydration, oxygen therapy, adequate analgesia (which often requires opiates) and antibiotics. Transfusion should be with fully genotyped blood wherever possible. Simple top-up transfusion may be used in a sequestration or aplastic crisis. A regular transfusion programme to suppress HbS production and maintain the HbS level below 30% may be indicated in patients with recurrent severe complications, such as cerebrovascular accidents in children or chest syndromes in adults. Exchange transfusion, in which a patient is simultaneously venesected and transfused to replace HbS with HbA, may be used in life-threatening crises or to prepare patients for surgery.

A high HbF level inhibits polymerisation of HbS and reduces sickling. Patients with sickle-cell disease and high HbF levels have a mild clinical course with few crises. Some agents are able to increase synthesis of HbF and this has been used to reduce the frequency of severe crises. The oral cytotoxic agent hydroxycarbamide has been shown to have clinical benefit with acceptable side-effects in children and adults who have recurrent severe crises.

Relatively few allogeneic stem cell transplants from HLA-matched siblings have been performed but this procedure appears to be potentially curative (p. 937).

Prognosis

In Africa, few children with sickle-cell anaemia survive to adult life without medical attention. Even with standard medical care, approximately 15% die by the age of 20 years and 50% by the age of 40 years.

Other abnormal haemoglobins

Another beta-chain haemoglobinopathy, haemoglobin C (HbC) disease, is clinically silent but associated with microcytosis and target cells on the blood film. Compound heterozygotes inheriting one *HbS* gene and one *HbC* gene from their parents have haemoglobin SC disease, which behaves like a mild form of sickle-cell disease. SC disease is associated with a reduced frequency of crises but is not uncommonly associated with complications in pregnancy and retinopathy.

Thalassaemias

Thalassaemia is an inherited impairment of haemoglobin production, in which there is partial or complete failure to synthesise a specific type of globin chain. In alpha-thalassaemia, disruption of one or both alleles on chromosome 16 may occur, with production of some or no alpha globin chains. In beta-thalassaemia, defective production usually results from disabling point mutations causing no (β^0) or reduced (β^-) beta chain production.

23

Beta-thalassaemia

Failure to synthesise beta chains (beta-thalassaemia) is the most common type of thalassaemia, most prevalent in the Mediterranean area. Heterozygotes have thalassaemia minor, a condition in which there is usually mild microcytic anaemia and little or no clinical disability, which may be detected only when iron therapy for a mild microcytic anaemia fails. Homozygotes (thalassaemia major) either are unable to synthesise haemoglobin A or, at best, produce very little; after the first 4–6 months of life, they develop profound transfusion-dependent hypochromic anaemia. The diagnostic features are summarised in Box 23.40. Intermediate grades of severity occur.

Management and prevention

See Box 23.41. Cure is now a possibility for selected children, with allogeneic HSCT (p. 937).

It is possible to identify a fetus with homozygous beta-thalassaemia by obtaining chorionic villous material for DNA

23.40 Diagnostic features of beta-thalassaemia

Beta-thalassaemia major (homozygotes)

- Profound hypochromic anaemia
- Evidence of severe red cell dysplasia
- Erythroblastosis
- Absence or gross reduction of the amount of haemoglobin A
- Raised levels of haemoglobin F
- Evidence that both parents have thalassaemia minor

Beta-thalassaemia minor (heterozygotes)

- Mild anaemia
- Microcytic hypochromic erythrocytes (not iron-deficient)
- Some target cells
- Punctate basophilia
- Raised haemoglobin A_2 fraction

23.41 Treatment of beta-thalassaemia major

Problem	Management
Erythropoietic failure	Allogeneic HSCT from HLA-compatible sibling Transfusion to maintain Hb >100 g/L Folic acid 5 mg daily
Iron overload	Iron therapy contraindicated Iron chelation therapy
Splenomegaly causing mechanical problems, excessive transfusion needs	Splenectomy; see Box 23.37

(Hb = haemoglobin; HLA = human leucocyte antigen; HSCT = haematopoietic stem cell transplantation)

23.42 Anaemia in old age

- **Mean haemoglobin**: falls with age in both sexes but remains well within the reference range. When a low haemoglobin does occur, it is generally due to disease.
- **Anaemia can never be considered 'normal' in old age**.
- **Symptoms**: may be subtle and insidious. Cardiovascular features such as dyspnoea and oedema, and cerebral features such as dizziness and apathy, tend to predominate.
- **Ferritin**: if lower than 45 µg/L in older people, is highly predictive of iron deficiency. Conversely, ferritin may be raised by chronic disease and so a normal ferritin does not exclude iron deficiency.
- **Serum iron and transferrin**: fall with age because of the prevalence of other disorders, and are not reliable indicators of deficiency.
- **Most common cause of iron deficiency**: gastrointestinal blood loss.
- **Most common cause of vitamin B_{12} deficiency**: pernicious anaemia, as the prevalence of chronic atrophic gastritis rises in old age.
- **Neuropsychiatric symptoms associated with vitamin B_{12} deficiency**: well-established association but a causal relationship has not been clearly shown. Dementia associated with vitamin B_{12} deficiency in the absence of haematological abnormalities is rare.
- **Anaemia of chronic disease**: frequent in old age because of the rising prevalence of diseases that inhibit iron transport.

analysis sufficiently early in pregnancy to allow termination. This examination is appropriate only if both parents are known to be carriers (beta-thalassaemia minor) and will accept a termination.

Alpha-thalassaemia

Reduced or absent alpha-chain synthesis is common in South-east Asia. There are two alpha gene loci on chromosome 16 and therefore each individual carries four alpha gene alleles.

- If one is deleted, there is no clinical effect.
- If two are deleted, there may be a mild hypochromic anaemia.
- If three are deleted, the patient has haemoglobin H disease.
- If all four are deleted, the baby is stillborn (hydrops fetalis).

Haemoglobin H is a beta-chain tetramer, formed from the excess of beta chains, which is functionally useless, so that patients rely on their low levels of HbA for oxygen transport. Treatment of haemoglobin H disease is similar to that of beta-thalassaemia of intermediate severity, involving folic acid supplementation, transfusion if required and avoidance of iron therapy.

Haematological malignancies

Haematological malignancies arise when the processes controlling proliferation or apoptosis are corrupted in blood cells because of acquired mutations in key regulatory genes. If mature differentiated cells are involved, the cells will have a low growth fraction and produce indolent neoplasms, such as the low-grade lymphomas or chronic leukaemias, when patients have an expected survival of many years. In contrast, if more primitive stem or progenitor cells are involved, the cells can have the highest growth fractions of all human neoplasms, producing rapidly progressive, life-threatening illnesses such as the acute leukaemias or high-grade lymphomas. Involvement of pluripotent stem cells produces the most aggressive acute leukaemias. In general, haematological neoplasms are diseases of elderly patients, the exceptions being acute lymphoblastic leukaemia, which predominantly affects children, and Hodgkin lymphoma, which affects people aged 20–40 years. Management of young patients with haematological malignancy is particularly challenging (Box 23.43).

Leukaemias

Leukaemias are malignant disorders of the haematopoietic stem cell compartment, characteristically associated with increased numbers of white cells in the bone marrow and/or peripheral blood. The course of leukaemia may vary from a few days or weeks to many years, depending on the type.

Epidemiology and aetiology

The incidence of leukaemia of all types in the population is approximately 10/100 000 per annum, of which just under half are cases of acute leukaemia. Males are affected more frequently than females, the ratio being about 3 : 2 in acute leukaemia, 2 : 1 in chronic lymphocytic leukaemia and 1.3 : 1 in chronic myeloid leukaemia. Geographical variation in incidence does occur, the most striking being the rarity of chronic lymphocytic leukaemia in Chinese and related races. Acute leukaemia occurs at all ages. Acute lymphoblastic leukaemia shows a peak of incidence in children aged 1–5 years. All forms of acute myeloid leukaemia

23.43 Consequences of haematological malignancy in adolescence

- **Tailored management protocols**: the most effective treatment schedules for leukaemia and lymphoma differ between children and adults. Adolescent patients may be most appropriately managed in specialist centres.
- **Psychosocial effects**: adolescents undergoing treatment for haematological malignancy may suffer significant consequences for their schooling and social development, and require support from a multidisciplinary team.
- **'Late effects'**: adolescents who have been treated with chemotherapy and/or radiotherapy in childhood may be at risk of a wide range of complications, depending on the region irradiated, radiation dose and the drugs used. Particularly relevant complications in this age group include short stature, growth hormone deficiency, delayed puberty, and cognitive dysfunction affecting schooling (after cranial irradiation). Life-long follow-up is often undertaken to detect and manage these late effects and to deal with consequences such as infertility and second malignancy.

23.44 Risk factors for leukaemia

Ionising radiation

- After atomic bombing of Japanese cities (myeloid leukaemia)
- Radiotherapy
- Diagnostic X-rays of the fetus in pregnancy

Cytotoxic drugs

- Especially alkylating agents (myeloid leukaemia, usually after a latent period of several years)
- Industrial exposure to benzene

Retroviruses

- Adult T-cell leukaemia/lymphoma (ATLL) caused by human T-cell lymphotropic virus 1(HTLV-1), most prevalent in Japan, the Caribbean and some areas of Central and South America and Africa

Genetic

- Identical twin of patients with leukaemia
- Down's syndrome and certain other genetic disorders

Immunological

- Immune deficiency states (e.g. hypogammaglobulinaemia)

have their lowest incidence in young adult life and there is a striking rise over the age of 50. Chronic leukaemias occur mainly in middle and old age.

The cause of the leukaemia is unknown in the majority of patients. Several risk factors have been identified (Box 23.44).

Terminology and classification

Leukaemias are traditionally classified into four main groups:

- acute lymphoblastic leukaemia (ALL)
- acute myeloid leukaemia (AML)
- chronic lymphocytic leukaemia (CLL)
- chronic myeloid leukaemia (CML).

In acute leukaemia, there is proliferation of primitive stem cells, with limited accompanying differentiation, leading to an accumulation of blasts, predominantly in the bone marrow, which causes bone marrow failure. In chronic leukaemia, the malignant clone is able to differentiate, resulting in an accumulation of more mature cells. Lymphocytic and lymphoblastic cells are those derived from the lymphoid stem cell (B cells and T cells).

23.45 WHO classification of acute leukaemia*

Acute myeloid leukaemia (AML) with recurrent genetic abnormalities

- AML with t(8;21)(q22;q22.1), gene product RUNX1-RUNX1T1
- AML with inv(16)(p13.1;q22), gene product CBFB-MYHL1
- Acute promyelocytic leukaemia t(15;17), gene product PML-RARA
- AML with t(9;11)(p21.3;q23.3), gene product MLLT3-KMT2A
- AML with t(6;9)(p23;q34), gene product DEK-NUP214
- AML with inv(3)(q21.3;q26.2) or t(3;3)(q21.3;q26.2), gene products GATA2, MECOM
- AML (megakaryoblastic) with t(1;22)(p13.3;q13.3), gene product RBM15-MKL1
- AML with mutated NPM1
- AML with biallelic mutations of CEBPA

Acute myeloid leukaemia with myelodysplasia-related changes

- e.g. Following a myelodysplastic syndrome

Therapy-related myeloid neoplasms

- e.g. Alkylating agent or topoisomerase II inhibitor

Myeloid sarcoma

Myeloid proliferations related to Down's syndrome

Acute myeloid leukaemia not otherwise specified

- e.g. AML with or without differentiation, acute myelomonocytic leukaemia, erythroleukaemia, megakaryoblastic leukaemia

Acute lymphoblastic leukaemia (ALL)

- B-lymphoblastic leukaemia/lymphoma
- T-lymphoblastic leukaemia/lymphoma

*Updated 2016; major subtypes.

Myeloid refers to the other lineages: that is, precursors of red cells, granulocytes, monocytes and platelets (see Fig. 23.2).

The diagnosis of leukaemia is usually suspected from an abnormal blood count, often a raised white count, and is confirmed by examination of the bone marrow. This includes the morphology of the abnormal cells, analysis of cell surface markers (immunophenotyping), clone-specific chromosome abnormalities and molecular changes. These results are incorporated in the World Health Organisation (WHO) classification of tumours of haematopoietic and lymphoid tissues; the subclassification of acute leukaemias is shown in Box 23.45. The features in the bone marrow not only provide an accurate diagnosis but also give valuable prognostic information, increasingly allowing therapy to be tailored to the patient's disease.

Acute leukaemia

There is a failure of cell maturation in acute leukaemia. Proliferation of cells that do not mature leads to an accumulation of primitive cells that take up more and more marrow space at the expense of the normal haematopoietic elements. Eventually, this proliferation spills into the blood. Acute myeloid leukaemia (AML) is about four times more common than acute lymphoblastic leukaemia (ALL) in adults. In children, the proportions are reversed, the lymphoblastic variety being more common. The clinical features are usually those of bone marrow failure (anaemia, bleeding or infection; pp. 923, 927 and 930).

Investigations

Blood examination usually shows anaemia with a normal or raised MCV. The leucocyte count may vary from as low as 1×10^9/L to as high as 500×10^9/L or more. In the majority of patients,

the count is below 100×10^9/L. Severe thrombocytopenia is usual but not invariable. Frequently, blast cells are seen in the blood film but sometimes the blast cells may be infrequent or absent. A bone marrow examination will confirm the diagnosis. The bone marrow is usually hypercellular, with replacement of normal elements by leukaemic blast cells in varying degrees (but more than 20% of the cells) (Fig. 23.23). The presence of Auer rods in the cytoplasm of blast cells indicates a myeloblastic type of leukaemia. Classification and prognosis are determined by immunophenotyping and chromosome and molecular analysis, as shown in Figure 23.24.

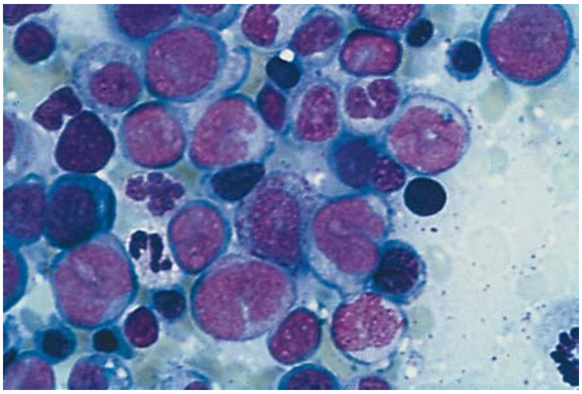

Fig. 23.23 Acute myeloid leukaemia. Bone marrow aspirate showing infiltration with large blast cells, which display nuclear folding and prominent nucleoli.

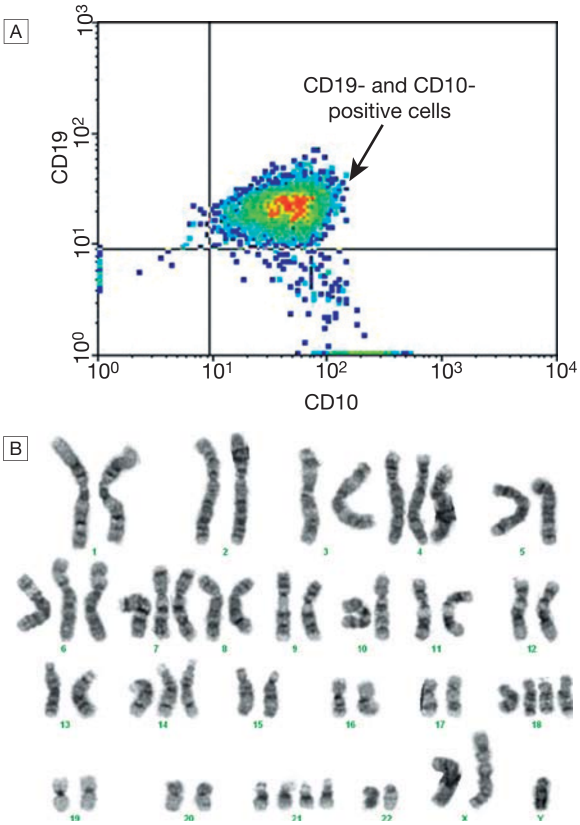

Fig. 23.24 Investigation of acute lymphoblastic leukaemia (ALL). **A** Flow cytometric analysis of blasts labelled with the fluorescent antibodies anti-CD19 (y axis) and anti-CD10 (x axis). ALL blasts are positive for both CD19 and CD10 (arrow). **B** Chromosome analysis (karyotype) of blasts showing additional chromosomes X, 4, 6, 7, 14, 18 and 21.

Management

The first decision must be whether or not to give specific treatment to attempt to achieve remission. This is generally aggressive, has numerous side-effects, and may not be appropriate for the very elderly or patients with serious comorbidities (Chs 32 and 33). In these patients, supportive treatment can effect considerable improvement in well-being. Low-intensity chemotherapy, such as low-dose cytosine arabinoside or, recently, azacitidine, is frequently used in elderly and more frail patients but only induces remission in less than 20% of patients.

Specific therapy

Ideally, whenever possible, patients with acute leukaemia should be treated within a clinical trial. If a decision to embark on specific therapy has been taken, the patient should be prepared as recommended in Box 23.46. It is unwise to attempt aggressive management of acute leukaemia unless adequate services are available for the provision of supportive therapy.

The aim of treatment is to destroy the leukaemic clone of cells without destroying the residual normal stem cell compartment from which repopulation of the haematopoietic tissues will occur. There are three phases:

- *Remission induction.* In this phase, a fraction of the tumour is destroyed by combination chemotherapy. The patient goes through a period of severe bone marrow hypoplasia lasting 3–4 weeks and requires intensive support and inpatient care from a specially trained multidisciplinary team. The aim is to achieve remission, a state in which the blood counts return to normal and the marrow blast count is less than 5%. Quality of life is highly dependent on achieving remission.
- *Remission consolidation.* If remission has been achieved, residual disease is attacked by therapy during the consolidation phase. This consists of a number of courses of chemotherapy, again resulting in periods of marrow hypoplasia. In poor-prognosis leukaemia, this may include allogeneic HSCT.
- *Remission maintenance.* If the patient is still in remission after the consolidation phase for ALL, a period of maintenance therapy is given, with the individual as an outpatient and treatment consisting of a repeating cycle of drug administration. This may extend for up to 3 years if relapse does not occur.

i 23.46 Preparation for specific therapy in acute leukaemia

- Existing infections identified and treated (e.g. urinary tract infection, oral candidiasis, dental, gingival and skin infections)
- Anaemia corrected by red cell concentrate transfusion
- Thrombocytopenic bleeding controlled by platelet transfusions
- If possible, central venous catheter (e.g. Hickman line) inserted to facilitate access to the circulation for delivery of chemotherapy, fluids, blood products and other supportive drugs
- Tumour lysis risk assessed and prevention started: fluids with allopurinol or rasburicase
- Therapeutic regimen carefully explained to the patient and informed consent obtained
- Consideration of entry into clinical trial

23.47 Drugs commonly used in the treatment of acute leukaemia

Phase	Acute lymphoblastic leukaemia	Acute myeloid leukaemia
Induction	Vincristine (IV) Prednisolone (oral) L-Asparaginase (IM) Daunorubicin (IV) Methotrexate (intrathecal) Imatinib (oral)*	Daunorubicin (IV) Cytarabine (IV) Etoposide (IV and oral) Gentuzumab ozogamicin (IV) All-*trans* retinoic acid (ATRA) (oral) Arsenic trioxide (ATO)
Consolidation	Daunorubicin (IV) Cytarabine (IV) Etoposide (IV) Methotrexate (IV) Imatinib (oral)*	Cytarabine (IV) Amsacrine (IV) Mitoxantrone (IV)
Maintenance	Prednisolone (oral) Vincristine (IV) Mercaptopurine (oral) Methotrexate (oral) Imatinib (oral)*	
Relapse	Fludarabine Cytarabine Idarubicin	Fludarabine Cytarabine Arsenic trioxide (ATO) Idarubicin

*If Philadelphia chromosome-positive.

In patients with ALL, it is necessary to give prophylactic treatment to the central nervous system, as this is a sanctuary site where standard therapy does not penetrate. This usually consists of a combination of cranial irradiation, intrathecal chemotherapy and high-dose methotrexate, which crosses the blood–brain barrier.

Thereafter, specific therapy is discontinued and the patient observed.

The detail of the schedules for these treatments can be found in specialist texts. The drugs most commonly employed are listed in Box 23.47. Generally, if a patient fails to go into remission with induction treatment, alternative drug combinations may be tried, but the outlook is poor unless remission can be achieved. Disease that relapses during treatment or soon after the end of treatment carries a poor prognosis and is difficult to treat. The longer after the end of treatment that relapse occurs, the more likely it is that further treatment will be effective.

In some patients, alternative palliative chemotherapy, not designed to achieve remission, may be used to curb excessive leucocyte proliferation. Drugs used for this purpose include hydroxycarbamide and mercaptopurine. The aim is to reduce the blast count without inducing bone marrow failure.

Supportive therapy

Aggressive and potentially curative therapy, which involves periods of severe bone marrow failure, would not be possible without appropriate supportive care. The following problems commonly arise.

Anaemia Anaemia is treated with red cell concentrate transfusions.

Bleeding Thrombocytopenic bleeding requires platelet transfusions, unless the bleeding is trivial. Recent trials have confirmed that in acute leukaemia prophylactic platelet transfusion should be given to maintain the platelet count above 10×10^9/L. Coagulation abnormalities occur and need accurate diagnosis and treatment (p. 971).

Infection Fever (>38°C) lasting over 1 hour in a neutropenic patient indicates possible sepsis (see also p. 218). Parenteral broad-spectrum antibiotic therapy is essential. Empirical therapy is given according to local bacteriological resistance patterns, such as with a combination of an aminoglycoside (e.g. gentamicin) and a broad-spectrum penicillin (e.g. piperacillin/tazobactam) or a single-agent beta-lactam (e.g. meropenem). The organisms most commonly associated with severe neutropenic sepsis are Gram-positive bacteria, such as *Staphylococcus aureus* and *Staphylococcus epidermidis*, which are present on the skin and gain entry via cannulae and central lines. Gram-negative infections often originate from the gastrointestinal tract, which is affected by chemotherapy-induced mucositis; organisms such as *Escherichia coli*, *Pseudomonas* and *Klebsiella* spp. are likely to cause rapid clinical deterioration and must be covered with initially empirical antibiotic therapy. Gram-positive infection may require vancomycin or teicoplanin therapy. If fever has not resolved after 3–5 days and there is evidence on CT scanning or sensitive blood tests for a disseminated fungal infection, empirical antifungal therapy (e.g. a liposomal amphotericin B preparation, voriconazole or caspofungin) is added.

Patients with ALL are susceptible to infection with *Pneumocystis jirovecii* (p. 318), which causes a severe pneumonia. Prophylaxis with co-trimoxazole is given during chemotherapy. Diagnosis may require either induced sputum, bronchoalveolar lavage or open lung biopsy. Treatment is with high-dose co-trimoxazole, initially intravenously, changing to oral treatment as soon as possible.

Oral and pharyngeal *Candida* infection is common. Fluconazole is effective for the treatment of established local infection and for prophylaxis against systemic candidaemia. Prophylaxis against other systemic fungal infections, including *Aspergillus*, using itraconazole or posaconazole, for example, is usual practice during high-risk intensive chemotherapy. This is often used along with sensitive markers of early fungal infection to guide treatment initiation (a 'pre-emptive approach').

For systemic fungal infection with *Candida* or aspergillosis, intravenous liposomal amphotericin, caspofungin or voriconazole is required for at least 3 weeks. In systemic *Candida* infection intravenous catheters should be removed.

Reactivation of herpes simplex infection (p. 247) occurs frequently around the lips and nose during ablative therapy for acute leukaemia, and is treated with aciclovir. This may also be prescribed prophylactically to patients with a history of cold sores or elevated antibody titres to herpes simplex. Herpes zoster manifesting as chickenpox or, after reactivation, as shingles (p. 239) should be treated in the early stage with high-dose aciclovir, as it can be fatal in immunocompromised patients.

The value of isolation facilities, such as laminar flow rooms, is debatable but may contribute to staff awareness of careful reverse barrier nursing practice. The isolation can be psychologically stressful for the patient.

Metabolic problems Frequent monitoring of fluid balance and renal, hepatic and haemostatic function is necessary. Patients are often severely anorexic and diarrhoea is common as a consequence of the side-effects of therapy; they may find drinking difficult and hence require intravenous fluids and electrolytes. Renal toxicity occurs with some antibiotics (e.g. aminoglycosides) and antifungal agents (amphotericin). Cellular breakdown during induction therapy

(tumour lysis syndrome; p. 1328) releases intracellular ions and nucleic acid breakdown products, causing hyperkalaemia, hyperuricaemia, hyperphosphataemia and hypocalcaemia. This may lead to renal failure. Allopurinol and intravenous hydration are given to try to prevent this. In patients at high risk of tumour lysis syndrome, prophylactic rasburicase (a recombinant urate oxidase enzyme) is used. Occasionally, dialysis may be required.

Psychological problems Psychological support is a key aspect of care. Patients should be kept informed, and their questions answered and fears allayed as far as possible. A multidisciplinary approach to patient care involves input from many services, including psychology. Key members of the team include haematology specialist nurses, who are often the central point of contact for patients and families throughout the illness.

Haematopoietic stem cell transplantation

This is described on page 936. In patients with high-risk acute leukaemia, allogeneic HSCT can improve 5-year survival from 20% to around 50%. Reduced-intensity conditioning has allowed HSCT to be delivered to a higher proportion of patients with acute leukaemias, up to the age of about 65 years.

Prognosis

Without treatment, the median survival of patients with acute leukaemia is about 5 weeks. This may be extended to a number of months with supportive treatment. Patients who achieve remission with specific therapy have a better outlook. Around 80% of adult patients under 60 years of age with ALL or AML achieve remission, although remission rates are lower for older patients. However, the relapse rate continues to be high. Box 23.48 shows the survival in ALL and AML and the influence of prognostic features. The level of detectable leukaemia cells, called minimal residual disease (MRD), measured after induction therapy in ALL by sensitive laboratory techniques, has been shown to be a powerful prognostic tool that is now used routinely to direct subsequent consolidation therapy.

Advances in treatment have led to steady improvement in survival from leukaemia. They include the introduction of drugs such as all-*trans* retinoic acid (ATRA) and arsenic trioxide (ATO) in acute promyelocytic leukaemia, which has greatly reduced induction deaths from bleeding in this good-risk leukaemia. A chemotherapy-free schedule of ATRA and ATO has recently produced cure rates of 90% in patients with low-risk acute promyelocytic leukaemia. Current trials aim to improve survival, especially in standard and poor-risk disease, with strategies that include better use of allogeneic HSCT and targeted therapies such as anti-CD33 monoclonal antibodies (Mylotarg) and FLT3 inhibitors. FLT3 is a cytokine receptor often expressed on AML blast cells and whose expression is associated with a poorer prognosis.

i 23.48 Outcome in adult acute leukaemia

Disease/risk	Risk factors	5-year overall survival
Acute myeloid leukaemia (AML)		
Good risk	Promyelocytic leukaemia t(15;17)	90%
	t(8;21)	65%
	inv 16 or t(16;16)	70%
Poor risk	Cytogenetic abnormalities −5, −7, del 5q, abn(3q), complex (>5)	21%
Intermediate risk	AML with none of the above	48%
Acute lymphoblastic leukaemia (ALL)		
Poor risk	Philadelphia chromosome High white count $>100\times10^9$/L Abnormal short arm of chromosome 11 t(1;19)	20%
Standard	ALL with none of the above	37%

Chronic myeloid leukaemia

Chronic myeloid leukaemia (CML) is a myeloproliferative stem cell disorder resulting in proliferation of all haematopoietic lineages but manifesting predominantly in the granulocytic series. Maturation of cells proceeds fairly normally. The disease occurs chiefly between the ages of 30 and 80 years, with a peak incidence at 55 years. It is rare, with an annual incidence in the UK of 1.8/100 000, and accounts for 20% of all leukaemias. It is found in all races.

The defining characteristic of CML is the chromosome abnormality known as the Philadelphia (Ph) chromosome. This is a shortened chromosome 22 resulting from a reciprocal translocation of material with chromosome 9. The break on chromosome 22 occurs in the breakpoint cluster region (BCR). The fragment from chromosome 9 that joins the BCR carries the *abl* oncogene, which forms a fusion gene with the remains of the BCR. This *BCR ABL* fusion gene codes for a 210 kDa protein with tyrosine kinase activity, which plays a causative role in the disease as an oncogene (p. 1318), influencing cellular proliferation, differentiation and survival. In some patients in whom conventional chromosomal analysis does not detect a Ph chromosome, the BCR ABL gene product is detectable by molecular techniques.

Natural history

The disease has three phases:

- *A chronic phase*, in which the disease is responsive to treatment and is easily controlled, which used to last 3–5 years. With the introduction of imatinib therapy, this phase has been prolonged to encompass a normal life expectancy in many patients.
- *An accelerated phase* (not always seen), in which disease control becomes more difficult.
- *Blast crisis*, in which the disease transforms into an acute leukaemia, either myeloblastic (70%) or lymphoblastic (30%), which is relatively refractory to treatment. This is the cause of death in the majority of patients; survival is therefore dictated by the timing of blast crisis, which cannot be predicted. Prior to imatinib therapy (see below), approximately 10% of patients per year would transform. In those treated with imatinib for up to 10 years, only between 0.5 and 2.5% have transformed each year.

Clinical features

Symptoms at presentation may include lethargy, weight loss, abdominal discomfort, gout and sweating, but about 25% of patients are asymptomatic at diagnosis. Splenomegaly is present in 90%; in about 10%, the enlargement is massive, extending to over 15 cm below the costal margin. A friction rub may be heard in cases of splenic infarction. Hepatomegaly occurs in about 50%. Lymphadenopathy is unusual.

Investigations

FBC results are variable between patients. There is usually a normocytic, normochromic anaemia. The leucocyte count can vary from 10 to 600×10^9/L. In about one-third of patients, there is a very high platelet count, sometimes as high as 2000×10^9/L. In the blood film, the full range of granulocyte precursors, from myeloblasts to mature neutrophils, is seen but the predominant cells are neutrophils and myelocytes (see Fig. 23.3). Myeloblasts usually constitute less than 10% of all white cells. There is often an absolute increase in eosinophils and basophils, and nucleated red cells are common. If the disease progresses through an accelerated phase, the percentage of more primitive cells increases. Blast transformation is characterised by a dramatic increase in the number of circulating blasts. In patients with thrombocytosis, very high platelet counts may persist during treatment, in both chronic and accelerated phases, but usually drop dramatically at blast transformation. Basophilia tends to increase as the disease progresses.

Bone marrow should be obtained to confirm the diagnosis and phase of disease by morphology, chromosome analysis to demonstrate the presence of the Ph chromosome, and RNA analysis to demonstrate the presence of the BCR ABL gene product. Blood LDH levels are elevated and the uric acid level may be high due to increased cell breakdown.

Management

Chronic phase

There are now five available tyrosine kinase inhibitors (TKIs) for the treatment of CML (Box 23.49). These specifically inhibit BCR ABL tyrosine kinase activity. Imatinib, nilotinib and dasatinib are recommended as first-line therapy in chronic phase CML; they usually normalise the blood count within a month and within 3–6 months produce complete cytogenetic response (disappearance of the Ph chromosome) in some 90% of patients. A sample of bone marrow is taken at 6 months to confirm complete cytogenetic response, and patients are subsequently monitored by 3-monthly real-time quantitative polymerase chain reaction (PCR) for BCR ABL mRNA transcripts in blood. The aim is to reduce the BCR ABL transcript levels by 3–5 logs from baseline and this is called major molecular response (MR3–MR5). A proportion of patients achieve a complete molecular response where the transcripts are not detectable by PCR. It may be possible for patients with a complete or major molecular response to stop TKI therapy and this is being investigated in clinical trials. For those failing to respond or who lose their response and progress on first-line therapy, options include switching to a different TKI (Box 23.49). Some patients develop detectable mutations in the *BCR ABL* gene, which renders them resistant to one or more of the TKIs. The T315I mutation has been particularly problematic, as this provides wide-ranging resistance. The third-generation TKI ponatinib is effective, however. Allogeneic HSCT (p. 937) is now reserved for patients who fail TKI therapy. Hydroxycarbamide and interferon were previously used for control of disease. Hydroxycarbamide is still useful in palliative situations and interferon is used in women planning pregnancy.

Accelerated phase and blast crisis

Management is more difficult. For patients in accelerated phase, TKI therapy is indicated, most commonly with nilotinib or dasatinib. When blast transformation occurs, the type of blast cell should be determined. Response to appropriate acute leukaemia treatment (see Box 23.49) is better if disease is lymphoblastic than if myeloblastic. Second- or third-generation TKIs such as dasatinib are used in combination with chemotherapy to try and achieve remission. In younger and fitter patients an allogeneic HSCT is appropriate therapy if a return to chronic phase is achieved. Hydroxycarbamide can be an effective single agent and low-dose cytarabine can also be used palliatively in older patients.

i 23.49 Tyrosine kinase inhibition in chronic myeloid leukaemia

Agents

First-line
- Imatinib
- Nilotinib
- Dasatinib

Second-line
- Imatinib
- Nilotinib
- Dasatinib
- Bosutinib
- Ponatinib*

Outcomes
- 90% achieve complete cytogenetic response
- Responses faster with nilotinib and dasatinib
- Median survival comparable to normal population

*For patients with T315I kinase domain mutations use ponatinib.

Chronic lymphocytic leukaemia

Chronic lymphocytic leukaemia (CLL) is the most common variety of leukaemia, accounting for 30% of cases. The male-to-female ratio is 2 : 1 and the median age at presentation is 65–70 years. In this disease, B lymphocytes, which would normally respond to antigens by transformation and antibody formation, fail to do so. An ever-increasing mass of immuno-incompetent cells accumulates, to the detriment of immune function and normal bone marrow haematopoiesis.

Clinical features

The onset is usually insidious. Indeed, in around 70% of patients, the diagnosis is made incidentally on a routine FBC. Presenting problems may be anaemia, infections, painless lymphadenopathy, and systemic symptoms such as night sweats or weight loss; these more often occur later in the course of the disease.

23

Investigations

The diagnosis is based on the peripheral blood findings of a mature lymphocytosis (>5×10^9/L) with characteristic morphology and cell surface markers. Immunophenotyping reveals the lymphocytes to be monoclonal B cells expressing the B-cell antigens CD19 and CD23, with either kappa or lambda immunoglobulin light chains and, characteristically, an aberrant T-cell antigen CD5. On flow cytometry, some people are shown to have circulating CLL cells at a level less than 5×10^9/L. This is known as monoclonal B lymphocytosis of uncertain significance.

Other useful investigations in CLL include a reticulocyte count and a direct Coombs test, as autoimmune haemolytic anaemia may occur (p. 949). Serum immunoglobulin levels should be estimated to establish the degree of hypogammaglobulinaemia, which is common and progressive. Bone marrow examination by aspirate and trephine is not essential for the diagnosis of CLL, but may be helpful in difficult cases, for prognosis (patients with diffuse marrow involvement have a poorer prognosis) and to monitor response to therapy. The main prognostic factor is

23.50 Staging of chronic lymphocytic leukaemia

Clinical stage A (60% patients)
• No anaemia or thrombocytopenia and fewer than three areas of lymphoid enlargement
Clinical stage B (30% patients)
• No anaemia or thrombocytopenia, with three or more involved areas of lymphoid enlargement
Clinical stage C (10% patients)
• Anaemia and/or thrombocytopenia, regardless of the number of areas of lymphoid enlargement

stage of disease (Box 23.50); however, loss of chromosome 17p or mutation in the *TP53* gene, which resides at this genetic locus, is a powerful prognostic marker and predictor of response to therapy. A mutation in *TP53* is present in <10% of patients at presentation but rises to 30% of cases at relapse. This test should be performed in all patients prior to the initiation of therapy.

Management

No specific treatment is required for most clinical stage A patients, unless progression occurs. Life expectancy is usually normal in older patients. The patient should be offered clear information about CLL and be reassured about the indolent nature of the disease, as the diagnosis of leukaemia inevitably causes anxiety.

Treatment is required only if there is evidence of bone marrow failure, massive or progressive lymphadenopathy or splenomegaly, systemic symptoms such as weight loss or night sweats, a rapidly increasing lymphocyte count, autoimmune haemolytic anaemia or thrombocytopenia. Initial therapy for those requiring treatment (progressive stage A and stages B and C) is based on the age and fitness of the patient and the *TP53* mutation status. For patients who are under 70 years, fit and *TP53* mutation-negative, fludarabine in combination with the alkylating agent cyclophosphamide and the anti-CD20 monoclonal antibody rituximab (FCR) is standard care. For older, less fit patients, rituximab is combined with gentler chemotherapy: bendamustine or oral chlorambucil. Recently, a more potent type 2 anti-CD20 antibody, obinutuzumab, has become available and produces better responses in combination with chlorambucil than rituximab.

CLL cells are dependent on abnormal and persistent signalling through the B-cell receptor (BCR) pathway. Drugs that can inhibit this pathway are now available and show great promise. Ibrutinib inhibits Bruton's tyrosine kinase and idelalisib inhibits PI3 kinase, both components of the BCR pathway. Ibrutinib and idelalisib are licensed for relapsed CLL but crucially are licensed and effective in *TP53*-mutated disease at all stages and are quickly becoming standard care in *TP53*-mutated CLL. Bone marrow failure or autoimmune cytopenias may respond to glucocorticoid treatment.

Supportive care is increasingly required in progressive disease, such as transfusions for symptomatic anaemia or thrombocytopenia, prompt treatment of infections and, for some patients with hypogammaglobulinaemia, immunoglobulin replacement. Radiotherapy may be used for lymphadenopathy that is causing discomfort or local obstruction, and for symptomatic splenomegaly. Splenectomy may be required to improve low blood counts due to autoimmune destruction or to hypersplenism, and can relieve massive splenomegaly.

Prognosis

The majority of clinical stage A patients have a normal life expectancy but patients with advanced CLL are more likely to die from their disease or infectious complications. Survival is influenced by prognostic features of the leukaemia, particularly *TP53* mutation status, and whether patients can tolerate and respond to fludarabine-based treatment. In those able to be treated with chemotherapy and rituximab, 90% are alive 4 years later. Rarely, CLL transforms to an aggressive high-grade lymphoma, called Richter's transformation.

Prolymphocytic leukaemia

Prolymphocytic leukaemia (PLL) is a variant of chronic lymphocytic leukaemia found mainly in males over the age of 60 years; 25% of cases are of the T-cell variety. There is typically massive splenomegaly with little lymphadenopathy and a very high leucocyte count, often in excess of 400×10^9/L. The characteristic cell is a large lymphocyte with a prominent nucleolus. Treatment is generally unsuccessful and the prognosis very poor. Leukapharesis, splenectomy and chemotherapy may be tried. The anti-CD52 antibody alemtuzumab, when given intravenously, has produced responses in some 90% of patients with T-PLL.

Hairy cell leukaemia

This is a rare chronic B-cell lymphoproliferative disorder. The male-to-female ratio is 6 : 1 and the median age at diagnosis is 50 years. Presenting symptoms are general ill health and recurrent infections. Splenomegaly occurs in 90% but lymph node enlargement is unusual.

Severe neutropenia, monocytopenia and the characteristic hairy cells in the blood and bone marrow are typical. These cells usually have a B-lymphocyte immunotype but they also characteristically express CD25 and CD103. Recently, all patients with hairy cell leukaemia have been found to have a mutation in the *BRAF* gene.

Over recent years, a number of treatments, including cladribine and deoxycoformycin, have been shown to produce long-lasting remissions.

Myelodysplastic syndromes

Myelodysplastic syndromes (MDSs) constitute a group of clonal haematopoietic disorders with the common features of ineffective blood cell production and a tendency to progress to AML. As such, they are pre-leukaemic and represent genetic steps in the development of leukaemia. These genetic abnormalities have been identified and are present as a manifestation of clonal haematopoiesis in about 3% of patients over the age of 80, at a time when their blood counts are normal (clonal haematopoiesis of indeterminate potential, CHIP). MDS presents with consequences of bone marrow failure (anaemia, recurrent infections or bleeding), usually in older people (median age at diagnosis is 73 years). The overall incidence is 4/100 000 in the population, rising to more than 30/100 000 in the over-seventies. The blood film is characterised by cytopenias and abnormal-looking (dysplastic) blood cells, including macrocytic red cells and hypogranular neutrophils with nuclear hyper- or hyposegmentation. The bone marrow is hypercellular, with dysplastic changes in at least 10% of cells of one or more cell lines. Blast cells may be increased but do not reach the 20% level that indicates acute leukaemia. Chromosome analysis frequently reveals abnormalities, particularly

23.51 WHO classification of myelodysplastic syndromes (MDSs)

Disease	Bone marrow findings
MDS with single-lineage dysplasia	<5% blasts and single-lineage dysplasia only
MDS with ring sideroblasts (MDS-RS)	>15% ring sideroblasts, or 6–14% and presence of *SF3B1* gene mutation
MDS with multilineage dysplasia	<5% blasts and dysplasia in 2 or more lineages
MDS with excess blasts	5–19% blasts
MDS with isolated del(5q)	Myelodysplastic syndrome associated with a del(5q) cytogenetic abnormality <5% blasts Often normal or increased blood platelet count
MDS, unclassifiable	None of the above or inadequate material

23.52 Revised International Prognostic Scoring System and outcomes in myelodysplasia*

Risk category	Overall score	Median survival (years)	25% progression to acute myeloid leukaemia (years)
Very low	≤1.5	8.8	Not reached
Low	>1.5–3	5.3	10.8
Intermediate	>3–4.5	3.0	3.2
High	>4.5–6	1.6	1.4
Very high	>6	0.8	0.73

*The IPSS-R is based on three prognostic factors: the blast percentage in bone marrow; karyotype; and number and degree of blood cytopenias. A score is derived from which patients can be stratified into five risk categories for survival and leukaemic transformation.

of chromosome 5 or 7. The WHO classification of MDS is shown in Box 23.51.

Prognosis

The natural history of MDS is progressive worsening of dysplasia leading to fatal bone marrow failure or progression to AML in 30% of cases. The time to progression varies (from months to years) with the subtype of MDS, being slowest in MDS with ring sideroblasts and single-lineage dysplasia and most rapid in MDS with excess blasts. The revised International Prognostic Scoring System (IPSS-R) predicts clinical outcome based on karyotype and cytopenias in blood, as well as percentage of bone marrow blasts (Box 23.52). There are five prognostic groups. The median survival for low-risk patients (IPSS-R very low and low) is 5–9 years, that for the intermediate group is 3 years and that for high-risk patients (IPSS-R high and very high) is 1–1.5 years.

Management

For the vast majority of patients who are elderly, the disease is incurable, and supportive care with red cell and platelet transfusions is the mainstay of treatment. A trial of erythropoiesis stimulating agents (ESA) and granulocyte–colony-stimulating factor (G–CSF) is recommended in some patients with low-risk MDS (IPSS-R very low, low and intermediate) to improve haemoglobin or neutrophil counts. A rare subtype called MDS with isolated del(5q) responds well to the immunomodulatory drug lenalidomide, with two-thirds of anaemic patients becoming transfusion-independent for up to 2 years. Allogeneic stem cell transplantation may afford a cure in patients with a good performance status and is considered in high-risk patients (IPSS-R high and very high) and some low-risk patients. More recently, the hypomethylating agent azacytidine has improved survival by a median of 9 months for high-risk patients, and in the UK is a recommended standard of care for those not eligible for transplantation.

Lymphomas

These neoplasms arise from lymphoid tissues, and are diagnosed from the pathological findings on biopsy as Hodgkin or non-Hodgkin lymphoma. The majority are of B-cell origin. Non-Hodgkin lymphomas are classified as low- or high-grade tumours on the basis of their proliferation rate. The normal architecture of the lymph node is outlined in Figure 23.25.

- *High-grade tumours* divide rapidly, are typically present for a matter of weeks before diagnosis, and may be life-threatening with frequent risk of extranodal involvement.
- *Low-grade tumours* divide slowly, may be present for many months before diagnosis, and typically behave in an indolent fashion.

Hodgkin lymphoma

The histological hallmark of Hodgkin lymphoma (HL) is the presence of Reed–Sternberg cells: large, malignant lymphoid cells of B-cell origin (Fig. 23.26). They are often present only in small numbers but are surrounded by large numbers of reactive non-malignant T cells, plasma cells and eosinophils.

The epidemiology of HL is shown in Box 23.53 and its histological WHO classification in Box 23.54.

Nodular lymphocyte-predominant HL is slow-growing, localised and rarely fatal. It has biological features, such as CD20-positive Hodgkin cells, and clinical features that make it more akin to a low-grade B-cell non-Hodgkin lymphoma. Classical HL is divided into four histological subtypes from the appearance of the

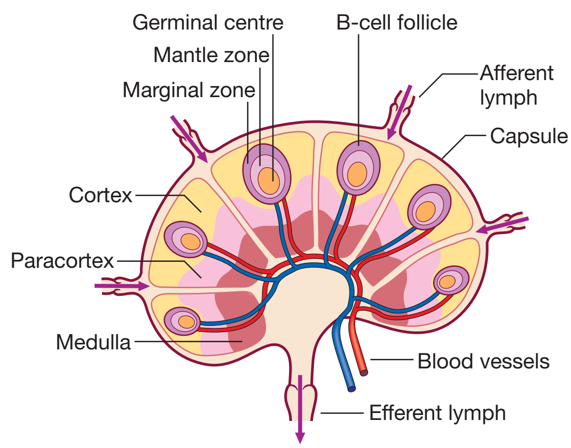

Fig. 23.25 Schema of lymph node architecture. Different lymphocyte populations reside in different areas of the node: B cells in the follicles, T cells in the paracortex and plasma cells in the medulla. B cells are selected for antigen in the follicle centre. Errors during this process result in B-cell lymphomas, which are by far the most common type.

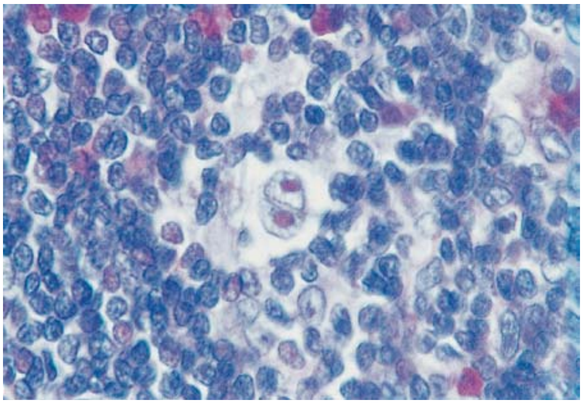

Fig. 23.26 Hodgkin lymphoma. In the centre of this lymph node biopsy is a large typical Reed–Sternberg cell with two nuclei containing a prominent eosinophilic nucleolus.

i 23.53 Epidemiology and aetiology of Hodgkin lymphoma

Incidence
- Approximately 4 new cases/100 000 population/year

Sex ratio
- Slight male excess (1.5 : 1)

Age
- Median age 31 years; first peak at 20–35 years and second at 50–70 years

Aetiology
- Unknown
- More common in patients from well-educated backgrounds and small families
- Three times more likely with a past history of infectious mononucleosis but no definitive causal link to Epstein–Barr virus infection proven

i 23.54 WHO pathological classification of Hodgkin lymphoma (HL)

Type	Histology classification	Proportion of HL
Nodular lymphocyte-predominant HL		5%
Classical HL	Nodular sclerosing Mixed cellularity Lymphocyte-rich Lymphocyte-depleted	70% 20% 5% Rare

Reed–Sternberg cells and surrounding reactive cells. The nodular sclerosing type is more common in young patients and in women. Mixed cellularity is more common in the elderly. Lymphocyte-rich HL usually presents in men. Lymphocyte-depleted HL is rare and probably represents large-cell or anaplastic non-Hodgkin lymphoma.

Clinical features

There is painless, rubbery lymphadenopathy, usually in the neck or supraclavicular fossae; the lymph nodes may fluctuate in size. Young patients with nodular sclerosing disease may have large mediastinal masses that are surprisingly asymptomatic

i 23.55 Clinical stages of Hodgkin lymphoma (Ann Arbor classification)

Stage	Definition
I	Involvement of a single lymph node region (I) or extralymphatic* site (I_E)
II	Involvement of two or more lymph node regions (II) or an extralymphatic site and lymph node regions on the same side of (above or below) the diaphragm (II_E)
III	Involvement of lymph node regions on both sides of the diaphragm with (III_E) or without (III) localised extralymphatic involvement or involvement of the spleen (III_S), or both (III_{SE})
IV	Diffuse involvement of one or more extralymphatic tissues, e.g. liver or bone marrow
Each stage is subclassified:	
A	No systemic symptoms
B	Weight loss >10%, drenching sweats, fever

*The lymphatic structures are defined as the lymph nodes, spleen, thymus, Waldeyer's ring, appendix and Peyer's patches.

but may cause dry cough and some breathlessness. Isolated subdiaphragmatic nodes occur in fewer than 10% at diagnosis. Hepatosplenomegaly may be present but does not always indicate disease in those organs. Spread is contiguous from one node to the next, and extranodal disease, such as bone, brain or skin involvement, is rare.

Investigations

Treatment of HL depends on the stage at presentation; investigations therefore aim not only to diagnose lymphoma but also to determine the extent of disease (Box 23.55).

- *FBC* may be normal. If a normochromic, normocytic anaemia or lymphopenia is present, this is a poor prognostic factor. An eosinophilia or a neutrophilia may be present.
- *ESR* may be raised.
- *Renal function tests* are required to ensure function is normal prior to treatment.
- *Liver function* may be abnormal in the absence of disease or may reflect hepatic infiltration. An obstructive pattern may be caused by nodes at the porta hepatis.
- *LDH measurements* showing raised levels are an adverse prognostic factor.
- *Chest X-ray* may show a mediastinal mass.
- *CT scan* of chest, abdomen and pelvis permits staging. Bulky disease (>10 cm in a single node mass) is an adverse prognostic feature.
- *Positron emission tomography (PET) scanning* identifies nodes involved with HL, which are ^{18}fluorodeoxyglucose (FDG)-avid, and this allows more accurate staging and monitoring of response (Fig. 23.27).
- *Lymph node biopsy* may be undertaken surgically or by percutaneous needle biopsy under radiological guidance (Fig. 23.28).

Management

Clinical trials have shown that patients with early-stage disease (stages IA and IIA) have better outcomes if limited cycles of chemotherapy are combined with radiotherapy, rather than using radiotherapy alone.

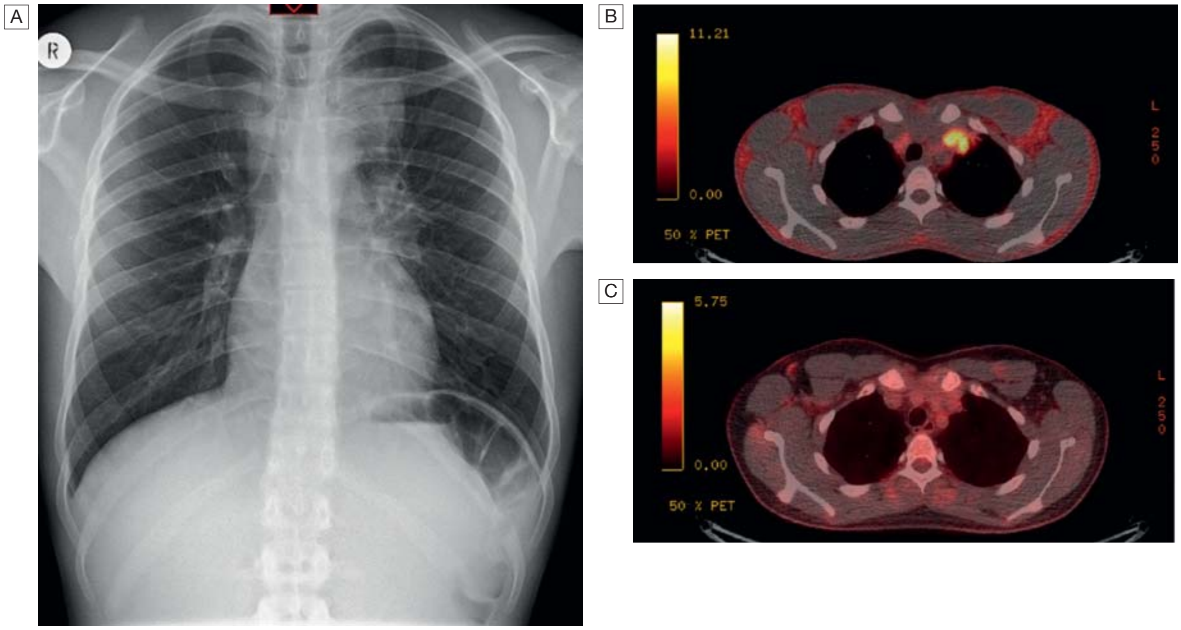

Fig. 23.27 Positron emission tomography (PET) scans in Hodgkin lymphoma, demonstrating response to treatment. **A** Chest X-ray from a young man with Hodgkin lymphoma at presentation, showing a left-sided anterior–superior mediastinal mass with tracheal deviation to the right. **B** Fused PET-CT image showing intense fluorodeoxyglucose (FDG) uptake (avidity) in the mass at presentation. **C** Fused PET-CT image showing no FDG uptake (PET negativity), representing complete response at the end of treatment.

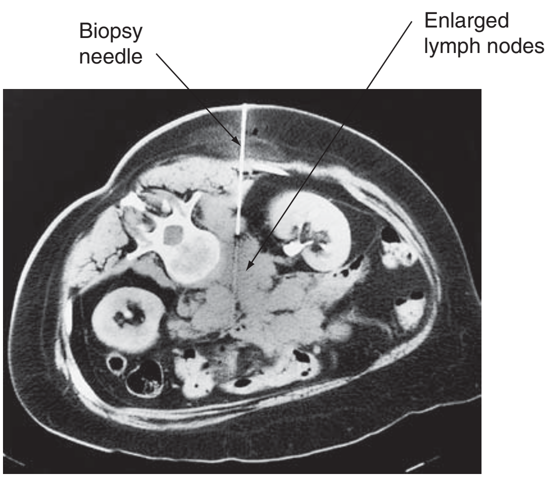

Fig. 23.28 CT-guided percutaneous needle biopsy of retroperitoneal nodes involved by lymphoma.

The ABVD regimen (doxorubicin, bleomycin, vinblastine and dacarbazine) is widely used in the UK. Standard therapy for early-stage patients without additional risk factors, such as bulk disease or high ESR, is two cycles of ABVD combined with 20 Gy radiotherapy to the involved sites of disease. Standard therapy for early-stage patients with additional risk factors is four cycles of ABVD combined with 30 Gy radiotherapy. Careful planning of radiotherapy is required to limit the doses delivered to normal tissues and new planning techniques continue to improve targeting of radiotherapy. Nevertheless, the long-term risks of second cancers and heart and lung disease within the radiation fields remain a concern, especially for young people with a high cure rate and decades of life ahead of them. Recent randomised trial data from the UK RAPID study have suggested that early-stage patients without bulk disease who have a negative PET scan after three cycles of ABVD can safely omit radiotherapy. Young women receiving breast irradiation during the treatment of chest disease have an increased risk of breast cancer and should participate in a screening programme. Patients continuing to smoke after lung irradiation are at particular risk of lung cancer.

ABVD chemotherapy can cause cardiac and pulmonary toxicity, due to doxorubicin and bleomycin, respectively. The incidence of infertility and secondary myelodysplasia/AML is low with this regimen.

Patients with advanced-stage disease are most commonly managed with chemotherapy alone. Standard treatment in the UK is 6–8 cycles of ABVD, followed by an assessment of response. The recent UK RATHL trial has confirmed previous data showing that achieving a PET-negative response after two cycles of ABVD (interim PET-2 response) predicts a very good outcome from continuing with up to six cycles of ABVD. Indeed, the same outcome can be achieved by omitting the bleomycin from the last four cycles and using just AVD, thus reducing the risk of lung toxicity. Patients who are PET-positive after two cycles, however, have a very high relapse risk if they continue with ABVD, only 13% being relapse-free at 2 years. The RATHL and other studies have demonstrated that changing to a more intensive regimen, BEACOPP (bleomycin, etoposide, adriamycin, cyclophosphamide, vincristine (oncovin), procarbazine, prednisolone), in these patients improves the relapse-free survival to approximately 65%.

Patients with relapsed disease that responds to salvage chemotherapy and ideally becomes PET-negative should be considered for autologous stem cell transplantation (p. 937). Those with resistant disease might benefit from an allogeneic

i 23.56 The Hasenclever prognostic index for advanced Hodgkin lymphoma

Score 1 for each of the following risk factors present at diagnosis:
- Age > 45 years
- Male gender
- Serum albumin < 40 g/L
- Hb < 105 g/L
- Stage IV disease
- White blood cell count > 15×10^9/L
- Lymphopenia < 0.6×10^9/L

Score	5-year rate of freedom from progression (%)	5-year rate of overall survival (%)
0–1	79	90
>2	60	74
>3	55	70
>4	47	59

stem cell transplant. Brentuximab vedotin is an antibody–drug conjugate directed against CD30 on the Reed–Sternberg cell surface. This antibody delivers the antimitotic toxin monomethyl auristatin E to the Hodgkin cells and, as a single agent, can produce good responses in patients who have failed, or are not suitable for, an autologous transplant and can be a 'bridge' to an allogeneic transplant.

Prognosis

Over 90% of patients with early-stage HL achieve complete remission when treated with chemotherapy followed by involved field radiotherapy, and the great majority are cured. The major challenge is how to reduce treatment intensity, and hence long-term toxicity, without reducing the excellent cure rates in this group. Omitting radiotherapy in the majority of PET-negative patients is one major step forward in this regard.

Historically, between 50 and 70% of those with advanced-stage HL were cured. The Hasenclever index (Box 23.56) can be helpful in assigning approximate chances of cure when discussing treatment plans with patients. More recent data using the PET scanner to direct therapy suggests that long-term survival is improving to beyond 80%. Patients who fail to respond to initial chemotherapy or relapse within a year of initial therapy have a poor prognosis but some may achieve long-term survival after autologous HSCT. Patients relapsing after 1 year may obtain long-term survival with further chemotherapy alone, but fit patients frequently proceed to autologous HSCT.

Non-Hodgkin lymphoma

Non-Hodgkin lymphoma (NHL) represents a monoclonal proliferation of lymphoid cells of B-cell (90%) or T-cell (10%) origin. The incidence of these tumours increases with age, to 62.8/million population per annum at age 75 years, and the overall rate is increasing at about 3% per year.

The epidemiology of NHL is shown in Box 23.57. Previous classifications were based principally on histological appearances. The current WHO classification stratifies according to cell lineage (T or B cells) and incorporates clinical features, histology, chromosomal abnormalities and concepts related to the biology of the lymphoma. Clinically, the most important factor is grade, which is a reflection of proliferation rate. High-grade NHL has high proliferation rates, rapidly produces symptoms, is fatal if untreated, but is potentially curable. Low-grade NHL has low proliferation rates, may be asymptomatic for many months or even years before presentation, runs an indolent course, but is not curable by conventional therapy. Of all cases of NHL in the developed world, over two-thirds are either diffuse large B-cell NHL (high-grade) or follicular NHL (low-grade) (Fig. 23.29). Other forms of NHL, including Burkitt lymphoma, mantle cell lymphoma, mucosa-associated lymphoid tissue (MALT) lymphomas and T-cell lymphomas, are less common.

i 23.57 Epidemiology and aetiology of non-Hodgkin lymphoma

Incidence
- 12 new cases/100 000 people/year

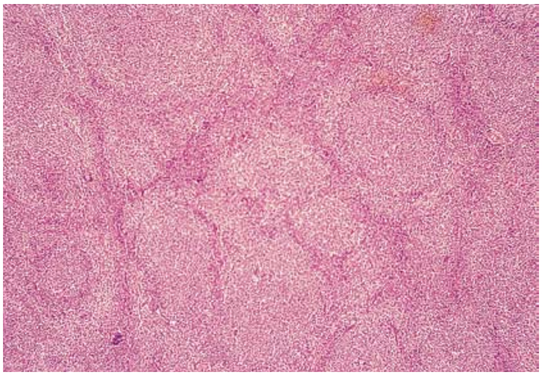
Sex ratio
- Slight male excess

Age
- Median age 65–70 years

Aetiology
- No single causative abnormality described
- Lymphoma is a late manifestation of HIV infection (p. 322)
- Specific lymphoma types are associated with viruses:
  e.g. Epstein–Barr virus (EBV) with post-transplant NHL, human herpesvirus 8 (HHV8) with a primary effusion lymphoma, and human T-cell lymphotropic virus (HTLV-1) with adult T-cell leukaemia lymphoma
- Gastric lymphoma can be associated with *Helicobacter pylori* infection
- Some lymphomas are associated with specific chromosomal translocations:
  - The t(14;18) in follicular lymphoma results in the dysregulated expression of the BCL-2 gene product, which inhibits apoptotic cell death
  - The t(8;14) found in Burkitt lymphoma and the t(11;14) in mantle cell lymphoma alter function of c-myc and cyclin D1, respectively, resulting in malignant proliferation
- Lymphoma occurs in congenital immunodeficiency states and in immunosuppressed patients after organ transplantation

Clinical features

Unlike Hodgkin lymphoma, NHL is often widely disseminated at presentation, including in extranodal sites. Patients present with lymph node enlargement (Fig. 23.30), which may be associated with systemic upset: weight loss, sweats, fever and itching. Hepatosplenomegaly may be present. Sites of extranodal involvement include the bone marrow, gut, thyroid, lung, skin, testis, brain and, more rarely, bone. Bone marrow involvement is more common in low-grade (50–60%) than high-grade (10%) disease. Compression syndromes may occur, including gut obstruction, ascites, superior vena cava obstruction and spinal cord compression.



The same staging system (see Box 23.55) is used for both HL and NHL, but NHL is more likely to be stage III or IV at presentation.

Investigations

These are as for HL, but in addition the following should be performed:

- *Bone marrow aspiration and trephine* to identify bone marrow involvement.
- *Immunophenotyping of surface antigens to distinguish T-cell from B-cell tumours*. This may be done on blood, marrow or nodal material.

A

B

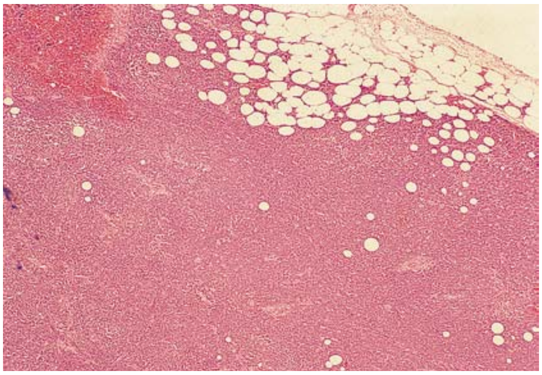


Fig. 23.29 Histology of non-Hodgkin lymphoma. A (Low-grade) follicular or nodular pattern. B (High-grade) diffuse pattern.

Fig. 23.30 Bulky axillary lymphadenopathy with distended superficial veins in a patient presenting with high-grade lymphoma. *From Howard MR, Hamilton PJ. Haematology: An illustrated colour text, 4th edn. Edinburgh: Elsevier Ltd; 2013.*

- *Cytogenetic analysis to detect chromosomal translocations* and molecular testing for T-cell receptor or immunoglobulin gene rearrangements.
- *Immunoglobulin determination*. Some lymphomas are associated with IgG or IgM paraproteins, which serve as markers for treatment response.
- *Measurement of uric acid levels*. Some very aggressive high-grade NHLs are associated with very high urate levels, which can precipitate renal failure when treatment is started.
- *HIV testing*. HIV is a risk factor for some lymphomas and affects treatment decisions.
- *Hepatitis B and C testing.* This should be done prior to therapy with rituximab.

Management

Low-grade NHL

The majority of patients (80%) present with advanced stage disease and will run a relapsing and remitting course over several years. Asymptomatic patients may not require therapy and are managed by 'watching and waiting'. Indications for treatment include marked systemic symptoms, lymphadenopathy causing discomfort or disfigurement, bone marrow failure or compression syndromes. In follicular lymphoma, the options are:

- *Radiotherapy*. This can be used for localised stage I disease, which is rare.
- *Chemotherapy*. Most patients will respond to oral therapy with chlorambucil, which is well tolerated but not curative. More intensive intravenous chemotherapy in younger patients produces better quality of life but no survival benefit.
- *Monoclonal antibody therapy*. Humanised monoclonal antibodies ('biological therapy'; p. 960) can be used to target surface antigens on tumour cells and to induce tumour cell apoptosis directly. The anti-CD20 antibody rituximab has been shown to induce durable clinical responses in up to 60% of patients when given alone, and acts synergistically when given with chemotherapy. Rituximab (R) in combination with cyclophosphamide, vincristine and prednisolone (R-CVP), cyclophosphamide, doxorubicin, vincristine, prednisolone (R-CHOP) or bendamustine (R-bendamustine) is commonly used as first-line therapy. Randomised trials have also confirmed that 2 years of maintenance therapy with single-agent rituximab, following achievement of first or second response, delays relapse and the time to next treatment. As yet, however, rituximab maintenance has not shown a survival benefit. New and more potent monoclonal antibodies are also in development and trials of obinutuzumab (p. 960) have been completed.
- *Kinase inhibitors*. Idelalisib is approved for relapsed follicular lymphoma and ibrutinib (p. 960) is approved for relapsed mantle cell lymphoma, a poor-prognosis lymphoma with low-grade histology but aggressive clinical behaviour. These targeted therapies are likely to become more widely used in low-grade lymphomas in the near future.
- *Transplantation*. High-dose chemotherapy and autologous HSCT can produce long remissions in patients with relapsed disease. Decisions on the timing of such treatment are complex in the context of rituximab maintenance and newer targeted therapies. However, younger patients with short first or second remissions or who relapse during rituximab maintenance should be considered.

23

High-grade NHL

Patients with diffuse large B-cell NHL need treatment at initial presentation:

- *Chemotherapy.* The majority (>90%) are treated with intravenous combination chemotherapy, typically with the CHOP regimen (cyclophosphamide, doxorubicin, vincristine and prednisolone).
- *Monoclonal antibody therapy*. When combined with CHOP chemotherapy, rituximab (R) increases the complete response rates and improves overall survival. R-CHOP is currently recommended as first-line therapy for those with stage II or higher diffuse large B-cell lymphoma.
- *Radiotherapy.* Stage I patients without bulky disease are treated with four cycles of CHOP or R-CHOP, followed by involved site radiotherapy. Radiotherapy is also indicated for a residual localised site of bulk disease after chemotherapy, and for spinal cord and other compression syndromes.
- *HSCT.* Autologous HSCT (p. 937) benefits patients with relapsed disease that is sensitive to salvage immunochemotherapy. As with HL, achieving PET negativity prior to autologous transplantation is desirable.

Prognosis

Low-grade NHL runs an indolent remitting and relapsing course, with an overall median survival of 12 years. Transformation to a high-grade NHL occurs in 3% per annum and is associated with poor survival.

In diffuse large B-cell NHL treated with R-CHOP, some 75% of patients overall respond initially to therapy and 50% will have disease-free survival at 5 years. The prognosis for patients with NHL is further refined according to the international prognostic index (IPI). For high-grade NHL, 5-year survival ranges from over 75% in those with low-risk scores (age <60 years, stage I or II, one or fewer extranodal sites, normal LDH and good performance status) to 25% in those with high-risk scores (increasing age, advanced stage, concomitant disease and a raised LDH).

Relapse is associated with a poor response to further chemotherapy (<10% 5-year survival), but in patients under 65 years HSCT improves survival.

Paraproteinaemias

A gammopathy refers to over-production of one or more classes of immunoglobulin. It may be polyclonal in association with acute or chronic inflammation, such as infection, sarcoidosis, autoimmune disorders or some malignancies. Alternatively, a monoclonal increase in a single immunoglobulin class may occur in association with normal or reduced levels of the other immunoglobulins. Such monoclonal proteins (also called M-proteins, paraproteins or monoclonal gammopathies) occur as a feature of myeloma, lymphoma and amyloidosis, in connective tissue disease such as rheumatoid arthritis or polymyalgia rheumatica, in infection such as HIV, and in solid tumours. In addition, they may be present with no underlying disease. Gammopathies are detected by plasma immunoelectrophoresis.

Monoclonal gammopathy of uncertain significance

In monoclonal gammopathy of uncertain significance (MGUS, also known as benign monoclonal gammopathy), a paraprotein is present in the blood but there are no other features of myeloma, Waldenström macroglobulinaemia (see below), lymphoma or related disease. It is a common condition associated with increasing age; a paraprotein can be found in 1% of the population aged over 50 years, increasing to 5% over 80 years.

Clinical features and investigations

Patients are usually asymptomatic, and the paraprotein is found on blood testing for other reasons. The routine blood count and biochemistry are normal, the paraprotein is usually present in small amounts with no associated immune paresis, and there are no lytic bone lesions. The bone marrow may have increased plasma cells but these usually constitute less than 10% of nucleated cells.

Prognosis

After follow-up of 20 years, only one-quarter of cases will progress to myeloma or a related disorder (i.e. around 1% per annum). There is no certain way of predicting progression in an individual patient. However, an abnormal ratio of kappa to lambda light chains (serum free light chain ratio, SFLR) increases the risk of progression. Patients with an abnormal ratio should be monitored for progression on an annual basis.

Waldenström macroglobulinaemia

This is a low-grade lymphoplasmacytic lymphoma associated with an IgM paraprotein, causing clinical features of hyperviscosity syndrome. It is a rare tumour occurring in the elderly and more commonly affects males.

Patients classically present with features of hyperviscosity, such as nosebleeds, bruising, delirium and visual disturbance. However, presentation may be with anaemia, systemic symptoms, splenomegaly or lymphadenopathy, or may be asymptomatic, with an IgM paraprotein detected on routine screening. Patients are found on investigation to have an IgM paraprotein associated with a raised plasma viscosity. The bone marrow has a characteristic appearance, with infiltration of lymphoid cells, plasma cells and sometimes prominent mast cells. A high proportion of patients have a mutation in the *MYD88* gene.

Management

If patients show symptoms of hyperviscosity and anaemia, plasmapheresis is required to remove IgM and make blood transfusion possible. Chemotherapy with alkylating agents, such as chlorambucil, has been the mainstay of treatment, controlling disease in over 50%. Fludarabine may be more effective in this disease but has more side-effects. Rituximab in combination with chemotherapy is most commonly used; ibrutinib is very effective and has recently been licensed for use. Rituximab alone can cause a rapid release of IgM and increase in viscosity. The median survival is 5 years.

Multiple myeloma

This is a malignant proliferation of plasma cells. Normal plasma cells are derived from B cells and produce immunoglobulins that contain heavy and light chains. Normal immunoglobulins are polyclonal, which means that a variety of heavy chains are produced and each may be of kappa or lambda light chain type (p. 68). In myeloma, plasma cells produce immunoglobulin of a single heavy and light chain, a monoclonal protein commonly referred to as a paraprotein. In most cases an excess of light chain is produced, and in some cases only light chain is produced;

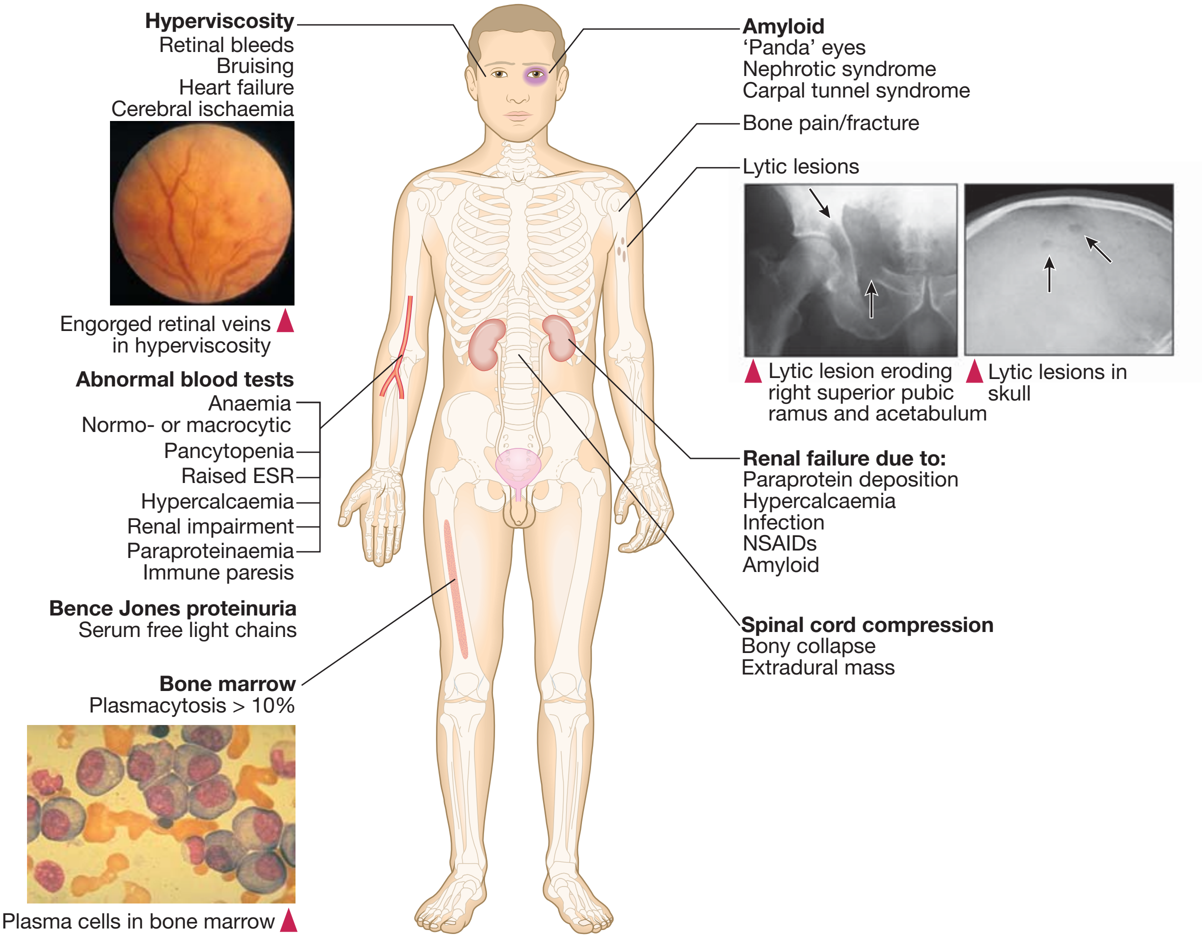

Fig. 23.31 Clinical and laboratory features of multiple myeloma. (ESR = erythrocyte sedimentation rate; NSAIDs = non-steroidal anti-inflammatory drugs)

i 23.58 Classification of multiple myeloma

Type of monoclonal (M)-protein	Relative frequency (%)
IgG	55
IgA	21
Light chain only	22
Others (D, E, non-secretory)	2

this appears in the urine as Bence Jones proteinuria and can be measured in the urine or serum as free light chain. The frequency of different isotypes of monoclonal protein in myeloma is shown in Box 23.58.

Although a small number of malignant plasma cells are present in the circulation, the majority are present in the bone marrow. The malignant plasma cells produce cytokines, which stimulate osteoclasts and result in net bone reabsorption. The resulting lytic lesions cause bone pain, fractures and hypercalcaemia. Marrow involvement can result in anaemia or pancytopenia.

Clinical features and investigations

The incidence of myeloma is 4/100 000 new cases per annum, with a male-to-female ratio of 2 : 1. The median age at diagnosis is 60–70 years and the disease is more common in Afro-Caribbeans. The clinical features are demonstrated in Figure 23.31.

Diagnosis of myeloma requires two of the following criteria to be fulfilled:

- increased malignant plasma cells in the bone marrow
- serum and/or urinary M-protein
- skeletal lytic lesions.

Bone marrow aspiration, plasma and urine electrophoresis, and a skeletal survey are thus required. Normal immunoglobulin levels, i.e. the absence of immunoparesis, should cast doubt on the diagnosis. Paraproteinaemia can cause an elevated ESR but this is a non-specific test; only approximately 5% of patients with a persistently elevated ESR above 100 mm/hr have underlying myeloma.

Management

If patients are asymptomatic with no evidence of end-organ damage (e.g. to kidneys, bone marrow or bone), treatment may not be required. So-called asymptomatic myeloma should be monitored closely for the development of end-organ damage.

Immediate support

- High fluid intake to treat renal impairment and hypercalcaemia (p. 661).
- Analgesia for bone pain.

23

- Bisphosphonates for hypercalcaemia and to delay other skeletal related events (p. 1047).
- Allopurinol to prevent urate nephropathy.
- Plasmapheresis, if necessary, for hyperviscosity.

Chemotherapy with or without HSCT

Myeloma therapy has improved with the addition of novel agents, initially thalidomide and more recently the proteasome inhibitor bortezomib and the second-generation immunomodulatory drug lenalidomide. For first-line therapy in older patients, thalidomide combined with the alkylating agent melphalan and prednisolone (MPT) has increased the median overall survival to more than 4 years. Lenalidomide is approved first-line treatment for patients not eligible for transplantation and who are intolerant of, or unsuitable for, thalidomide. Thalidomide and lenalidomide both have anti-angiogenic effects against tumour blood vessels and immunomodulatory effects. Both can cause somnolence, constipation, peripheral neuropathy and thrombosis, though lenalidomide has a better side-effect profile. It is vital that females of child-bearing age use adequate contraception, as thalidomide and lenalidomide are teratogenic. Treatment is administered until paraprotein levels have stopped falling. This is termed 'plateau phase' and can last for weeks or years.

In younger, fitter patients, standard treatment includes first-line therapies, such as cyclophosphamide, thalidomide and dexamethasone (CTD) or bortezomib (Velcade), thalidomide and dexamethasone (VTD) to maximum response, and then autologous HSCT, which improves quality of life and prolongs survival but does not cure myeloma. In all patients who have achieved maximal response, lenalidomide maintenance has been shown to prolong the response.

When myeloma progresses, treatment is given to induce a further plateau phase. In the UK, the proteosome inhibitor bortezomib and lenalidomide have been used as second- and third-line therapy, as appropriate. As they have been used more frequently in the first or second line with prognostic benefit, however, subsequent relapses are more difficult to treat. A second-generation proteasome inhibitor, carfilzomib, and the anti-CD38 antibody daratumumab show promise in relapsed/refractory disease. Responding patients may benefit from a second autologous HSCT.

Radiotherapy

This is effective for localised bone pain not responding to simple analgesia and for pathological fractures. It is also useful for the emergency treatment of spinal cord compression complicating extradural plasmacytomas.

Bisphosphonates

Long-term bisphosphonate therapy reduces bone pain and skeletal events. These drugs protect bone (p. 1047) and may cause apoptosis of malignant plasma cells. There is evidence that intravenous zoledronate in combination with anti-myeloma therapy confers a survival advantage over oral bisphosphonates. Osteonecrosis of the jaw may be associated with long-term use or poor oral hygiene and gum sepsis; regular dental review, including a check before starting therapy, is therefore important.

Prognosis

The international staging system (ISS) identifies poor prognostic features, including a high β_2-microglobulin and low albumin at diagnosis (ISS stage 3, median survival 29 months). Those with a normal albumin and a low β_2-microglobulin (ISS stage 1) have a median survival of 62 months. Increasingly, cytogenetic analysis is used to identify poor-risk patients, e.g. t(4;14), del(17/17p), t(14;16), t(14;20), non-hyperdiploidy and gain(1q). Use of autologous HSCT and advances in drug therapy with the newer agents have increased survival. Over one-third of patients are now surviving for 5 years, compared with only one-quarter 10 years ago. The outlook may improve further with new drugs and combinations of treatments.

23.59 Haematological malignancy in old age

- **Median age**: approximately 70 years for most haematological malignancies.
- **Poor-risk biological features**: adverse cytogenetics or the presence of a multidrug resistance phenotype are more frequent.
- **Prognosis**: increasing age is an independent adverse variable in acute leukaemia and aggressive lymphoma.
- **Chemotherapy**: may be less well tolerated. Older people are more likely to have antecedent cardiac, pulmonary or metabolic problems, tolerate systemic infection less well and metabolise cytotoxic drugs differently.
- **Cure rates**: similar to those in younger patients, in those who do tolerate treatment.
- **Decision to treat**: should be based on the individual's biological status, the level of social support available, and the patient's wishes and those of the immediate family, but not on chronological age alone.

Aplastic anaemias

Primary idiopathic acquired aplastic anaemia

This is a rare disorder in Europe and North America, with 2–4 new cases per million population per annum. The disease is much more common in certain other parts of the world, e.g. east Asia. The basic problem is failure of the pluripotent stem cells because of an autoimmune attack, producing hypoplasia of the bone marrow with a pancytopenia in the blood. The diagnosis rests on exclusion of other causes of secondary aplastic anaemia (see below) and rare congenital causes, such as Fanconi's anaemia.

Clinical features and investigations

Patients present with symptoms of bone marrow failure, usually anaemia or bleeding, and less commonly, infections. An FBC demonstrates pancytopenia, low reticulocytes and often macrocytosis. Bone marrow aspiration and trephine reveal hypocellularity. The severity of aplastic anaemia is graded according to the Camitta criteria (Box 23.60).

23.60 Camitta criteria

Severe AA (SAA)

- Marrow cellularity <25% (or 25–50% with <30% residual haematopoietic cells), plus at least two of:
  - Neutrophils $<0.5\times10^9$/L
  - Platelets $<20\times10^9$/L
  - Reticulocyte count $<20\times10^9$/L

Very severe AA (VSAA)

- As for SAA but neutrophils $<0.2\times10^9$/L

Non-severe AA (NSAA)

- AA not fulfilling the criteria for SAA or VSAA

Management

All patients will require blood product support and aggressive management of infection. The prognosis of severe aplastic anaemia managed with supportive therapy only is poor and more than 50% of patients die, usually in the first year. The curative treatment for patients under 35 years of age with severe idiopathic aplastic anaemia is allogeneic HSCT if there is an available sibling donor (p. 937). Older patients (35–50) may be candidates if they have no comorbidities (p. 937). Those with a compatible sibling donor should proceed to transplantation as soon as possible; they have a 75–90% chance of long-term cure. In older patients and those without a suitable donor, immunosuppressive therapy (IST) with anti-thymocyte globulin (ATG) and ciclosporin is the treatment of choice and gives 5-year survival rates of 75%. Unrelated donor allografts are considered for suitable patients who fail IST. The thrombopoietin receptor agonist eltrombopag (p. 971) has produced trilineage responses in patients who fail IST and is licensed for this indication. Non-transplanted patients may relapse or other clonal disorders of haematopoiesis may evolve, such as paroxysmal nocturnal haemoglobinuria (p. 950), myelodysplastic syndrome (p. 960) and AML (p. 955). Patients with aplastic anaemia must be followed up long-term.

Secondary aplastic anaemia

Causes of this condition are listed in Box 23.61. It is not practical to list all the drugs that have been suspected of causing aplasia. It is important to check the reported side-effects of all drugs taken over the preceding months. In some instances, the cytopenia is more selective and affects only one cell line, most often the neutrophils. Frequently, this is an incidental finding, with no ill health. It probably has an immune basis but this is difficult to prove.

23.61 Causes of secondary aplastic anaemia

- Drugs:
  - Cytotoxic drugs
  - Antibiotics – chloramphenicol, sulphonamides
  - Antirheumatic agents – penicillamine, gold, phenylbutazone, indometacin
  - Antithyroid drugs – carbimazole, propylthiouracil
  - Anticonvulsants
  - Immunosuppressants – azathioprine
- Chemicals:
  - Benzene, toluene solvent misuse – glue-sniffing
  - Insecticides – chlorinated hydrocarbons (DDT), organophosphates and carbamates (pp. 145 and 146)
- Radiation
- Viral hepatitis
- Pregnancy
- Paroxysmal nocturnal haemoglobinuria

The clinical features and methods of diagnosis are the same as for primary idiopathic aplastic anaemia. An underlying cause should be treated or removed, but otherwise management is as for the idiopathic form.

Myeloproliferative neoplasms

These make up a group of chronic conditions characterised by clonal proliferation of marrow precursor cells. Polycythaemia rubra vera (PRV), essential thrombocythaemia and myelofibrosis are the non-leukaemic myeloproliferative neoplasms. Although the majority of patients are classifiable as having one of these disorders, some have overlapping features and there is often progression from one to another, e.g. PRV to myelofibrosis. The recent discovery of the molecular basis of these disorders will lead to changes in classification and treatment; a mutation in the gene on chromosome 9 encoding the signal transduction molecule *JAK-2* has been found in more than 90% of PRV cases and 50% of those with essential thrombocythaemia and myelofibrosis. Mutations in the calreticulin gene (*CALR*), which produces a chaperone protein that protects proteins moving from the endoplasmic reticulin to the cytoplasm, have been found in a further 25% of patients with essential thrombocythaemia. Less commonly, mutations can be detected in the thrombopoietin receptor gene *MPL*.

Myelofibrosis

In myelofibrosis, the marrow is initially hypercellular, with an excess of abnormal megakaryocytes that release growth factors, such as platelet-derived growth factor, to the marrow microenvironment, resulting in a reactive proliferation of fibroblasts. As the disease progresses, the marrow becomes fibrosed.

Most patients present over the age of 50 years, with lassitude, weight loss and night sweats. The spleen can be massively enlarged due to extramedullary haematopoiesis (blood cell formation outside the bone marrow), and painful splenic infarcts may occur.

The characteristic blood picture is leucoerythroblastic anaemia, with circulating immature red blood cells (increased reticulocytes and nucleated red blood cells) and granulocyte precursors (myelocytes). The red cells are shaped like teardrops (teardrop poikilocytes), and giant platelets may be seen in the blood. The white count varies from low to moderately high and the platelet count may be high, normal or low. Urate levels may be high due to increased cell breakdown, and folate deficiency is common. The marrow is often difficult to aspirate and a trephine biopsy shows an excess of megakaryocytes, increased reticulin and fibrous tissue replacement. The presence of a *JAK-2* mutation supports the diagnosis.

Management and prognosis

Median survival is 4 years from diagnosis, but ranges from 1 year to over 20 years. Treatment is directed at control of symptoms, e.g. red cell transfusions for anaemia. Folic acid should be given to prevent deficiency. Cytotoxic therapy with hydroxycarbamide may help control spleen size, the white cell count or systemic symptoms. Splenectomy may be required for a grossly enlarged spleen or symptomatic pancytopenia secondary to splenic pooling of cells and hypersplenism. HSCT may be considered for younger patients. Ruxolitinib, an inhibitor of *JAK-2*, is now licensed in myelofibrosis and is effective at reducing systemic symptoms and splenomegaly.

Essential thrombocythaemia

Uncontrolled proliferation of megakaryocytes results in a raised level of circulating platelets that are often dysfunctional. Prior to a diagnosis of essential thrombocythaemia being made, reactive causes of thrombocytosis must be excluded (see Box 23.15). The presence of a *JAK-2, CALR* or, rarely, *MPL* mutation supports the diagnosis but is not universal. Patients present at a median age of 60 years with vascular occlusion or bleeding, or with an asymptomatic isolated raised platelet count. A small

percentage (around 5%) will transform to acute leukaemia and others to myelofibrosis.

It is likely that most patients with essential thrombocythaemia benefit from low-dose aspirin to reduce the risk of occlusive vascular events. Low-risk patients (age <40 years, platelet count $<1500\times10^9$/L and no bleeding or thrombosis) may not require treatment to reduce the platelet count. For those with a platelet count above 1500×10^9/L, with symptoms, or with other risk factors for thrombosis such as diabetes or hypertension, treatment to control platelet counts should be given. Agents include oral hydroxycarbamide or anagrelide, an inhibitor of megakaryocyte maturation. Intravenous radioactive phosphorus (^{32}P) may be useful in old age and interferon-alfa has a role in younger patients.

Polycythaemia rubra vera

PRV occurs mainly in patients over the age of 40 years and presents either as an incidental finding of a high haemoglobin, or with symptoms of hyperviscosity, such as lassitude, loss of concentration, headaches, dizziness, blackouts, pruritus and epistaxis. Some patients present with manifestations of peripheral arterial or cerebrovascular disease. Venous thromboembolism may also occur. Peptic ulceration is common, sometimes complicated by bleeding. Patients are often plethoric and many have a palpable spleen at diagnosis.

Investigation of polycythaemia is discussed on page 925. The diagnosis of PRV now rests on the demonstration of a high haematocrit and the presence of the *JAK-2 V617F* mutation (positive in 95% of cases). In the occasional *JAK-2*-negative cases, a raised red cell mass and absence of causes of a secondary erythrocytosis must be established. The spleen may be enlarged and neutrophil and platelet counts are frequently raised, an abnormal karyotype may be found in the marrow, and in vitro culture of the marrow can be used to demonstrate autonomous growth in the absence of added growth factors.

Management and prognosis

Aspirin reduces the risk of thrombosis. Venesection gives prompt relief of hyperviscosity symptoms. Between 400 and 500 mL of blood (less if the patient is elderly) are removed and the venesection is repeated every 5–7 days until the haematocrit is reduced to below 45%. Less frequent but regular venesection will maintain this level until the haemoglobin remains reduced because of iron deficiency.

Suppression of marrow proliferation with hydroxycarbamide or interferon-alfa may reduce the risk of vascular occlusion, control spleen size and reduce transformation to myelofibrosis. Intravenous ^{32}P, which is reserved for older patients as it increases the risk of transformation to acute leukaemia by 6–10-fold, is rarely used now in Europe and North America.

Median survival after diagnosis in treated patients exceeds 10 years. Some patients survive more than 20 years; however, cerebrovascular or coronary events occur in up to 60% of patients. The disease may convert to another myeloproliferative disorder, with about 15% developing acute leukaemia or myelofibrosis.

Bleeding disorders

Disorders of primary haemostasis

The initial formation of the platelet plug (see Fig. 23.6A, p. 918; also known as 'primary haemostasis') may fail in thrombocytopenia (p. 929), von Willebrand disease (p. 974), and also in platelet function disorders and diseases affecting the vessel wall.

Vessel wall abnormalities

Vessel wall abnormalities may be:

- congenital, such as hereditary haemorrhagic telangiectasia
- acquired, as in a vasculitis (p. 1040) or scurvy.

Hereditary haemorrhagic telangiectasia

Hereditary haemorrhagic telangiectasia (HHT) is a dominantly inherited condition caused by mutations in the genes encoding endoglin and activin receptor-like kinase, which are endothelial cell receptors for transforming growth factor-beta (TGF-β), a potent angiogenic cytokine. Telangiectasia and small aneurysms are found on the fingertips, face and tongue, and in the nasal passages, lung and gastrointestinal tract. A significant proportion of these patients develop larger pulmonary arteriovenous malformations (PAVMs) that cause arterial hypoxaemia due to a right-to-left shunt. These predispose to paradoxical embolism, resulting in stroke or cerebral abscess. All patients with HHT should be screened for PAVMs; if these are found, ablation by percutaneous embolisation should be considered.

Patients present either with recurrent bleeds, particularly epistaxis, or with iron deficiency due to occult gastrointestinal bleeding. Treatment can be difficult because of the multiple bleeding points but regular iron therapy often allows the marrow to compensate for blood loss. Local cautery or laser therapy may prevent single lesions from bleeding. A variety of medical therapies have been tried but none has been found to be universally effective.

Ehlers–Danlos disease

Vascular Ehlers–Danlos syndrome (type 4) is a rare autosomal dominant disorder (1/100 000) caused by a defect in type 3 collagen that results in fragile blood vessels and organ membranes, leading to bleeding and organ rupture. Classical joint hypermobility (p. 1059) is often limited in this form of the disease but skin changes and facial appearance are typical. The diagnosis should be considered when there is a history of bleeding with normal laboratory tests.

Scurvy

Vitamin C deficiency affects the normal synthesis of collagen and results in a bleeding disorder characterised by perifollicular and petechial haemorrhage, bruising and subperiosteal bleeding. The key to diagnosis is the dietary history (p. 715).

Platelet function disorders

Bleeding may result from thrombocytopenia (see Box 23.14, p. 929) or from congenital or acquired abnormalities of platelet function. The most common acquired disorders are iatrogenic, resulting from the use of aspirin, clopidogrel, ticagrelor, dipyridamole and the glycoprotein IIb/IIIa inhibitors to prevent arterial thrombosis (see Box 23.26, p. 938). Inherited platelet function abnormalities are relatively rare. Congenital abnormalities may be due to deficiency of the membrane glycoproteins, e.g. Glanzmann's thrombasthenia (IIb/IIIa) or Bernard–Soulier syndrome (Ib), or due to the presence of defective platelet granules, e.g. a deficiency of dense (delta) granules (see Fig. 23.7, p. 920) giving rise to storage pool disorders. The congenital macrothrombocytopathies that are due to mutations in the myosin heavy chain gene *MYH-9* are characterised by large platelets,

inclusion bodies in the neutrophils (Döhle bodies) and a variety of other features, including sensorineural deafness and renal abnormalities. Other familial thrombocytopathies are important, as they can be associated with somatic features, and some are associated with a propensity for development of bone marrow failure or dysplasia (e.g. *RUNX-1*-associated thrombocytopenia).

Apart from Glanzmann's thrombasthenia, these conditions are mild disorders, with bleeding typically occurring after trauma or surgery, but rarely spontaneous. Glanzmann's thrombasthenia is an autosomal recessive condition associated with a variable but often severe bleeding disorder. These conditions are usually managed by local mechanical measures, but antifibrinolytics, such as tranexamic acid, may be useful and, in severe bleeding, platelet transfusion may be required. Recombinant VIIa is licensed for the treatment of resistant bleeding in Glanzmann's thrombasthenia.

Thrombocytopenia

Thrombocytopenia occurs in many disease processes, as listed in Box 23.14 (p. 929), many of which are discussed elsewhere in this chapter.

Idiopathic thrombocytopenic purpura

Idiopathic thrombocytopenic purpura (ITP) is immune-mediated with involvement of autoantibodies, most often directed against the platelet membrane glycoprotein IIb/IIIa, which sensitise the platelet, resulting in premature removal from the circulation by cells of the reticulo-endothelial system. It is not a single disorder; some cases occur in isolation while others are associated with underlying immune dysregulation in conditions such as connective tissue diseases, HIV infection, B-cell malignancies, pregnancy and certain drug therapies. The clinical presentation and pathogenesis are similar, however, whatever the cause of ITP.

Clinical features and investigations

The presentation depends on the degree of thrombocytopenia. Spontaneous bleeding typically occurs only when the platelet count is below 20×10^9/L. At higher counts, the patient may complain of easy bruising or sometimes epistaxis or menorrhagia. Many cases with counts of more than 50×10^9/L are discovered by chance.

In adults, ITP more commonly affects females and may have an insidious onset. Unlike ITP in children, it is unusual for there to be a history of a preceding viral infection. Symptoms or signs of a connective tissue disease may be apparent at presentation or emerge several years later. Patients aged over 65 years should be considered for a bone marrow examination to look for an accompanying B-cell malignancy, and appropriate autoantibody testing performed if a diagnosis of connective tissue disease is likely. HIV testing should be considered because a positive result will have major implications for appropriate therapy. The peripheral blood film is normal, apart from a greatly reduced platelet number, while the bone marrow reveals an obvious increase in megakaryocytes.

Management

Many patients with stable compensated ITP and a platelet count of more than 30×10^9/L do not require treatment to raise the platelet count, except at times of increased bleeding risk, such as surgery and biopsy. First-line therapy for patients with spontaneous bleeding is with high doses of glucocorticoids, either prednisolone (1 mg/kg daily) or dexamethasone (40 mg daily for 4 days), to suppress antibody production and inhibit phagocytosis of sensitised platelets by reticulo-endothelial cells. Administration of intravenous immunoglobulin can raise the platelet count by blocking antibody receptors on reticulo-endothelial cells, and is combined with glucocorticoid therapy if there is severe haemostatic failure, especially with evidence of significant mucosal bleeding or a slow response to glucocorticoids alone. Persistent or potentially life-threatening bleeding should be treated with platelet transfusion in addition to the other therapies.

The condition may become chronic, with remissions and relapses. Relapses should be treated by re-introducing glucocorticoids. If a patient has two relapses or primary refractory disease, second-line therapies are considered. The options for second-line therapy include the thrombopoietin receptor agonists (TPO-RA) eltrombopag and romiplostim, splenectomy and immunosuppression. Where splenectomy is considered, the precautions shown in Box 23.40 need to be in place. Splenectomy produces complete remission in about 70% of patients and improvement in a further 20–25% in favourable cases. The TPO-RAs induce response in around 75% of cases, usually within 10–14 days. Low-dose glucocorticoid therapy and immunosuppressants such as rituximab, ciclosporin, mycophenolate and tacrolimus may also produce remissions. The order in which therapies should be used is not entirely clear, although the TPO-RAs are licensed for this indication while the immunosuppressive agents are not.

Coagulation disorders

Normal coagulation is explained in Figure 23.6 (p. 918). Coagulation factor deficiency may be congenital or acquired, and may affect one or several of the coagulation factors (Box 23.62). Inherited disorders are almost uniformly related to decreased synthesis, as a result of mutation in the gene encoding a key protein in coagulation. Von Willebrand disease is the most common inherited bleeding disorder. Haemophilia A and B are the most common single coagulation factor deficiencies but inherited deficiencies of all the other coagulation factors are seen. Acquired disorders may be due to under-production (e.g. in liver failure), increased consumption (e.g. in DIC) or inhibition of function of coagulation factors (such as heparin therapy or immune inhibitors of coagulation, e.g. acquired haemophilia A).

Haemophilia A

Factor VIII deficiency resulting in haemophilia A affects 1/10 000 individuals. It is the most common congenital coagulation factor deficiency. Factor VIII is primarily synthesised by the liver and endothelial cells and has a half-life of about 12 hours. It is protected from proteolysis in the circulation by binding to von Willebrand factor (vWF).

Genetics

The factor VIII gene is located on the X chromosome. Haemophilia is associated with a range of mutations in the factor VIII gene; these include major inversions, large deletions and missense, nonsense and splice site abnormalities. As the factor VIII gene is on the X chromosome, haemophilia A is a sex-linked disorder (p. 48). Thus all daughters of a patient with haemophilia are obligate carriers and they, in turn, have a 1 in 4 chance of each pregnancy resulting in the birth of an affected male baby, a normal male baby, a carrier female or a normal female. Antenatal diagnosis by chorionic villous sampling is possible in families with a known mutation.

23.62 Causes of coagulopathy

Congenital

X-linked
- Haemophilia A and B

Autosomal
- Von Willebrand disease
- Factor II, V, VII, X, XI and XIII deficiencies
- Combined II, VII, IX and X deficiency
- Combined V and VIII deficiency
- Hypofibrinogenaemia
- Dysfibrinogenaemia

Acquired

Under-production
- Liver failure
- Vitamin K deficiency

Increased consumption
- Coagulation activation:
  Disseminated intravascular coagulation (DIC)
- Immune-mediated:
  Acquired haemophilia and von Willebrand disease
- Others:
  Acquired factor X deficiency (in amyloid)
  Acquired von Willebrand disease in Wilms' tumour
  Acquired factor VII deficiency in sepsis

Drug-induced
- Inhibition of function:
  Heparins
  Argatroban
  Bivalirudin
  Fondaparinux
  Rivaroxaban
  Apixaban
  Dabigatran
  Edoxaban
- Inhibition of post-translational modification:
  Warfarin

23.63 Severity of haemophilia (ISTH criteria)

Severity	Factor VIII or IX level	Clinical presentation
Severe	<0.01 U/mL	Spontaneous haemarthroses and muscle haematomas
Moderate	0.01–0.05 U/mL	Mild trauma or surgery causes bleeding
Mild	> 0.05–0.4 U/mL	Major injury or surgery results in excess bleeding

(ISTH = International Society on Thrombosis and Haemostasis)

Haemophilia 'breeds true' within a family; all members have the same factor VIII gene mutation and a similarly severe or mild phenotype. Female carriers of haemophilia may have reduced factor VIII levels because of random inactivation of their normal X chromosome in the developing fetus (p. 49). This can result in a mild bleeding disorder; thus all known or suspected carriers of haemophilia A should have their factor VIII level measured.

Clinical features

The extent and patterns of bleeding are closely related to residual factor VIII levels (Box 23.63). Patients with severe haemophilia (factor VIII levels <0.01 U/mL) present with spontaneous bleeding into skin, muscle and joints. Retroperitoneal and intracranial bleeding is also a feature. Babies with severe haemophilia have an increased risk of intracranial haemorrhage and, although there is insufficient evidence to recommend routine caesarean section for these births, it is appropriate to avoid head trauma and to perform imaging of the newborn within the first 24 hours of life. Individuals with moderate and mild haemophilia (factor VIII levels 0.01–0.4 U/mL) present with the same pattern of bleeding but usually after trauma or surgery, when bleeding is disproportionate to the severity of the insult.

The major morbidity of recurrent bleeding in severe haemophilia is musculoskeletal. Bleeding is typically into large joints, especially knees, elbows, ankles and hips. Muscle haematomas are also characteristic, most commonly in the calf and psoas muscles. If early treatment is not given to arrest bleeding, a hot, swollen and very painful joint or muscle haematoma develops. Recurrent bleeding into joints leads to synovial hypertrophy, destruction of the cartilage and chronic haemophilic arthropathy (Fig. 23.32). Complications of muscle haematomas depend on their location. A large psoas bleed may extend to compress the femoral nerve; calf haematomas may increase pressure within the inflexible fascial sheath, causing a compartment syndrome with ischaemia, necrosis, fibrosis, and subsequent contraction and shortening of the Achilles tendon.

Management

The key to the management of severe haemophilia A (and B; p. 974) in more affluent countries is prophylactic coagulation factor replacement. The aim of this treatment is to maintain trough levels of factor VIII (or IX in the case of haemophilia B) above 0.02 U/mL. Doing this substantially reduces the number of bleeding episodes for men with severe haemophilia and so reduces the rate of deterioration of joints, which is the major long-term morbidity. Prophylaxis can be provided in many different ways: daily, on alternate days, or on information from pharmacokinetic studies that inform on the best way of scheduling prophylaxis. Practice in haemophilia A and B is in the process of changing somewhat due to the introduction of a variety of recombinant factor concentrates that have been manipulated to alter their half-life. In addition to standard half-life recombinant factor VIII, there are new products produced by Fc fusion and pegylation/glycopegylation that extend the half-life of factor VIII to the degree that it can be used to alter dosing schedules for prophylaxis.

The alternative approach, which still needs to be used in less affluent countries, is to treat on demand. In severe haemophilia A, bleeding episodes should be treated by raising the factor VIII level, usually by intravenous infusion of factor VIII concentrate. Factor VIII concentrates are freeze-dried and stable at 4°C and can therefore be stored in domestic refrigerators, allowing patients to treat themselves at home at the earliest indication of bleeding. Factor VIII concentrate prepared from blood donor plasma is now screened for HBV, HCV and HIV, and undergoes two separate virus inactivation processes during manufacture; these preparations have a good safety record. However, factor VIII concentrates prepared by recombinant technology are now widely available and, although more expensive, are perceived as being safer than those derived from human plasma in relation to infection risk. In addition to raising factor VIII concentrations, resting of the bleeding site with either bed rest or a splint reduces continuing haemorrhage. Once bleeding has settled, the patient should be mobilised and physiotherapy used to restore strength to the surrounding muscles. All non-immune potential recipients

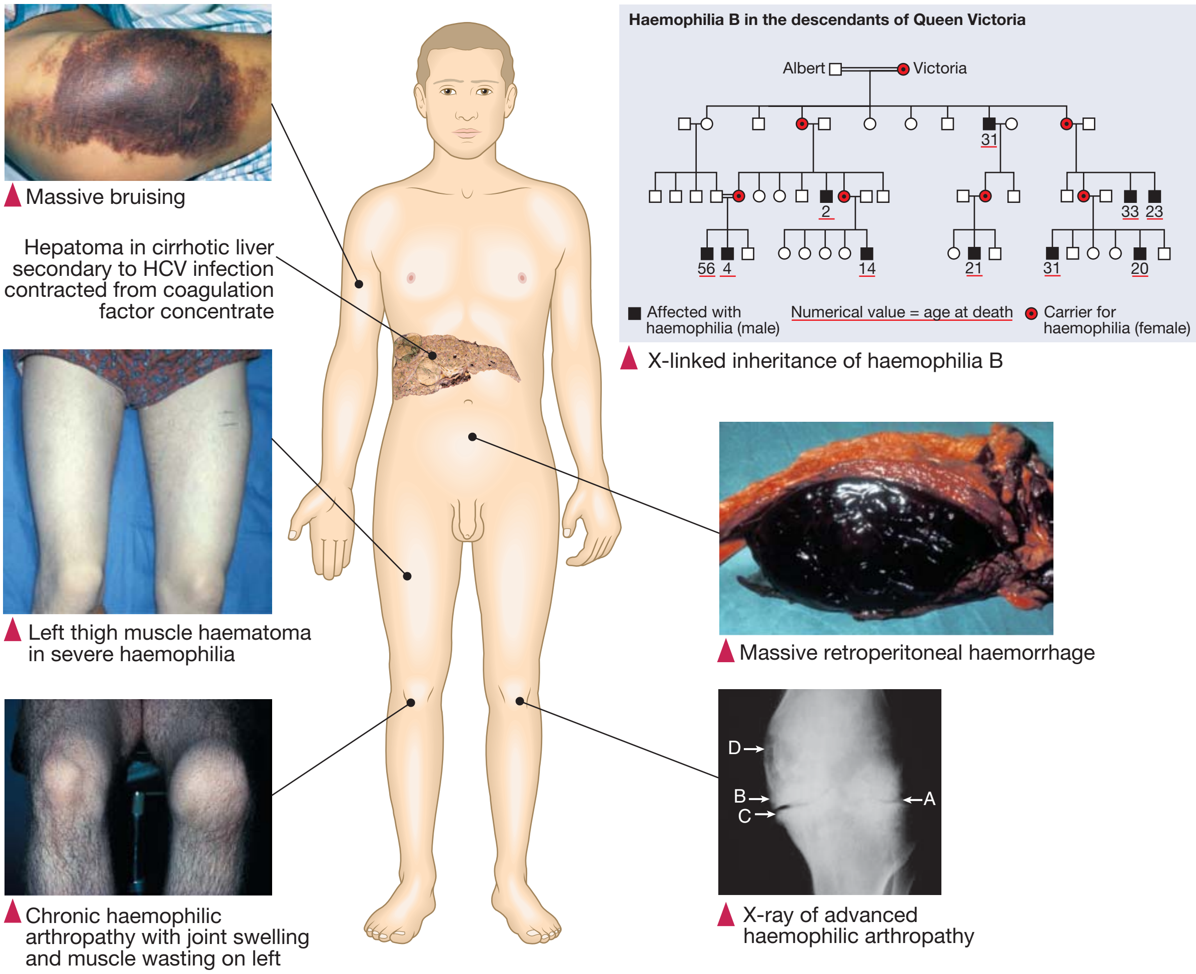

Fig. 23.32 Clinical manifestations of haemophilia. On the knee X-ray, repeated bleeds have led to broadening of the femoral epicondyles, and there is no cartilage present, as evidenced by the close proximity of the femur and tibia (A); sclerosis (B), osteophyte (C) and bony cysts (D) are present. (HCV = hepatitis C virus) *Inset (Massive bruising) From Hoffbrand VA. Color atlas of clinical hematology, 3rd edn. Philadelphia: Mosby, Elsevier Inc.; 2000.*

of pooled blood products should be offered hepatitis A and B immunisation.

The vasopressin receptor agonist desmopressin (p. 688) raises the vWF and factor VIII levels 3–4-fold, which is useful in arresting bleeding in patients with mild or moderate haemophilia A. The dose required for this purpose is higher than that used in diabetes insipidus, usually 0.3 µg/kg, and is given intravenously or subcutaneously. Alternatively, the same effect can be achieved by intranasal administration of 300 µg. Following repeated administration of desmopressin, patients need to be monitored for evidence of water retention, which can result in significant hyponatraemia. Desmopressin is contraindicated in patients with a history of severe arterial disease because of a propensity to provoke a thrombotic event, and in young children where hyponatraemia can result in fits.

Complications of coagulation factor therapy

Before 1986, coagulation factor concentrates from human plasma were not virally inactivated and many patients became infected with HIV and HBV/HCV. In patients with haemophilia treated with pooled concentrates that were not virally inactivated before 1988, infection with HCV is almost universal, 80–90% have evidence of HBV exposure, and 60% became HIV-positive. Management is described in Chapters 22 and 12.

Concern that the infectious agent that causes vCJD (p. 1127) might be transmissible by blood and blood products has been confirmed in recipients of red cell transfusion (p. 931), and in one recipient of factor VIII. Pooled plasma products, including factor VIII concentrate, are now manufactured from plasma collected in countries with a low incidence of bovine spongiform encephalopathy.

Another serious complication of factor VIII infusion is the development of anti-factor VIII antibodies, which arise in about 20% of those with severe haemophilia. Such antibodies rapidly neutralise therapeutic infusions, making treatment relatively ineffective. Infusions of activated clotting factors, e.g. VIIa or factor VIII inhibitor bypass activity (FEIBA), may stop bleeding.

Haemophilia B (Christmas disease)

Aberrations of the factor IX gene, which is also present on the X chromosome, result in a reduction of the plasma factor IX level, giving rise to haemophilia B. This disorder is clinically indistinguishable from haemophilia A but is less common. The

frequency of bleeding episodes is related to the severity of the deficiency of the plasma factor IX level. Treatment is with a factor IX concentrate, used in much the same way as factor VIII for haemophilia A. The new extended half-life recombinant factor IX products made by Fc fusion, albumin fusion and pegylation offer the possibility of prophylaxis on a once-weekly or even two-weekly schedule. Although factor IX concentrates shared the problems of virus transmission seen with factor VIII, they do not commonly induce inhibitor antibodies (<1% patients); when this does occur, however, it may be heralded by the development of a severe allergic-type reaction.

Von Willebrand disease

Von Willebrand disease is a common but usually mild bleeding disorder caused by a quantitative (types 1 and 3) or qualitative (type 2) deficiency of von Willebrand factor (vWF). This protein is synthesised by endothelial cells and megakaryocytes, and is involved in both platelet function and coagulation. It normally forms a multimeric structure that is essential for its interaction with subendothelial collagen and platelets (see Fig. 23.7, p. 920). vWF acts as a carrier protein for factor VIII, to which it is non-covalently bound; deficiency of vWF lowers the plasma factor VIII level. vWF also forms bridges between platelets and subendothelial components (e.g. collagen; see Fig. 23.6B, p. 918), allowing platelets to adhere to damaged vessel walls; deficiency of vWF therefore leads to impaired platelet plug formation. Blood group antigens (A and B) are expressed on vWF, reducing its susceptibility to proteolysis; as a result, people with blood group O have lower circulating vWF levels than individuals with non-O groups. This needs to be borne in mind when making a diagnosis of von Willebrand disease.

Most patients with von Willebrand disease have a type 1 disorder, characterised by a quantitative decrease in a normal functional protein. Patients with type 2 disorders inherit vWF molecules that are functionally abnormal. The type of abnormality depends on the site of the mutation in the *vWD* gene and how it affects binding to platelets, collagen and factor VIII. Patients with type 2A disease have abnormalities in vWF-dependent platelet adhesion; those with mutations in the platelet glycoprotein Ib binding site, resulting in increased affinity for glycoprotein 1b, have type 2B disease; those with mutations in the factor VIII binding site have type 2N disease; and those with other abnormalities in platelet binding but with normal vWF multimeric structure have type 2M disease. The patterns of laboratory abnormality accompanying these types are described in Box 23.64. The gene for vWF is located on chromosome 12 and the disease is usually autosomal dominantly inherited, except in type 2N and type 3, where inheritance is autosomal recessive.

Clinical features

Patients present with haemorrhagic manifestations similar to those in individuals with reduced platelet function. Superficial bruising, epistaxis, menorrhagia and gastrointestinal haemorrhage are common. Bleeding episodes are usually much less frequent than in severe haemophilia, and excessive haemorrhage may be observed only after trauma or surgery. Within a single family, the disease has variable penetrance, so that some members may have quite severe and frequent bleeds, whereas others are relatively asymptomatic.

Investigations

The disorder is characterised by reduced activity of vWF and factor VIII. The disease can be classified using a combination of assays that include functional and antigenic measures of vWF, multimeric analysis of the protein, and specific tests of function to determine binding to platelet glycoprotein Ib (RIPA) and factor VIII (Box 23.64). In addition, analysis for mutations in the *vWF* gene is informative in most cases.

23.64 Classification of von Willebrand disease

Type	Defect	Inheritance	Investigations/patterns
1	Partial quantitative	AD	Parallel decrease in vWF:Ag, RiCoF and VIII:c
2A	Qualitative	AD	Absent HWM of vWF Ratio of vWF activity to antigen <0.7
2B	Qualitative	AD	Reduced HWM of vWF Enhanced platelet agglutination (RIPA)
2M	Qualitative	AD	Ratio of vWF activity to antigen ≪0.7 Normal multimers of vWF Abnormal vWF/platelet interactions
2N	Qualitative	AR	Defective binding of vWF to VIII Low VIII
3	Severe quantitative	AR or CH	Very low vWF and VIII:c activity Absent multimers

(AD = autosomal dominant; AR = autosomal recessive; CH = compound heterozygote; HWM = high-weight multimers of vWF; RiCoF = ristocetin co-factor; RIPA = ristocetin-induced platelet agglutination; VIII:c = coagulation factor VIII activity in functional assay; vWF = von Willebrand factor; vWF:Ag = vWF antigen measured by ELISA)

Management

Many episodes of mild haemorrhage can be successfully treated by local means or with desmopressin, which raises the vWF level, resulting in a secondary increase in factor VIII. Tranexamic acid may be useful in mucosal bleeding. For more serious or persistent bleeds, haemostasis can be achieved with selected factor VIII concentrates, which contain considerable quantities of vWF in addition to factor VIII. Young children and patients with severe arterial disease should not receive desmopressin, and patients with type 2B disease develop thrombocytopenia that may be troublesome following desmopressin. Bleeding in type 3 patients responds only to factor VIII/vWF concentrate.

Rare inherited bleeding disorders

Severe deficiencies of factor VII, X and XIII occur as autosomal recessive disorders. They are rare but are associated with severe bleeding. Typical features include haemorrhage from the umbilical stump and intracranial haemorrhage. Factor XIII deficiency in women is typically associated with recurrent fetal loss.

Factor XI deficiency may occur in heterozygous or homozygous individuals. Bleeding is very variable and is not accurately predicted by coagulation factor levels. In general, severe bleeding is confined to patients with levels below 15% of normal.

Acquired bleeding disorders

DIC is an important cause of bleeding that begins with exaggerated and inappropriate intravascular coagulation. It is discussed under thrombotic disease on page 978.

Liver disease

Although, traditionally, severe parenchymal liver disease (Ch. 22) has been described as a state associated with an excess of bleeding, it is now clear that these patients also have an increased risk of venous thrombosis. Although there is reduced hepatic synthesis of procoagulant factors, this is balanced to a degree by the reduced production of natural anticoagulant proteins and reduced fibrinolytic activity in patients with advanced liver disease. In severe parenchymal liver disease, bleeding may arise from many different causes. Pathological sources of potential major bleeding, such as oesophageal varices or peptic ulcer, are common. There is reduced hepatic synthesis, for example, of factors V, VII, VIII, IX, X, XI, prothrombin and fibrinogen. Clearance of plasminogen activator is reduced. Thrombocytopenia may occur secondary to hypersplenism in portal hypertension. In cholestatic jaundice, there is reduced vitamin K absorption, leading to deficiency of factors II, VII, IX and X, but also of proteins C and S. Treatment with plasma products or platelet transfusion should be reserved for acute bleeds or to cover interventional procedures such as liver biopsy. Vitamin K deficiency can be readily corrected with parenteral administration of vitamin K.

Renal failure

The severity of the haemorrhagic state in renal failure is proportional to the plasma urea concentration. Bleeding manifestations are those of platelet dysfunction, with gastrointestinal haemorrhage being particularly common. The causes are multifactorial and include anaemia, mild thrombocytopenia and the accumulation of low-molecular-weight waste products, normally excreted by the kidney, that inhibit platelet function. Treatment is by dialysis to reduce the urea concentration. Rarely, in severe or persistent bleeding, platelet concentrate infusions and red cell transfusions are indicated. Increasing the concentration of vWF, either by cryoprecipitate or by desmopressin, may promote haemostasis.

Thrombotic disorders

Venous thromboembolic disease (venous thromboembolism)

While the most common presentations of venous thromboembolism (VTE) are deep vein thrombosis (DVT) of the leg (p. 186) and/or pulmonary embolism (PE; see also p. 619), similar management principles apply to rarer manifestations such as jugular vein thrombosis, upper limb DVT, cerebral sinus thrombosis (p. 1128) and intra-abdominal venous thrombosis (e.g. Budd–Chiari syndrome; p. 898).

VTE has an annual incidence of approximately 1 : 1000 in Western populations. The relative incidence of DVT:PE is approximately 2 : 1. Mortality 30 days after DVT is approximately 10%, compared to 15% for PE. All forms of VTE are increasingly common with age and many of the deaths are related to coexisting medical conditions, such as active cancer or inflammatory disease, which predispose the patient to thrombosis in the first place. Risk factors for VTE are often present (Box 23.65) and it is appropriate to seek evidence of these risk factors in determining the long-term management strategy. Figure 23.33 illustrates some of the causes and consequences of VTE. The diagnosis of DVT and PE are discussed on pages 187 and 619, respectively.

23.65 Factors predisposing to venous thrombosis

Patient factors
- Increasing age
- Obesity
- Varicose veins
- Previous deep vein thrombosis
- Family history, especially of unprovoked venous thromboembolism when young
- Transient additional risk factors:
  - Pregnancy/puerperium
  - Oestrogen-containing oral contraceptives and hormone replacement therapy
  - Immobility, e.g. long-distance travel (>4 hrs)
  - Intravenous drug use involving the femoral vein
  - Surgery (see below)
  - Medical illnesses (see below)

Surgical conditions
- Major surgery, especially if >30 mins' duration
- Abdominal or pelvic surgery, especially for cancer
- Major lower limb orthopaedic surgery, e.g. joint replacement and hip fracture surgery

Medical conditions
- Myocardial infarction/heart failure
- Inflammatory bowel disease
- Malignancy (anti-cancer chemotherapy increases the risk of venous thromboembolism compared with cancer alone)
- Nephrotic syndrome
- Chronic obstructive pulmonary disease
- Pneumonia
- Neurological conditions associated with immobility, e.g. stroke, paraplegia, Guillain–Barré syndrome
- Any high-dependency admission

Haematological disorders
- Polycythaemia rubra vera
- Essential thrombocythaemia
- Deficiency of natural anticoagulants: antithrombin, protein C, protein S
- Paroxysmal nocturnal haemoglobinuria
- Gain-of-function prothrombotic mutations: factor V Leiden, prothrombin gene *G20210A*
- Myelofibrosis

Antiphospholipid syndrome

23

Management of VTE

The mainstay of treatment for all forms of VTE is anticoagulation. This can be achieved in several ways. One option is to use LMWH followed by a coumarin anticoagulant, such as warfarin. Treatment of acute VTE with LMWH should continue for a minimum of 5 days. Patients treated with warfarin should achieve a target INR of 2.5 (range 2–3; pp. 922 and 938) with LMWH continuing until the INR is above 2. Alternatively, patients may be treated with a DOAC. Rivaroxaban and apixaban may be used immediately from diagnosis without the need for LMWH, while the licences for dabigatran and edoxaban include initial treatment with LMWH for a minimum of 5 days before commencing the DOAC. In patients with active cancer and VTE, there is evidence that maintenance anticoagulation with LMWH is associated with a lower recurrence rate than warfarin. Patients who have had VTE and have a strong contraindication to anticoagulation and those who continue to have new pulmonary emboli despite therapeutic anticoagulation should have an inferior vena cava (IVC) filter inserted to prevent life-threatening PE (p. 619).

The optimal *initial* period of anticoagulation is between 6 weeks and 6 months. Patients with a provoked VTE in the

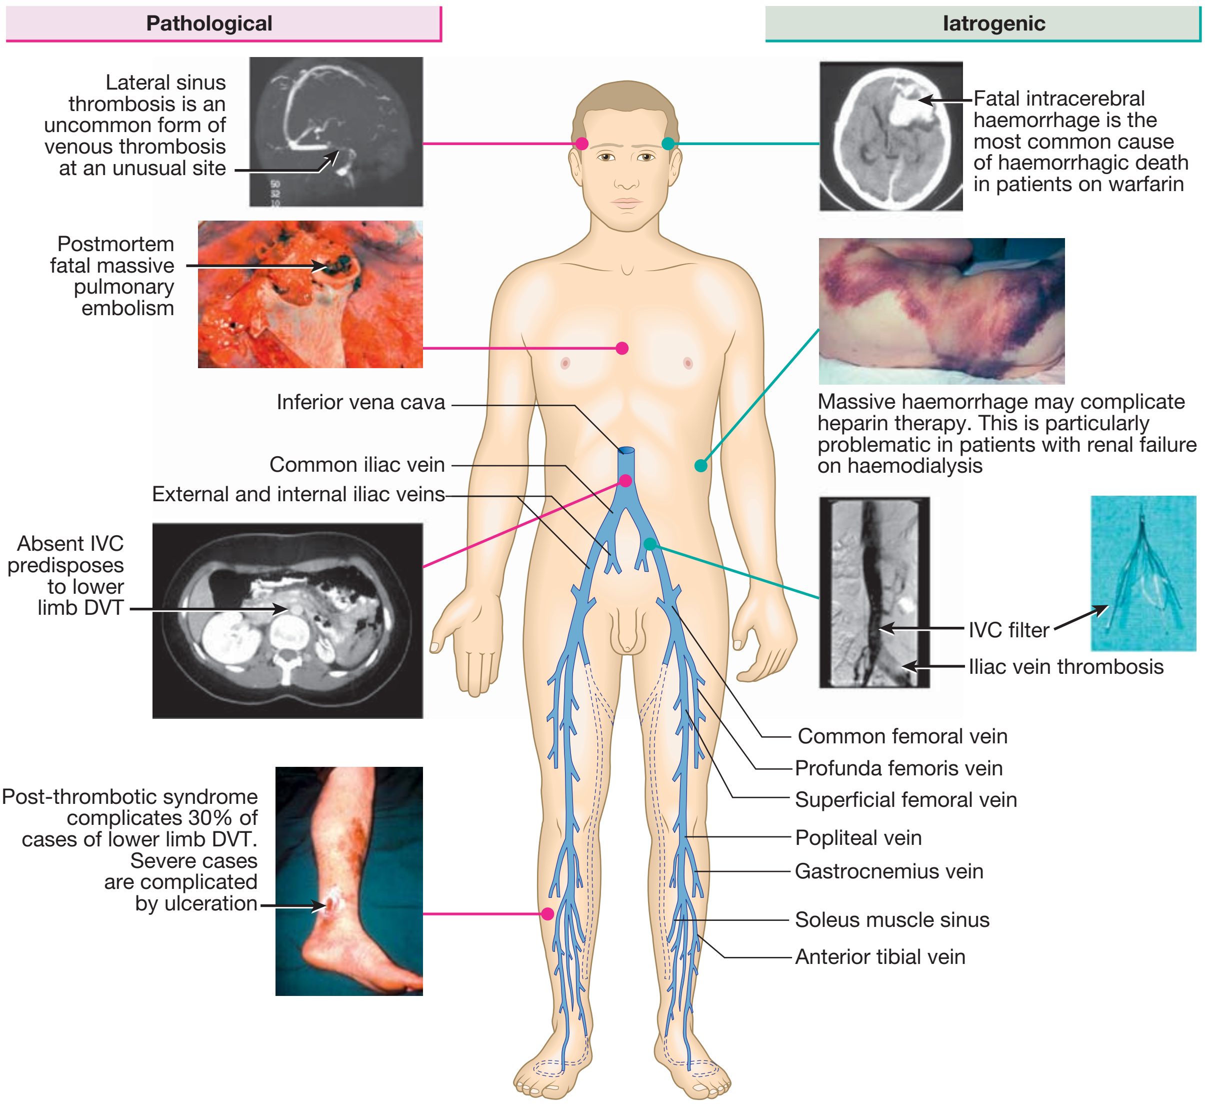

Fig. 23.33 Causes and consequences of venous thromboembolic disease and its treatment. (DVT = deep vein thrombosis; IVC = inferior vena cava)

presence of a temporary risk factor, which is then removed, can usually be treated for short periods (e.g. 3 months), and indeed anticoagulation for more than 6 months does not alter the rate of recurrence following discontinuation of therapy. If there are ongoing risk factors that cannot be alleviated, such as active cancer, long-term anticoagulation is usually recommended, provided that the risk of bleeding is not deemed excessive.

For patients with unprovoked VTE, the optimum duration of anticoagulation can be difficult to establish. Recurrence of VTE is about 2–3% per annum in patients who have a temporary medical risk factor at presentation and about 7–10% per annum in those with apparently unprovoked VTE. This plateaus at around 30–40% recurrence at 5 years. As such, many patients who have had unprovoked episodes of VTE will benefit from long-term anticoagulation. Several factors predict risk of recurrence following an episode of unprovoked VTE. The strongest predictors of recurrence are male sex and a positive D-dimer assay measured 1 month after stopping anticoagulant therapy. These factors are incorporated into scoring systems to predict recurrence such as the DASH score and the Vienna prediction model.

The management of DVT of the leg should also include elevation and analgesia; in limb-threatening DVT, thrombolysis may also be considered. Thrombolysis for PE is discussed on page 621. Post-thrombotic syndrome is due to damage of venous valves by the thrombus. It occurs in around 30% of patients who sustain a proximal lower limb DVT and results in persistent leg swelling, heaviness and discoloration. The most severe complication of this syndrome is ulceration around the medial malleolus (Fig. 23.33). Recent trial evidence suggests that use of elastic compression stockings following a DVT does not reduce the incidence of post-thrombotic syndrome.

Prophylaxis of VTE

All patients admitted to hospital should be assessed for their risk of developing VTE and appropriate prophylactic measures should be put in place. Both medical and surgical patients are at increased risk. A summary of the risk categories is given in Box 23.66. Early mobilisation of patients is important to prevent DVT, and those at medium or high risk require additional antithrombotic measures; these may be pharmacological or mechanical. There

i 23.66 Antithrombotic prophylaxis

Indications

Patients in the following categories should be considered for specific antithrombotic prophylaxis:

Moderate risk of DVT
- Major surgery:
  In patients > 40 years or with other risk factor for VTE
- Major medical illness, e.g.:
  Heart failure
  Myocardial infarction with complications
  Sepsis
  Inflammatory conditions, including inflammatory bowel disease
  Active malignancy
  Nephrotic syndrome
  Stroke and other conditions leading to lower limb paralysis

High risk of DVT
- Major abdominal or pelvic surgery for malignancy or with history of DVT or known thrombophilia (see Box 23.4, p. 923)
- Major hip or knee surgery
- Neurosurgery

Methods of VTE prophylaxis

Mechanical
- Intermittent pneumatic compression
- Mechanical foot pumps
- Graduated compression stockings

Pharmacological
- LMWHs
- Unfractionated heparin
- Fondaparinux
- Dabigatran
- Rivaroxaban
- Apixaban
- Warfarin

(DVT = deep vein thrombosis; VTE = venous thromboembolism)

is increasing evidence in high-risk groups, such as patients who have had major lower limb orthopaedic surgery and abdominal or pelvic cancer surgery, for protracted thromboprophylaxis for as long as 30 days or so after the procedure. Particular care should be taken with the use of pharmacological prophylaxis in patients with a high risk of bleeding or with specific risks of haemorrhage related to the site of surgery or the use of spinal or epidural anaesthesia.

Inherited and acquired thrombophilia and prothrombotic states

Several inherited conditions predispose to VTE (see Box 23.65), and have several points in common that are worth noting:

- None of them is strongly associated with arterial thrombosis.
- All are associated with a slightly increased incidence of adverse outcome of pregnancy, including recurrent early fetal loss, but there are no data to indicate that any specific intervention changes that outcome.
- Apart from in antithrombin deficiency and homozygous factor V Leiden, most carriers of these genes will never have an episode of VTE; if they do, it will be associated with the presence of an additional temporary risk factor.
- There is little evidence that detection of these abnormalities predicts recurrence of VTE.
- None of these conditions per se requires treatment with anticoagulants. Patients with thrombosis should receive anticoagulation, as discussed on page 975. Patients who are deemed to be at high risk of thrombosis, e.g. those with antithrombin deficiency in pregnancy, should receive treatment or prophylactic doses of heparin to cover the period of risk only.

Antithrombin deficiency

Antithrombin (AT) is a serine protease inhibitor (SERPIN) that inactivates the activated coagulation factors IIa, IXa, Xa and XIa. Heparins and fondaparinux achieve their therapeutic effect by potentiating the activity of AT. Familial deficiency of AT is inherited in an autosomal dominant manner; homozygosity for mutant alleles is not compatible with life. Around 70% of affected individuals will have an episode of VTE before the age of 60 years and the relative risk for thrombosis compared with the background population is 10–20. Pregnancy is a high-risk period for VTE and this requires fairly aggressive management with doses of LMWH that are greater than the usual prophylactic doses (≥100 U/kg/day). AT concentrate (either plasma-derived or recombinant) is available; this is required for cardiopulmonary bypass and may be used as an adjunct to heparin in surgical prophylaxis and in the peripartum period.

Protein C and S deficiencies

Protein C and its co-factor protein S are vitamin K-dependent natural anticoagulants involved in switching off coagulation factor activation (factors Va and VIIIa) and thrombin generation (see Fig. 23.6F, p. 919). Inherited deficiency of either protein C or S results in a prothrombotic state with a fivefold relative risk of VTE compared with the background population.

Factor V Leiden

Factor V Leiden results from a gain-of-function, single-base-pair mutation which prevents the cleavage and hence inactivation of activated factor V. This results in a relative risk of venous thrombosis of 5 in heterozygotes and 50 or more in rare homozygotes. The mutation is found in about 5% of Northern Europeans, 2% of Hispanics, 1.2% of African–Americans, 0.5% of Asian–Americans and 1.25% of Native Americans, and is rare in Chinese and Malay people.

Prothrombin G20210A

This gain-of-function mutation in the non-coding 3′ end of the prothrombin gene is associated with an increased plasma level of prothrombin. It is present in about 2% of Northern Europeans but is rare in native populations of Korea, China, India and Africa. In the heterozygous state, it is associated with a 2–3-fold increase in risk of VTE compared with the background population.

23

Antiphospholipid syndrome

Antiphospholipid syndrome (APS) is a clinicopathological entity in which a constellation of clinical conditions, alone or in combination, is found in association with a persistently positive test for an antiphospholipid antibody. The antiphospholipid antibodies are heterogeneous and typically are directed against proteins that bind to phospholipids (Box 23.67). Although causal roles for these antibodies have been proposed, the mechanisms underlying the clinical features of APS are not clear. In clinical practice, two types of test are used, which detect:

- antibodies that bind to negatively charged phospholipid on an ELISA plate (called an anticardiolipin antibody test). These assays usually contain β_2-glycoprotein 1 (β_2-GP1)

23.67 Antiphospholipid syndrome (APS)

Clinical manifestations

- Adverse pregnancy outcome
  - Recurrent first trimester abortion (≥3)
  - Unexplained death of morphologically normal fetus after 10 weeks' gestation
  - Severe early pre-eclampsia
- Venous thromboembolism
- Arterial thromboembolism
- Livedo reticularis, catastrophic APS, transverse myelitis, skin necrosis, chorea

Conditions associated with secondary APS

- Systemic lupus erythematosus
- Rheumatoid arthritis
- Systemic sclerosis
- Behçet's disease
- Temporal arteritis
- Sjögren's syndrome

Targets for antiphospholipid antibodies

- β_2-glycoprotein 1
- Protein C
- Annexin V
- Prothrombin (may result in haemorrhagic presentation)

- those that interfere with phospholipid-dependent coagulation tests like the APTT or the dilute Russell viper venom time (DRVVT; called a lupus anticoagulant test).

The term antiphospholipid antibody encompasses both a lupus anticoagulant and an anticardiolipin antibody/ anti-β_2-GP1; individuals may be positive for one, two or all three of these activities. It has been shown that patients who are 'triple-positive' have an increased likelihood of thrombotic events.

Clinical features and management

APS may present in isolation (primary APS) or in association with one of the conditions shown in Box 23.67, most typically systemic lupus erythematosus (secondary APS). Most patients present with a single manifestation and APS is now most frequently diagnosed in women with adverse outcomes of pregnancy. It is extremely important to make the diagnosis in patients with APS, whatever the manifestation, because it affects the prognosis and management of arterial thrombosis, VTE and pregnancy.

Arterial thrombosis, typically stroke, associated with APS should probably be treated with warfarin, as opposed to aspirin. APS-associated VTE is one of the situations in which the predicted recurrence rate is high enough to indicate long-term anticoagulation after a first event. In women with obstetric presentations of APS, intervention with heparin and aspirin is almost routinely prescribed, although there is little evidence from clinical trials that it is an effective therapy in increasing the chance of a successful pregnancy outcome.

Disseminated intravascular coagulation

Disseminated intravascular coagulation (DIC) may complicate a range of illnesses (Box 23.68). It is characterised by systemic activation of the pathways involved in coagulation and its regulation. This may result in the generation of intravascular fibrin clots causing multi-organ failure, with simultaneous coagulation factor and platelet consumption, causing bleeding. The systemic coagulation activation is induced either through cytokine pathways, which are activated as part of a systemic inflammatory response, or by the release of procoagulant substances such as tissue factor. In addition, suboptimal function of the natural anticoagulant pathways and dysregulated fibrinolysis contribute to DIC. There is consumption of platelets, coagulation factors (notably factors V and VIII) and fibrinogen. The lysis of fibrin

23.68 Disseminated intravascular coagulation (DIC)

Underlying conditions

- Infection/sepsis
- Trauma
- Obstetric, e.g. amniotic fluid embolism, placental abruption, pre-eclampsia
- Severe liver failure
- Malignancy, e.g. solid tumours and leukaemias
- Tissue destruction, e.g. pancreatitis, burns
- Vascular abnormalities, e.g. vascular aneurysms, liver haemangiomas
- Toxic/immunological, e.g. ABO incompatibility, snake bites, recreational drugs

ISTH scoring system for diagnosis of DIC

Presence of an associated disorder	Essential
Platelets (× 10^9/L)	>100 = 0 <100 = 1 <50 = 2
Elevated fibrin degradation products	No increase = 0 Moderate = 2 Strong = 3
Prolonged prothrombin time	<3 secs = 0 >3 secs but <6 secs = 1 >6 secs = 2
Fibrinogen	>1 g/L = 0 <1 g/L = 1

Total score
≥5 = Compatible with overt DIC
<5 = Repeat monitoring over 1–2 days

(ISTH = International Society for Thrombosis and Haemostasis)

23.69 Haemostasis and thrombosis in old age

- **Thrombocytopenia**: not uncommon because of the rising prevalence of disorders in which it may be a secondary feature, and also because of the greater use of drugs that can cause it.
- **'Senile' purpura**: presumed to be due to an age-associated loss of subcutaneous fat and the collagenous support of small blood vessels, making them more prone to damage from minor trauma.
- **Thrombosis**: incidence of thromboembolic disease rises with increasing age. This may be due to stasis and concurrent illness, to which older people are prone; some studies show increased platelet aggregation with age, and others age-associated hyperactivity of the haemostatic system, which could contribute to a prothrombotic state.
- **Thromboprophylaxis**: should be considered in all older patients who are immobile as a result of acute illness. Prophylaxis is not required in chronic immobility without a medical cause, as there is no associated increase in thromboembolism.
- **Anticoagulation**: older patients are more sensitive to the anticoagulant effects of warfarin, partly due to the concurrent use of other drugs and the presence of other pathology. Life-threatening or fatal bleeds on warfarin are significantly more common in those over 80 years.

clot results in production of fibrin degradation products (FDPs), including D-dimers.

Investigations

DIC should be suspected when any of the conditions listed in Box 23.68 are met. Measurement of coagulation times (APTT and PT; p. 920), along with fibrinogen, platelet count and FDPs, helps in the assessment of prognosis and aids clinical decision-making with regard to both bleeding and thrombotic complications.

Management

Therapy is primarily aimed at the underlying cause. These patients will often require intensive care to deal with concomitant issues, such as acidosis, dehydration, renal failure and hypoxia. Blood component therapy, such as fresh frozen plasma, cryoprecipitate and platelets, should be given if the patient is bleeding or to cover interventions with a high bleeding risk, but should not be prescribed routinely based on coagulation tests and platelet counts alone. Prophylactic doses of heparin should be given, unless there is a clear contraindication. Established thrombosis should be treated cautiously with therapeutic doses of unfractionated heparin, unless clearly contraindicated. Patients with DIC should not, in general, be treated with antifibrinolytic therapy, e.g. tranexamic acid.

Thrombotic thrombocytopenic purpura

Like DIC and also heparin-induced thrombocytopenia (p. 938), thrombotic thrombocytopenic purpura (TTP) is a disorder in which thrombosis is accompanied by paradoxical thrombocytopenia. TTP is characterised by a pentad of findings, although few patients have all five components:

- thrombocytopenia
- microangiopathic haemolytic anaemia
- neurological sequelae
- fever
- renal impairment.

It is an acute autoimmune disorder mediated by antibodies against ADAMTS-13 (a disintegrin and metalloproteinase with a thrombospondin type 1 motif).

This enzyme normally cleaves vWF multimers to produce normal functional units, and its deficiency results in large vWF multimers that cross-link platelets. The features are of microvascular occlusion by platelet thrombi affecting key organs, principally brain and kidneys. It is a rare disorder (1 in 750 000 per annum), which may occur alone or in association with drugs (ticlopidine, ciclosporin), HIV, shiga toxins (p. 263) and malignancy. It should be treated by emergency plasma exchange. Glucocorticoids, aspirin and rituximab also have a role in management. Untreated mortality rates are 90% in the first 10 days, and even with appropriate therapy, the mortality rate is 20–30% at 6 months.

General Assessment of Locomotor System (GALS) and Schöber's test

Disorders of the musculoskeletal system affect all ages and ethnic groups. In the UK, about 25% of new consultations in general practice are for musculoskeletal symptoms. Musculoskeletal diseases may arise from processes affecting bones, joints, muscles, or connective tissues such as skin and tendon. The principal manifestations are pain and impairment of locomotor function.

Diseases of the musculoskeletal system tend to be more common in women and most increase in frequency with increasing age. They are the most common cause of physical disability in older people and account for one-third of physical disability at all ages.

Functional anatomy and physiology

The musculoskeletal system is responsible for movement of the body, provides a structural framework to protect internal organs, and acts as a reservoir for storage of calcium and phosphate in the regulation of mineral homeostasis. The main components of the musculoskeletal system are depicted in Figure 24.1.

Bone

Bones fall into two main types, based on their embryonic development. Flat bones, such as the skull, develop by intramembranous ossification, in which embryonic fibroblasts differentiate directly into bone within condensations of mesenchymal tissue during early fetal life. Long bones, such as the femur and radius, develop by endochondral ossification from a cartilage template. During development, the cartilage is invaded by vascular tissue containing osteoprogenitor cells and is gradually replaced by bone from centres of ossification situated in the middle and at the ends of the bone. A thin remnant of cartilage called the growth plate or epiphysis remains at each end of long bones, and chondrocyte proliferation here is responsible for skeletal growth during childhood and adolescence. At the end of puberty, the increased levels of sex hormones halt cell division in the growth plate. The cartilage remnant then disappears as the epiphysis fuses and longitudinal bone growth ceases.

Two types of bone tissue are present in the normal skeleton (Fig. 24.1). Cortical bone is formed from Haversian systems, comprising concentric lamellae of bone tissue surrounding a central canal that contains blood vessels. Cortical bone is dense and forms a hard envelope around the long bones. Trabecular or cancellous bone fills the centre of the bone and consists of an interconnecting meshwork of trabeculae, separated by spaces filled with bone marrow. The most important cell types in bone are:

- *Osteoclasts*: multinucleated cells of haematopoietic origin, responsible for bone resorption.
- *Osteoblasts*: mononuclear cells of derived from marrow stromal cells responsible for bone formation.

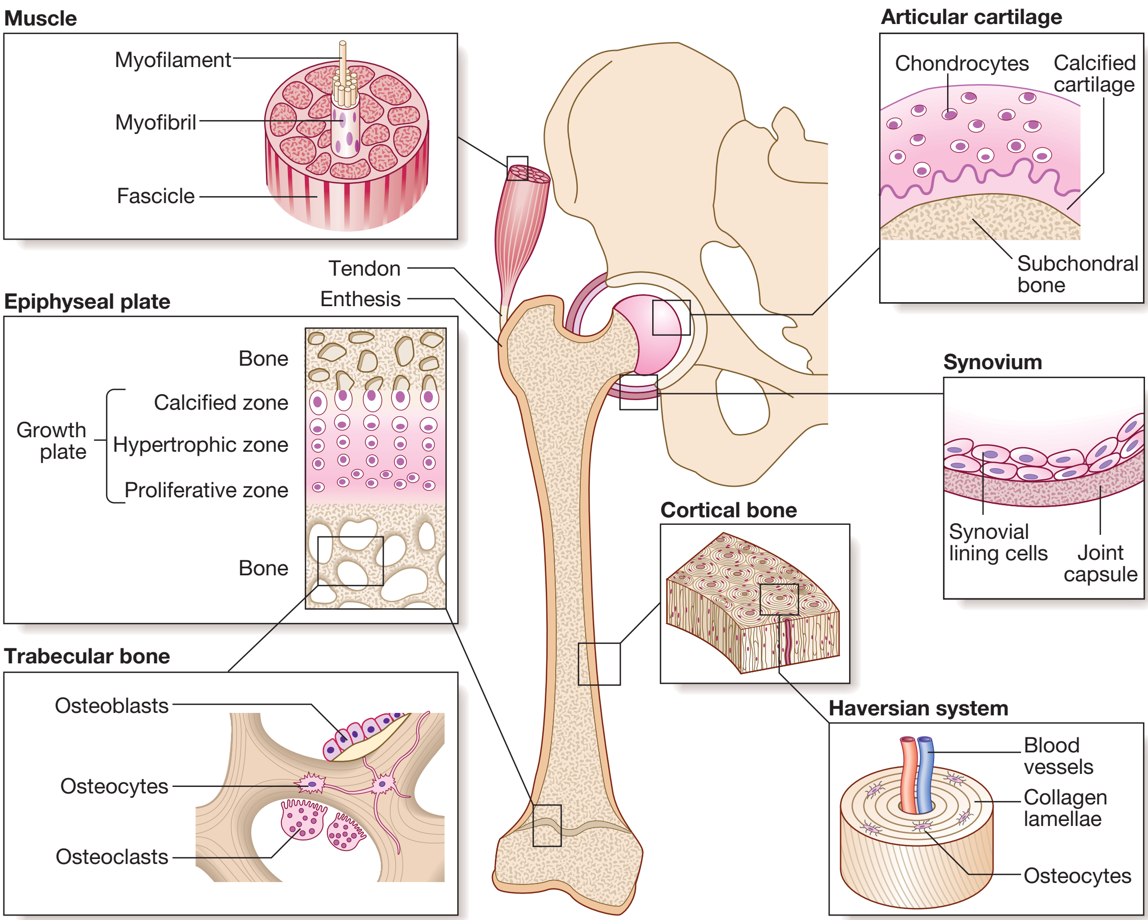

Fig. 24.1 Structure of the major musculoskeletal tissues.

- *Osteocytes*: cells that differentiate from osteoblasts that become embedded in bone matrix during bone formation. They are responsible for sensing and responding to mechanical stimuli and for coordinating osteoclast and osteoblast activity.
- *Bone marrow stromal cells*: cells that produce receptor activator of nuclear factor kappa B ligand (RANKL) and macrophage colony-stimulating factor (M-CSF), which stimulate osteoclast formation, and other cytokines that support haematopoiesis (p. 914).
- *Bone lining cells*: flattened cells lining the bone surface that differentiate from osteoblasts when bone formation is complete.

Bone matrix and mineral

The most abundant protein of bone is type I collagen, which is formed from two α1 peptide chains and one α2 chain wound together in a triple helix. Type I collagen is proteolytically processed inside the cell before being laid down in the extracellular space, releasing propeptide fragments that can be used as biochemical markers of bone formation. Subsequently, the collagen fibrils become 'cross-linked' to one another by pyridinium molecules, a process that enhances bone strength. When bone is broken down by osteoclasts, the cross-links are released into the circulation. These can be measured biochemically and are sometimes used clinically to assess levels of bone resorption. Bone is normally laid down in an orderly fashion, but when bone turnover is high, as in Paget's disease or severe hyperparathyroidism, it is laid down in a chaotic pattern, giving rise to 'woven bone' that is mechanically weak. Bone matrix also contains growth factors, other structural proteins and proteoglycans, thought to be involved in helping bone cells attach to bone matrix and in regulating bone cell activity. The other major component of bone is mineral, comprised of calcium and phosphate crystals deposited between the collagen fibrils in the form of hydroxyapatite [$Ca_{10}(PO_4)_6(OH)_2$]. Mineralisation is essential for bone's rigidity and strength but over-mineralisation causes the bone to become brittle. In clinical practice, increased mineralisation can occur in some types of osteogenesis imperfecta and in response to long-term bisphosphonate therapy.

Bone remodelling

Bone remodelling is required for renewal and repair of the skeleton throughout life. This is a cyclical process that has four phases; quiescence, resorption, reversal and formation, as illustrated in Figure 24.2. Remodelling starts with the attraction of osteoclast precursors in peripheral blood to the target site, probably by local release of chemotactic factors from areas of microdamage. The osteoclasts resorb bone and, after about 10 days, undergo programmed cell death (apoptosis), heralding the start of the reversal phase, when osteoblast precursors are recruited to the resorption site. The osteoblast precursors differentiate into mature osteoblasts and form new bone during the formation phase. Initially, the matrix is unmineralised (osteoid) but eventually becomes mineralised to form mature bone. Some osteoblasts become trapped in bone matrix and differentiate into osteocytes, which play a key regulatory role in coordinating bone formation and resorption, whereas others differentiate into bone-lining cells.

The cellular and molecular mediators of this bone remodelling are shown in more detail in Figure 24.3. Osteoclast precursors are derived from haematopoietic stem cells and differentiate

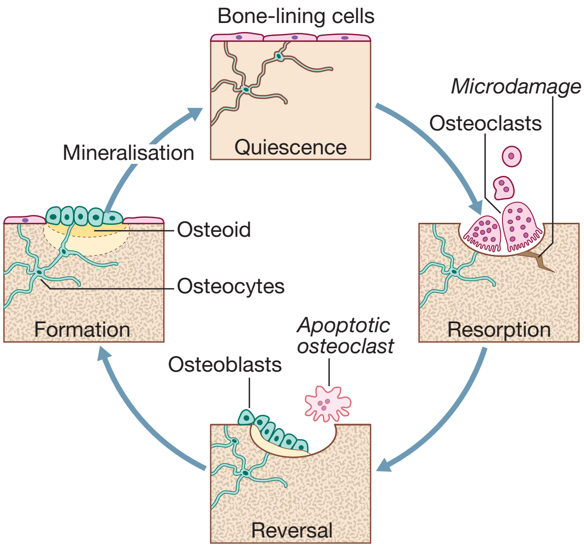

Fig. 24.2 The bone remodelling cycle. Bone is renewed and repaired by the process of bone remodelling. This begins by removal of old and damaged bone by osteoclasts during the phase of bone resorption. After about 10 days, the osteoclasts undergo programmed cell death (apoptosis) and during the reversal phase are replaced by osteoclasts, which begin to fill in the resorbed area with new bone matrix, heralding the start of bone formation. The bone matrix is initially uncalcified (osteoid) but then becomes mineralised to form mature bone.

into mature osteoclasts in response to M-CSF, produced by bone marrow stromal cells, and RANKL, produced by both osteocytes and bone marrow stromal cells. The RANKL binds to and activates a receptor called RANK (receptor activator of nuclear factor kappa B) on osteoclast precursors, promoting osteoclast differentiation and bone resorption. This effect is blocked by osteoprotegerin (OPG), which is a decoy receptor for RANKL that inhibits osteoclast formation. Once formed, mature osteoclasts attach to the bone surface by a tight sealing zone and secrete hydrochloric acid and proteolytic enzymes, including cathepsin K, into the space underneath, which is known as the Howship's lacuna. The acid dissolves the mineral and cathepsin K degrades collagen. Osteocytes also produce sclerostin (SOST), which is a potent inhibitor of bone formation. Under conditions of mechanical loading, sclerostin production by osteocytes is inhibited, allowing bone formation to proceed, stimulated by members of the Wnt family of signalling proteins. The Wnt molecules stimulate bone formation by activating members of the lipoprotein receptor-related protein (LRP) family, the most important of which are LRP4, LRP5 and LRP6. Sclerostin antagonises the effects of Wnt family members by blocking their interaction with LRP family members. Finally, osteocytes play a critical role in phosphate homeostasis by producing the hormone FGF23, which regulates renal tubular phosphate reabsorption. Key regulators of bone remodelling are summarised in Box 24.1.

Mineralisation of bone is critically dependent on the enzyme alkaline phosphatase (ALP), which is produced by osteoblasts and degrades pyrophosphate, an inhibitor of mineralisation. Bone remodelling is predominantly regulated at a local level but can be influenced by circulating hormones or mechanical loading, which can up-regulate or down-regulate remodelling across the whole skeleton (Box 24.1).

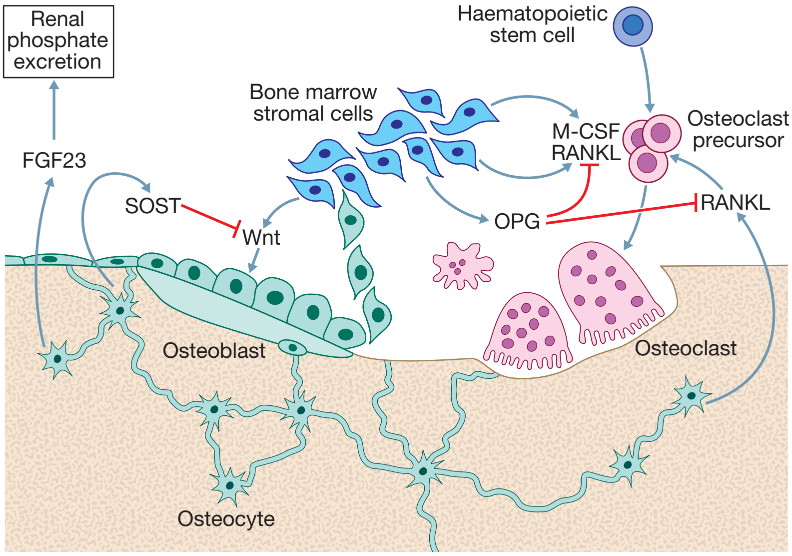

Fig. 24.3 Cellular and molecular regulators of bone remodelling Osteoclast precursors are derived from haematopoietic stem cells. They differentiate into mature osteoclasts in response to the receptor activator of nuclear factor kappa B ligand (RANKL), which is produced by osteocytes, bone marrow stromal cells and activated T cells (not shown), and macrophage colony-stimulating factor (M-CSF), which is produced by bone marrow stromal cells. Osteoprotegerin (OPG) is also produced in the bone microenvironment, where it inhibits osteoclastic bone resorption by blocking the effect of RANKL. Osteoblasts, which are derived from bone marrow stromal cells, are responsible for bone formation. Osteoblast activity is stimulated by signalling molecules in the Wnt family but inhibited by sclerostin (SOST), which is produced by osteocytes. In addition to their role in regulating osteoclast and osteoblast activity, osteocytes have an endocrine function in regulating phosphate homeostasis by producing fibroblast growth factor 23 (FGF23), which acts on the kidney to promote phosphate excretion.

24.1 Key regulators of bone remodelling

Mediator	Source	Effects	Comment
RANKL	Osteocytes Stromal cells Activated T cells	Stimulates bone resorption	Activates RANK
Osteoprotegerin	Stromal cells Lymphocytes	Inhibits bone resorption	Acts as decoy receptor for RANKL
Wnt	Stromal cells	Stimulates bone formation	Activates LRP receptors
Sclerostin	Osteocytes	Inhibits bone formation	Blocks effect of Wnt on LRP receptors
Parathyroid hormone	Parathyroid glands	Increases bone resorption and formation	
Thyroid hormone	Thyroid gland	Increases bone resorption and formation	
Oestrogen	Ovary	Inhibits bone resorption	
Glucocorticoid	Adrenal gland Exogenous	Inhibits bone formation	

(LRP = lipoprotein receptor-related protein; RANKL = receptor activator of nuclear factor kappa B ligand)

Joints

There are three main types of joint: fibrous, fibrocartilaginous and synovial (Box 24.2).

Fibrous and fibrocartilaginous joints

These comprise a simple bridge of fibrous or fibrocartilaginous tissue joining two bones together where there is little requirement for movement. The intervertebral disc is a special type of fibrocartilaginous joint in which an amorphous area, called the nucleus pulposus, lies in the centre of the fibrocartilaginous bridge. The nucleus has a high water content and acts as a cushion to improve the disc's shock-absorbing properties.

24.2 Types of joint

Type	Range of movement	Examples
Fibrous	Minimal	Skull sutures
Fibrocartilaginous	Limited	Symphysis pubis Costochondral junctions Intervertebral discs Sacroiliac joints
Synovial	Large	Most limb joints Temporomandibular Costovertebral

Synovial joints

These are complex structures containing several cell types. They are found where a wide range of movement is needed (Fig. 24.4).

Articular cartilage

This avascular tissue covers the bone ends in synovial joints. Cartilage cells (chondrocytes) are responsible for synthesis and turnover of cartilage, which consists of a mesh of type II collagen fibrils that extend through a hydrated 'gel' of proteoglycan molecules. The most important proteoglycan is aggrecan, which consists of a core protein to which several glycosaminoglycan (GAG) side chains are attached (Fig. 24.5). The GAGs are polysaccharides that consist of long chains of disaccharide repeats comprising one normal sugar and an amino sugar. The most abundant GAGs in aggrecan are chondroitin sulphate and keratan sulphate. Hyaluronan is another important GAG that binds to aggrecan molecules to form very large complexes with a total molecular weight of more than 100 million. Aggrecan has a strong negative charge and avidly binds water molecules to assume a shape that occupies the maximum possible volume available. The expansive force of the hydrated aggrecan, combined with the restrictive strength of the collagen mesh, gives articular cartilage excellent shock-absorbing properties.

With ageing, the concentration of chondroitin sulphate decreases, whereas that of keratan sulphate increases, resulting in reduced water content and shock-absorbing properties. These changes differ from those found in osteoarthritis (p. 1007), where there is abnormal chondrocyte division, loss of proteoglycan from matrix and an increase in water content. Cartilage matrix is constantly turning over and in health there is a perfect balance between synthesis and degradation. Degradation of cartilage matrix is carried out by aggrecanases and matrix metalloproteinases, responsible for the breakdown of proteins and proteoglycans, and by glycosidases, responsible for the breakdown of GAGs. Pro-inflammatory cytokines, such as interleukin-1 (IL-1) and tumour necrosis factor (TNF), which are released during inflammation, stimulate production of aggrecanase and metalloproteinases, causing cartilage degradation.

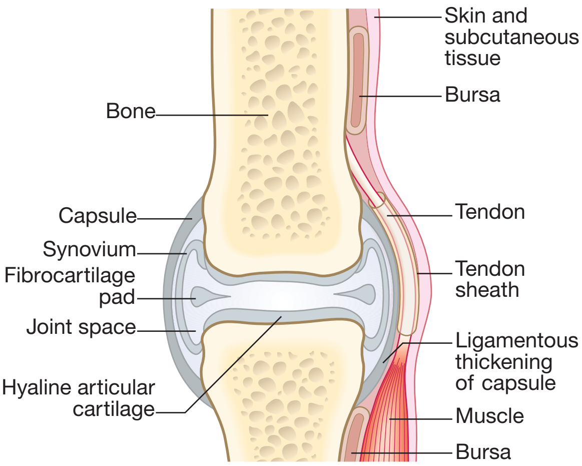

Fig. 24.4 Structure of a synovial joint.

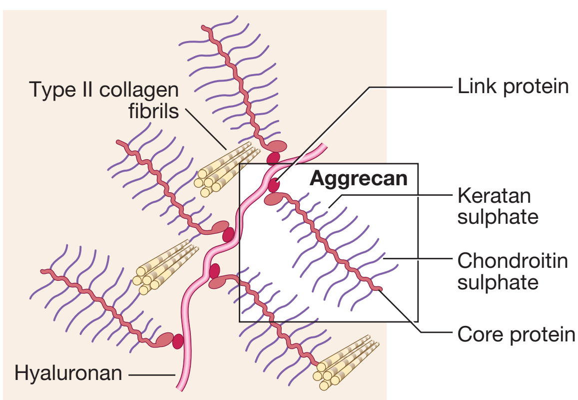

Fig. 24.5 Ultrastructure of articular cartilage.

Synovial fluid

The surfaces of articular cartilage are separated by a space filled with synovial fluid (SF), a viscous liquid that lubricates the joint. It is an ultrafiltrate of plasma, into which synovial cells secrete hyaluronan and proteoglycans.

Intra-articular discs

Some joints contain fibrocartilaginous discs within the joint space that act as shock absorbers. The most clinically important are the menisci of the knee. These are avascular structures that remain viable because of diffusion of oxygen and nutrients from the SF.

Synovial membrane, joint capsule and bursae

The bones of synovial joints are connected by the joint capsule, a fibrous structure richly supplied with blood vessels, nerves and lymphatics that encases the joint. Ligaments are discrete, regional thickenings of the capsule that act to stabilise joints (see Fig. 24.4). The inner surface of the joint capsule is the synovial membrane, comprising an outer layer of blood vessels and loose connective tissue that is rich in type I collagen, and an inner layer 1–4 cells thick consisting of two main cell types. Type A synoviocytes are phagocytic cells derived from the monocyte/macrophage lineage and are responsible for removing particulate matter from the joint cavity; type B synoviocytes are fibroblast-like cells that secrete SF. Most inflammatory and degenerative joint diseases associate with thickening of the synovial membrane and infiltration by lymphocytes, polymorphs and macrophages.

Bursae are hollow sacs lined with synovium and contain a small amount of SF. They help tendons and muscles move smoothly in relation to bones and other articular structures.

Skeletal muscle

Skeletal muscles are responsible for body movements and respiration. Muscle consists of bundles of cells (myocytes) embedded in fine connective tissue containing nerves and blood vessels. Myocytes are large, elongated, multinucleated cells formed by fusion of mononuclear precursors (myoblasts) in early embryonic life. The nuclei lie peripherally and the centre of the cell contains actin and myosin molecules, which interdigitate with one another to form the myofibrils that are responsible for muscle contraction. The molecular mechanisms of skeletal muscle contraction are the same as for cardiac muscle (p. 446). Myocytes contain many mitochondria that provide the large amounts of adenosine triphosphate (ATP) necessary for muscle contraction and are rich in the protein myoglobin, which acts as a reservoir for oxygen during contraction.

Individual myofibrils are organised into bundles (fasciculi) that are bound together by a thin layer of connective tissue (the

perimysium). The surface of the muscle is surrounded by a thicker layer of connective tissue, the epimysium, which merges with the perimysium to form the muscle tendon. Tendons are tough, fibrous structures that attach muscles to a point of insertion on the bone surface called the enthesis.

Investigation of musculoskeletal disease

Clinical history and examination usually provide sufficient information for the diagnosis and management of many musculoskeletal diseases. Investigations are helpful in confirming the diagnosis, assessing disease activity and indicating prognosis.

Joint aspiration

Joint aspiration with examination of SF is pivotal in patients suspected of having septic arthritis, crystal arthritis or intra-articular bleeding. It should be carried out in all individuals with acute monoarthritis, and samples should be sent for microbiology and clinical chemistry.

It is possible to obtain SF by aspiration from most peripheral joints and only a small amount is required for diagnostic purposes. Normal SF is present in small volume, is clear and either colourless or pale yellow, and has a high viscosity. It contains few cells. With joint inflammation, the volume increases, the cell count and the proportion of neutrophils rise (causing turbidity), and the viscosity reduces (due to enzymatic degradation of hyaluronan and aggrecan). Turbid fluid with a high neutrophil count occurs in sepsis, crystal arthritis and reactive arthritis. High concentrations of urate crystals or cholesterol can make SF appear white. Non-uniform blood-staining usually reflects needle trauma to the synovium. Uniform blood-staining is most commonly due to a bleeding diathesis, trauma or pigmented villonodular synovitis (p. 1059) but can occur in severe inflammatory synovitis. A lipid layer floating above blood-stained fluid is diagnostic of intra-articular fracture and is caused by release of bone marrow fat into the joint.

Crystals can be identified by compensated polarised light microscopy of fresh SF (to avoid crystal dissolution and post-aspiration crystallisation). Urate crystals are long and needle-shaped, and show a strong light intensity and negative birefringence (Fig. 24.6A). Calcium pyrophosphate crystals are smaller, rhomboid in shape and usually less numerous than urate crystals; they have weak intensity and positive birefringence (Fig. 24.6B).

A B

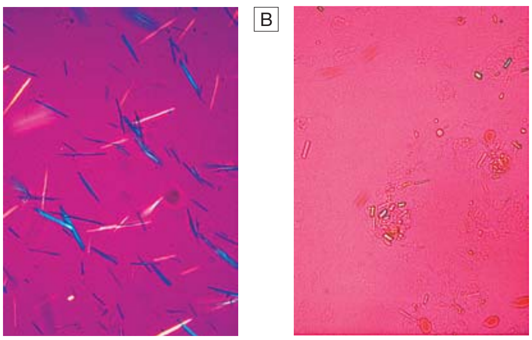

Fig. 24.6 Compensated polarised light microscopy of synovial fluids (×400). **A** Monosodium urate crystals show bright negative birefringence under polarised light and needle-shaped morphology. **B** Calcium pyrophosphate crystals show weak positive birefringence under polarised light and are few in number. They are more difficult to detect than urate crystals.

Imaging

Plain X-rays

X-rays show structural changes that are of value in the differential diagnosis and monitoring of many bone and joint diseases (Box 24.3).

24.3 Radiographic abnormalities in selected rheumatic diseases

Rheumatoid arthritis	
• Periarticular osteoporosis • Marginal joint erosions	• Joint subluxation • Joint space narrowing
Osteoporosis	
• Osteopenia • Vertebral fractures	• Non-vertebral fractures • Cortical thinning
Paget's disease	
• Bone expansion • Abnormal trabecular pattern	• Osteosclerosis and lysis • Pseudofractures
Psoriatic arthritis	
• Sacroiliitis • Syndesmophytes • Bone sclerosis	• Proliferative enthesis erosions • Enthesophytes • Juxta-articular new bone
Osteoarthritis	
• Joint space narrowing • Osteophytes • Subchondral sclerosis	• Joint deformity • Subchondral cysts

They are of diagnostic value in osteoarthritis (OA), where they demonstrate joint space narrowing that tends to be focal rather than widespread, as in inflammatory arthritis. Other features of OA detected on X-rays include osteophytes, subchondral sclerosis, bone cysts and calcified loose bodies within the synovium (see Fig. 24.21, p. 1010). Erosions and sclerosis of the sacroiliac joints and syndesmophytes in the spine may be observed in patients with spondyloarthritis (SpA; see Fig. 24.40, p. 1030). In peripheral joints, proliferative erosions, associated with new bone formation and periosteal reaction, occur in SpA. In tophaceous gout, well-defined punched-out erosions may occur (see Fig. 24.27, p. 1015). Calcification of cartilage, tendons and soft tissues or muscle occurs mainly in chondrocalcinosis (see Fig. 24.28, p. 1016), calcium-containing crystal diseases, tumoral calcinosis and autoimmune connective tissue diseases.

X-rays are of limited value in the diagnosis of rheumatoid arthritis (RA) because features such as erosions, joint space narrowing and periarticular osteoporosis may be detectable only after several months or even years. The main indication for X-rays in RA is in the assessment of disease over time when structural damage to the joints is suspected.

Bone scintigraphy

Bone scintigraphy is useful in the diagnosis of metastatic bone disease and Paget's disease of bone. Abnormalities may also be observed in primary bone tumours, complex regional pain syndrome, osteoarthritis and inflammatory arthritis. It involves

24.4 Conditions identified by ^{99m}Tc-labelled bisphosphonate bone scintigraphy

- Skeletal metastases
- Paget's disease of bone
- Stress fractures and osteomalacia (e.g. Looser's zones)
- Complex regional pain syndrome (p. 1055)
- Sclerosing bone disorders (e.g. hypertrophic pulmonary osteoarthropathy; p. 1057)
- Spondyloarthritides (abnormalities at sacroiliac joints and tendon/ligament insertions)

24.5 Conditions detected by magnetic resonance imaging

- Osteonecrosis
- Intervertebral disc disease
- Nerve root entrapment
- Spinal cord compression
- Spinal stenosis
- Sepsis
- Complex regional pain syndrome
- Malignancy
- Fractures
- Meniscal disease
- Synovitis
- Sacroiliitis and enthesitides
- Inflammatory myositis
- Rotator cuff tears, bursitis and tenosynovitis

gamma-camera imaging following an intravenous injection of ^{99m}Tc-labelled bisphosphonate. Early post-injection images reflect blood flow and can show increased perfusion of inflamed synovium, Pagetic bone or primary or secondary bone tumours. Delayed images taken a few hours later reflect bone remodelling as the ^{99m}Tc-labelled bisphosphonate localises to sites of active bone turnover. Scintigraphy has a high sensitivity for detecting important bone and joint pathology that is not apparent on X-rays (Box 24.4). Single photon emission computed tomography (SPECT) combines radionuclide imaging with computed tomography. It can provide accurate anatomical localisation of abnormal tracer uptake within the bone and is of particular value in the assessment of patients with chronic low back pain of unknown cause.

Magnetic resonance imaging

Magnetic resonance imaging (MRI) gives detailed information on anatomy, allowing three-dimensional visualisation of bone and soft tissues that cannot be adequately assessed by plain X-rays. The technique is valuable in the assessment and diagnosis of many musculoskeletal diseases (Box 24.5). T1-weighted sequences are useful for defining anatomy, whereas T2-weighted sequences are useful for assessing tissue water content, which is often increased in synovitis and other inflammatory disorders (Fig. 24.7). MRI sequences that suppress signal from fat, such as short TI inversion recovery (STIR), are helpful when evaluating inflammatory disease. Contrast agents, such as gadolinium, can be administered to increase sensitivity in detecting erosions and synovitis.

Ultrasonography

Ultrasonography is a useful investigation for confirmation of small joint synovitis and erosions, for anatomical location of periarticular lesions, for characterisation of tendon lesions and for guided injection of joints and bursae. Ultrasound is more sensitive than clinical examination for the detection of early synovitis and is used increasingly in the diagnosis and assessment of patients with suspected inflammatory arthritis. In addition to locating synovial thickening and effusions, ultrasound can detect increased blood flow within synovium using power Doppler imaging, an option that is available on most modern ultrasound machines (Fig. 24.8).

Computed tomography

Computed tomography (CT) is used selectively for assessing patients with bone and joint disease. CT may be used when skeletal configuration needs defining, when calcific lesions are being assessed (crowned dens syndrome, p. 1017), when MRI is contraindicated, or when articular regions are being evaluated in which an adjacent joint replacement creates signal artefacts on MRI, using specific metal artefact reduction algorithms.

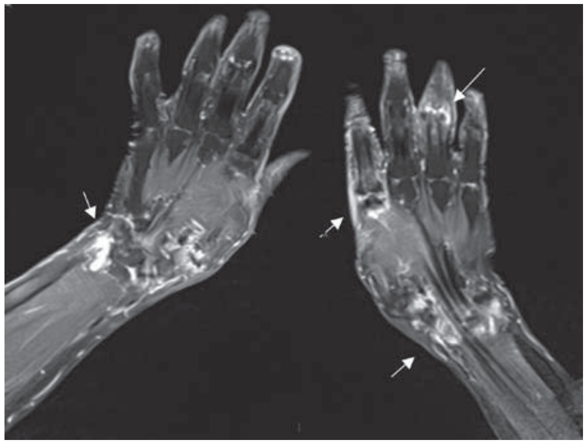

Fig. 24.7 Magnetic resonance image showing joint synovitis. Coronal post-contrast T1-weighted image shows extensive enhancement consistent with synovitis (white areas, arrowed) in both wrists, at the second metacarpophalangeal joint and proximal interphalangeal joints of the right hand. *Courtesy of Dr I. Beggs.*

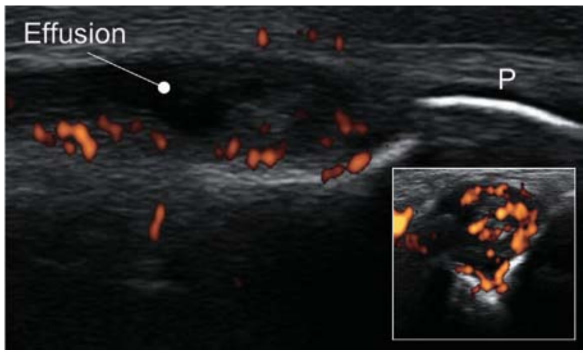

Fig. 24.8 Ultrasound image showing synovitis. Lateral image of a metacarpophalangeal joint in inflammatory arthritis. The periosteum (P) of the phalanx shows as a white line. The dark, hypo-echoic area indicates an effusion. The coloured areas demonstrated by power Doppler indicate increased vascularity. The inset shows a transverse image of the same joint. *Courtesy of Dr N. McKay.*

Dual X-ray absorptiometry

Estimation of bone mineral density (BMD) has a key role in the diagnosis and management of osteoporosis and is best made using dual X-ray absorptiometry (DXA). Measurements at lumbar spine, hip and sometimes forearm are obtained. DXA works on the principle that calcium in bone attenuates passage of X-rays through the tissue in proportion to the amount of mineral present: the more bone mineral present, the higher the BMD value.

Bone density measurements are often presented as T-scores, which measure of the number of standard deviations by which the patient's BMD value differs from that in a young healthy control (Fig. 24.9). Osteoporosis is defined in postmenopausal women and men of more than 50 years old by a T-score of 2.5 or below (shaded red in the figure); osteopenia is diagnosed when the T-score lies between –1.0 and –2.5 (shaded pink). BMD values above –1.0 and below +2.5 are considered normal (yellow/green), whereas values above +2.5 indicate high bone mass, the most common cause being OA. The results need to be interpreted carefully and in reference to coexisting conditions, such as aortic calcification, vertebral fractures, degenerative disc disease and OA, all of which can artefactually raise BMD results. Radiographic correlation is then advisable.

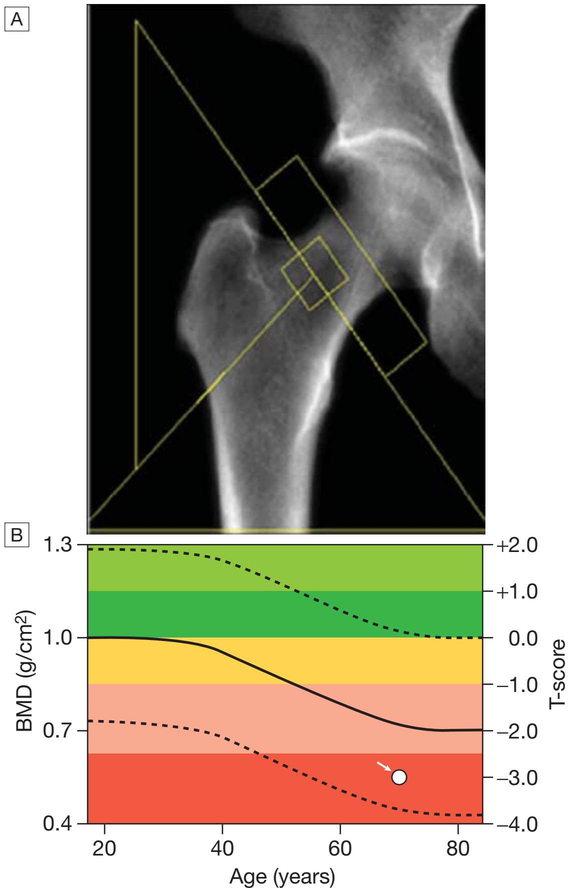

Fig. 24.9 Typical output from a dual X-ray absorptiometry (DXA) scan. **A** Image from hip DXA scan. **B** Bone mineral density (BMD) values plotted in g/cm^2 (left axis) and as the T-score values (right axis). The solid line represents the population average plotted against age, and the interrupted lines are ±2 standard deviations. The BMD T-score result from the patient shown aged 70 years (arrow) is –3.0, indicating osteoporosis. Note that, while the patient's BMD is below average, it lies within the reference range for someone of that age, since BMD normally falls with age.

Blood tests

Haematology

Abnormalities in the full blood count (FBC) often occur in inflammatory rheumatic diseases but changes are usually non-specific. Examples include neutrophilia in crystal arthritides and sepsis; neutropenia in lupus; and lymphopenia in autoimmune rheumatic and connective tissue diseases. Reduced levels of haemoglobin and raised platelets are a common and important finding in active inflammatory rheumatological disorders. Many synthetic and biologic disease-modifying antirheumatic drugs (DMARDs) can cause marrow toxicity and require regular monitoring of the FBC. Additional tests that are useful in assessing rheumatic diseases include the direct antiglobulin test (which can indicate intravascular haemolysis in systemic lupus erythematosus (SLE); p. 948) and the dilute Russell viper venom test (a functional assay for a lupus anticoagulant; p. 978).

Biochemistry

Routine biochemistry is useful for assessing metabolic bone disease, muscle diseases and gout, and is essential in monitoring DMARDs and biologic drugs (renal and hepatic function). Several bone diseases, including Paget's disease, renal bone disease and osteomalacia, give a characteristic pattern that can be helpful diagnostically (Box 24.6). Serum levels of uric acid are usually raised in gout but a normal level does not exclude it, especially during an acute attack, when urate levels temporarily fall. Equally, an elevated serum uric acid does not confirm the diagnosis, since most hyperuricaemic people never develop gout. Levels of C-reactive protein (CRP) are a useful marker of infection and inflammation, and are more specific than the erythrocyte sedimentation rate (ESR). An exception is in autoimmune connective tissue diseases, such as SLE and systemic sclerosis, where CRP may be normal but the ESR raised in active disease. Accordingly, an elevated CRP in a patient with lupus or systemic sclerosis suggests an intercurrent illness, such as sepsis, rather than active disease. More detail on the

i 24.6 Typical biochemical abnormalities in various skeletal diseases (in serum)

	Calcium	Phosphate	ALP	PTH	FGF23	25(OH)D
Osteoporosis	N	N	N (↑ after fracture)	N or ↑	N	N or ↓
Paget's disease	N	N	↑↑	N or ↑	N	N or ↓
Renal osteodystrophy	N or ↓	N or ↑	↑	↑↑	↑↑	N or ↓
Vitamin D-deficient osteomalacia	N or ↓	N or ↓	↑	↑↑	N or ↓	↓↓
Hypophosphataemic rickets	N	↓↓	↑	N or ↑	↑↑	N or ↓
Primary hyperparathyroidism	↑/↑↑	N or ↓	N or ↑	↑↑	N or ↑	N or ↓

(ALP = alkaline phosphatase; FGF23 = fibroblast growth factor 23; PTH = parathyroid hormone)
(N = normal; single arrow = increased or decreased; double arrow = greatly increased or decreased)

24.7 Causes of an elevated serum creatinine phosphokinase (CPK)

- Inflammatory myositis ± vasculitis
- Muscular dystrophy
- Motor neuron disease
- Alcohol, drugs (especially statins)
- Myocardial infarction*
- Trauma, strenuous exercise, prolonged immobilisation after a fall
- Hypothyroidism, metabolic myopathy
- Viral myositis

*The CK-MB cardiac-specific isoform is disproportionately elevated compared with total CPK.

interpretation of CRP and ESR changes is given on page 72. Serum creatine phosphokinase levels are useful in the diagnosis of myopathy or myositis, but specificity and sensitivity are poor and raised levels may occur in some conditions (Box 24.7).

Immunology

Autoantibody tests are widely used in the diagnosis of rheumatic diseases. Whatever test is used, the results must be interpreted in light of the clinical picture and the different detection and assay systems used in different hospitals.

Rheumatoid factor

Rheumatoid factor (RF) is an antibody directed against the Fc fragment of human immunoglobulin. In routine clinical practice, immunoglobulin M (IgM) RF is usually measured, although different methodologies allow measurement of IgG and IgA RFs too. Positive RF occurs in a wide variety of diseases and some normal adults (Box 24.8), particularly with increasing age. Although the specificity is poor, about 70% of patients with RA test positive. High RF titres are associated with more severe disease and extra-articular disease.

Anti-citrullinated peptide antibodies

Anti-citrullinated peptide antibodies (ACPAs) recognise peptides in which the amino acid arginine has been converted to citrulline by peptidylarginine deiminase, an enzyme abundant in inflamed synovium and in a variety of mucosal structures. ACPAs have similar sensitivity to RF for RA (70%) but much higher specificity (>95%), and should be used in preference to RF in the diagnosis of RA. ACPAs are associated with more severe disease progression and can be detected in asymptomatic patients several years before the development of RA. Their pathological role is still debated but it is likely that they amplify the synovial response to an inflammatory stimulus.

24.8 Conditions associated with a positive rheumatoid factor*

Condition	Approximate frequency (%)
Rheumatoid arthritis with nodules and extra-articular manifestations	100
Rheumatoid arthritis (overall)	70
Sjögren's syndrome	90
Mixed essential cryoglobulinaemia	90
Primary biliary cholangitis	50
Infective endocarditis	40
Systemic lupus erythematosus	30
Tuberculosis	15
Age >65 years	20

*Normal healthy people can be positive for rheumatoid factor.

Antinuclear antibodies

Antinuclear antibodies (ANAs) are directed against one or more components of the cell nucleus, including nucleic acids themselves and the proteins concerned with the processing of DNA or RNA. They occur in many inflammatory rheumatic diseases but are also found at low titre in normal individuals and in other diseases (Box 24.9). ANAs are not associated with disease severity or activity. The most common indication for ANA testing is in patients suspected of having SLE or other autoimmune connective tissue diseases. ANA has high sensitivity for SLE (100%) but low specificity (10–40%). A negative ANA virtually excludes SLE but a positive result does not confirm it.

Anti-DNA antibodies bind to double-stranded DNA (dsDNA) and are useful in SLE monitoring as very high titres are associated with more severe disease, including renal or central nervous system (CNS) involvement, and an increase in antibody titre may precede relapse. Anti-DNA antibodies are routinely tested by enzyme-linked immunosorbent assay (ELISA; see also p. 1036).

Antibodies to extractable nuclear antigens (ENAs) act as markers for certain autoimmune connective tissue diseases and some complications of SLE but sensitivity and specificity are poor (Box 24.10). For example, antibodies to Sm are found in a minority of patients with SLE but are associated with renal involvement. Antibodies to Ro occur in SLE and in Sjögren's syndrome (in association with anti-La antibodies), and are associated with a photosensitive rash and congenital heart block. Antibodies to ribonucleoprotein (RNP) occur in SLE and also in mixed connective tissue disease, where features of lupus, myositis and systemic sclerosis coexist. Anti-topoisomerase 1 (also termed Scl-70) antibodies occur in diffuse systemic sclerosis, whereas anti-centromere antibodies are more specific for limited systemic sclerosis.

Antiphospholipid antibodies

Antiphospholipid antibodies bind to a number of phospholipid binding proteins but the most clinically relevant are those that target beta$_2$-glycoprotein 1 (β_2GP1). They may be detected in

24.9 Conditions associated with a positive antinuclear antibody*

Condition	Approximate frequency (%)
Systemic lupus erythematosus	100%
Systemic sclerosis	60–80%
Sjögren's syndrome	40–70%
Dermatomyositis or polymyositis	30–80%
Mixed connective tissue disease	100%
Autoimmune hepatitis	100%
Rheumatoid arthritis	30–50%
Autoimmune thyroid disease	30–50%
Malignancy	Varies widely
Infectious diseases	Varies widely

*Low-titre positive antinuclear antibody can occur in people without autoimmune disease, without obvious clinical consequences, particularly in the elderly.

24

24.10 Conditions associated with antibodies to extractable nuclear antigens

Antibody (target/other name)	Disease association
Anti-centromere antibody	Localised cutaneous systemic sclerosis (sensitivity 60%, specificity 98%)
Anti-histone antibody	Drug-induced lupus (80%)
Anti-Jo-1 (anti-histidyl-tRNA synthetase)	Polymyositis, dermatomyositis or polymyositis–systemic sclerosis overlap (20–30%) Particularly associated with interstitial lung disease
Anti-La antibody (anti-SS-B)	Sjögren's syndrome (60%) SLE (20–60%)
Anti-ribonucleoprotein antibody (anti-RNP)	Mixed connective tissue disease (100%) SLE (25–50%), usually in conjunction with anti-Sm antibodies
Anti-Ro antibody (anti-SS-A)	SLE (35–60%): associated with photosensitivity, thrombocytopenia and subacute cutaneous lupus Maternal anti-Ro antibodies associated with neonatal lupus and congenital heart block Sjögren's syndrome (40–80%)
Anti-RNA polymerase	Diffuse systemic sclerosis (15%)
Anti Sm (anti-Smith antibody)	SLE (15–30%); associated with renal disease
Anti-Scl-70 (anti-topoisomerase I antibody)	Diffuse systemic sclerosis (15%); associated with more severe organ involvement, including pulmonary fibrosis

(SLE = systemic lupus erythematosus)

SLE and other autoimmune connective tissue diseases and are key in diagnosing antiphospholipid antibody syndrome (p. 977).

Antineutrophil cytoplasmic antibodies

Antineutrophil cytoplasmic antibodies (ANCAs) are IgG antibodies directed against the cytoplasmic constituents of granulocytes and are useful in the diagnosis and monitoring of systemic vasculitis. Two common patterns are described by immunofluorescence: cytoplasmic fluorescence (c-ANCA), which is caused by antibodies to proteinase-3 (PR3); and perinuclear fluorescence (p-ANCA), which is caused by antibodies to myeloperoxidase (MPO) and other proteins, such as lactoferrin and elastase. These antibodies are not specific for vasculitis and positive results may be found in autoimmune liver disease, malignancy, infection (bacterial and human immunodeficiency virus, HIV), inflammatory bowel disease, RA, SLE and pulmonary fibrosis.

Complement

Low complement C3 is an indicator of active SLE, owing to 'consumption' of complement by immune complexes (see Fig. 4.4, p. 66). Low C4 is less specific for SLE activity. High C3 and functional measures of complement activation are non-specific features of inflammation.

Tissue biopsy

Tissue biopsy is useful in confirming the diagnosis in certain musculoskeletal diseases.

Synovial biopsy can be useful in selected patients with chronic inflammatory monoarthritis or tenosynovitis to rule out chronic infectious causes, especially mycobacterial infections. Synovial biopsy can be obtained arthroscopically (by conventional means or by use of needle arthroscope) or by using ultrasound guidance under local anaesthetic.

Temporal artery biopsy can be of value in patients suspected of having temporal arteritis, especially when the presentation is atypical, but a negative result does not exclude the diagnosis. Biopsies of affected tissues, such as skin, lung, nasopharynx, gut, kidney and muscle, should be sought by default in confirming a diagnosis of systemic vasculitis.

Muscle biopsy plays an important role in the investigation of myopathy and inflammatory myositis. It is usually taken from the quadriceps or deltoid through a small skin incision under local anaesthetic. Since myositis can be patchy in nature, MRI is sometimes used to localise the best site for biopsy. Immunohistochemical staining, together with plain histology, gives information on primary and secondary muscle and neuromuscular disease. Repeat biopsies are sometimes used to monitor the response to treatment.

Bone biopsy is occasionally required where non-invasive tests give inconclusive results, in the diagnosis of infiltrative disorders, in patients with renal bone disease, suspected chronic infection or malignancy, and rarely to confirm or exclude the presence of osteomalacia. Bone is taken from the iliac crest using a large-diameter (8 mm) trephine needle under local anaesthetic and processed without demineralisation. For focal lesions, the biopsy should be taken under X-ray guidance or at open surgery, from an affected site.

Electromyography

Electromyography (p. 1076) is of value in the investigation of suspected myopathy and inflammatory myositis, when it shows the diagnostic triad of:

- spontaneous fibrillation
- short-duration action potentials in a polyphasic disorganised outline
- repetitive bouts of high-voltage oscillations on needle contact with diseased muscle.

Presenting problems in musculoskeletal disease

Acute monoarthritis

The most important causes of acute arthritis in a single joint are crystal arthritis, sepsis, SpA and oligoarticular juvenile idiopathic arthritis (JIA; p. 1026). Other potential causes are shown in Box 24.11.

Clinical assessment

The clinical history, pattern of joint involvement, speed of onset, and age and gender of the patient all give clues to the most likely diagnosis. Gout classically affects the first metatarsophalangeal (MTP) joint, whereas pseudogout, which can be a presenting feature of calcium pyrophosphate dihydrate (CPPD) disease, can affect the hand/wrist, ankle, knee or hip. A very rapid onset (6–12 hours) is suggestive of crystal arthritis; joint sepsis develops more slowly and continues to progress until treated.

i 24.11 Causes of acute monoarthritis

Common

- Gout
- Pseudogout
- Trauma
- Haemarthrosis
- Spondyloarthritis
- Psoriatic arthritis
- Reactive arthritis
- Enteropathic arthritis

Less common

- Rheumatoid arthritis
- Juvenile idiopathic arthritis
- Pigmented villonodular synovitis
- Foreign body reaction
- Tuberculosis
- Leukaemia*
- Gonococcal infection
- Osteomyelitis*

*In children, both leukaemia and osteomyelitis may present with monoarthritis.

Haemarthrosis typically causes a large effusion, in the absence of periarticular swelling or skin change, in a patient who has suffered an injury. Pigmented villonodular synovitis (p. 1059) also presents with synovial swelling and a large effusion, although the onset is gradual. A previous diarrhoeal illness or genital infection suggests reactive arthritis, whereas intercurrent illness, dehydration or surgery may act as a trigger for crystal-induced arthritis. Rheumatoid arthritis seldom presents with monoarthritis but psoriatic arthritis (PsA) can typically present this way. Osteoarthritis can present with pain and stiffness affecting a single joint, but the onset is gradual and there is usually no evidence of significant joint swelling unless it is complicated by crystal-induced inflammation.

Investigations

Aspiration of the affected joint is mandatory. If sepsis is suspected in a large joint, arthroscopic washout is advisable. The fluid should be sent for culture and Gram stain to seek the presence of organisms and should be checked by polarised light microscopy for crystals. Blood cultures should also be taken in patients suspected of having septic arthritis. CRP levels and ESR are raised in sepsis, crystal arthritis and reactive arthritis, and this can be useful in assessing the response to treatment. Serum uric acid measurements may be raised in gout but a normal level does not exclude the diagnosis. Ruling out primary hyperparathyroidism is essential if there is pseudogout.

Management

If there is any suspicion of sepsis, intravenous antibiotics (see Box 24.50, p. 1020) should be given promptly, pending the results of cultures. Unless atypical infections/tuberculosis (requiring prolonged or special culture) are suspected, intra-articular glucocorticoid injection may be considered after 48 hours of negative synovial fluid culture. Otherwise, management should be directed towards the underlying cause.

Polyarthritis

This term is used to describe pain and swelling affecting five or more joints or joint groups. The possible causes are listed in Box 24.12.

i 24.12 Common causes of polyarthritis

Cause	Characteristics
Rheumatoid arthritis	Symmetrical, small and large joints, upper and lower limbs
Viral arthritis	Symmetrical, small joints; may be associated with rash and prodromal illness; self-limiting
Osteoarthritis	Symmetrical, targets PIP, DIP and first CMC joints in hands, knees, hips, back and neck; associated with Heberden's and Bouchard's nodes
Psoriatic arthritis	Asymmetrical, targets all joints and entheses; associated with nail pitting/ onycholysis, dactylitis
Axial spondyloarthritis and enteropathic arthritis	Tends to affect midsize and large joints and entheses, lower more than upper limbs; history of inflammatory back pain
Systemic lupus erythematosus	Symmetrical, typically affecting small joints; clinical evidence of synovitis unusual
Juvenile idiopathic arthritis	Various patterns (p. 1026): polyarticular, oligoarticular and systemic but also enthesitis-predominant
Chronic gout	Affects distal more than proximal joints; history of acute attacks
Chronic sarcoidosis (p. 608)	Varies: small and large joints, often involves ankles
Calcium pyrophosphate arthritis	Chronic polyarthritis with involvement of wrists, ankles, knees and oligoarticular small hand joints

(CMC = carpometacarpal; DIP = distal interphalangeal; PIP = proximal interphalangeal)

Clinical assessment

The hallmarks of inflammatory arthritis are early-morning stiffness and worsening of symptoms with inactivity, along with synovial swelling and tenderness on examination. Clinical features in other systems can be helpful in determining the underlying cause (Box 24.13). The most important diagnoses to consider are PsA, RA and inflammatory small joint OA. RA is characterised by symmetrical involvement of the small joints of the hands and feet, wrists, ankles and knees. PsA is strongly associated with enthesitis. Viral arthritis (p. 1020), Poncet's disease (in regions where tuberculosis is highly prevalent; p. 588), polyarticular JIA (in children) and post-streptococcal arthritis should also be considered.

The pattern of involvement can be helpful in reaching a diagnosis (Fig. 24.10). Asymmetry, lower limb predominance, enthesitis and greater involvement of large joints are characteristic of the SpAs. In PsA there may be involvement of the proximal and distal interphalangeal (PIP and DIP) joints, as opposed to the metacarpophalangeal (MCP) and PIP joints in RA. Inflammatory OA can appear similar to small-joint PsA in the pattern of joint involvement. In PsA there may be nail pitting or early onycholysis. Psoriasis may not be present. SLE can be associated with polyarthritis but more usually causes polyarthralgia and tenosynovitis, mainly of distal limb joints/tendons (p. 1035).

Investigations

Blood samples should be taken for routine haematology, biochemistry, ESR, CRP, viral serology and an immunological screen, including ANA, RF and ACPA. Ultrasound examination or MRI may be required to confirm the presence of synovitis, if this is not obvious clinically.

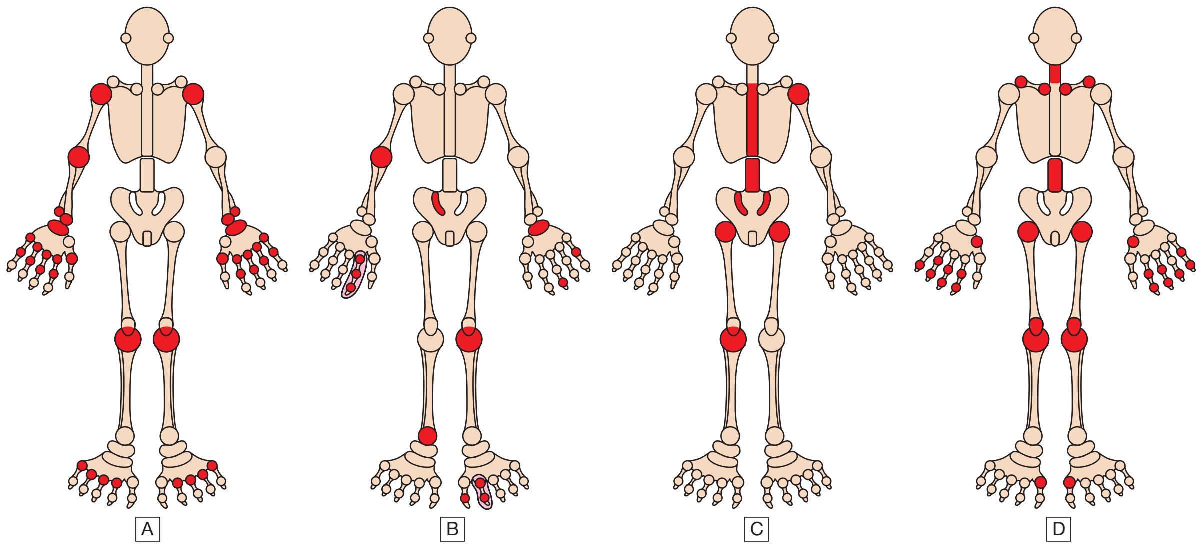

Fig. 24.10 Patterns of joint involvement in different forms of polyarthritis. A Rheumatoid arthritis typically targets the metacarpophalangeal and proximal interphalangeal joints of the hands and metatarsophalangeal joints of the feet, as well as other joints, in a symmetrical pattern. B Psoriatic arthritis targets proximal and distal interphalangeal joints of the hands, entheses and larger joints in an asymmetrical pattern. Sacroiliitis (often asymmetrical) may occur. C Axial spondyloarthritis/ankylosing spondylitis targets the spine, sacroiliac joints, entheses and large peripheral joints in an asymmetrical pattern. D Osteoarthritis targets the proximal and distal interphalangeal joints of the hands, first carpometacarpal joint at the base of the thumb, knees, hips, lumbar and cervical spine.

i 24.13 Extra-articular features of inflammatory arthritis

Clinical feature	Disease association
Skin, nails and mucous membranes	
Psoriasis, nail pitting and dystrophy	Psoriatic arthritis
Raynaud's phenomenon	Systemic sclerosis, antiphospholipid syndrome, SLE
Photosensitivity	SLE
Livedo reticularis	SLE, antiphospholipid syndrome
Splinter haemorrhages, nail-fold infarcts, purpuric lesions	Vasculitis
Urticaria and erythemas	SLE, adult-onset Still's disease, systemic JIA, rheumatic fever
Oral ulcers	SLE, reactive arthritis, Behçet's disease
Nodules	RA (mainly extensor surfaces), gout (tophi; eccentric, white deposits within), rheumatic fever
Xerostomia, dry skin, various rashes	Primary Sjögren's syndrome
Eyes	
Uveitis	SpA, sarcoid, JIA, Behçet's disease
Conjunctivitis	Reactive arthritis
Episcleritis, scleritis	RA, vasculitis
Heart, lungs	
Pleuro-pericarditis	SLE, RA, rheumatic fever
Aortic valve/root disease	HLA-B27-related SpA
Interstitial lung disease	RA, SLE, primary Sjögren's syndrome
Abdominal organs	
Hepatosplenomegaly	RA, SLE
Haematuria, proteinuria	SLE, vasculitis, systemic sclerosis
Urethritis	Reactive arthritis and SpA (sterile)
Fever, lymphadenopathy	Infection, systemic JIA, rheumatic fever

(HLA = human leucocyte antigen; JIA = juvenile idiopathic arthritis; RA = rheumatoid arthritis; SLE = systemic lupus erythematosus; SpA = spondyloarthritis)

Management

Treatment with non-steroidal anti-inflammatory drugs (NSAIDs) and analgesics will help. Systemic glucocorticoids can be considered if symptoms are very severe or having a great functional impact, but early immunotherapy (DMARDs) is required in RA and in some cases of PsA. An early accurate and specific diagnosis is very important.

Fracture

Fractures are a common presenting symptom of osteoporosis but they also occur in other bone diseases, in osteopenia and in some patients with normal bone.

Clinical assessment

The presentation is with localised bone pain, which is worsened by movement of the affected limb or region. There is usually a history of trauma but spontaneous fractures can occur in the absence of trauma in severe osteoporosis. Fractures can be divided into several subtypes, based on the precipitating event and presence or absence of an underlying disease (Box 24.14). The main differential diagnosis is soft tissue injury but fracture should be suspected when there is marked pain and swelling, abnormal movement of the affected limb, crepitus or deformity. Femoral neck fractures typically produce a shortened, externally rotated leg that is painful to move. The pain from vertebral fracture is variable and a high index of suspicion is key to making the diagnosis by imaging, as discussed below.

Investigations

X-rays of the affected site should be taken in at least two planes and examined for discontinuity of the cortical outline (Box 24.15). In addition to demonstrating the fracture, X-rays may also show evidence of an underlying disorder, such as osteoporosis, Paget's disease or osteomalacia. If the X-ray fails to show evidence of a fracture but clinical suspicion remains high, MRI should be

24.14 Characteristics of different fracture types

Fracture type	Precipitation factor	Disease
Fragility fracture	Fall from standing height or less	Osteoporosis Osteopenia
Vertebral fracture	Bending, lifting, falling	Osteoporosis
Stress fracture	Running, excessive training	Normal
High-energy fracture	Major trauma	Normal
Pathological fracture	Spontaneous, minimal trauma	Malignancy Paget's disease Osteomalacia

24.15 How to investigate a suspected fracture

- Order X-rays in two projections at right angles to one another
- Include the whole bone and the joints at either end (this may reveal an additional unsuspected fracture)
- Check for evidence of displacement
- Check for a break in the cortex
- In suspected vertebral fracture, check for depression of the end plate
- If clinical suspicion is high but no fracture is seen, request magnetic resonance imaging

obtained. Patients who are over the age of 50 and present with fragility fractures should be screened for osteoporosis by DXA.

Management

Management of fracture in the acute stage requires adequate pain relief, with opiates if necessary, reduction of the fracture to restore normal anatomy, and immobilisation of the affected limb to promote healing. This can be achieved either by the use of an external cast or splint, or by internal fixation. Femoral neck fractures present a special management problem since non-union and avascular necrosis are common. This is especially true with intracapsular hip fractures, which should be treated by joint replacement surgery. Following the fracture, rehabilitation is required with physiotherapy and a supervised exercise programme. If the DXA scan shows evidence of osteoporosis or other metabolic bone disease, this should be treated appropriately (p. 1046). Options for management of painful vertebral fracture are discussed on page 1002.

Generalised musculoskeletal pain

Clinical assessment

Clinical history and examination need to be wide-ranging (Box 24.16). Relentlessly progressive pain occurring in association with weight loss suggests malignant disease with bone metastases. Generalised bone pain may also arise in severe osteomalacia, primary hyperparathyroidism and polyostotic Paget's disease. Widespread pain can occur in PsA if there is enthesial as well as, or instead of, joint involvement; fatigue is also often present. Polyarticular RA or OA pains tend to be localised to sites of involvement, such as the lumbar spine, hips, knees and hands. Fibromyalgia (FM) syndrome (p. 1018) presents with generalised pain that particularly affects the trunk, back and neck. Accompanying features include fatigue, poor concentration and focal areas of hyperalgesia. Widespread pain may also occur in association with hypermobility, most notably Ehlers–Danlos syndrome hypermobility subtype (hEDS; p. 1059).

24.16 Some common causes of generalised pain

- Myopathies
- Psoriatic arthritis (enthesopathic)
- Fibromyalgia
- Parvovirus arthromyalgia
- Rheumatic fever/post-streptococcal infection
- Metastatic cancer
- Severe osteomalacia

Investigations

Bone scintigraphy is of value in patients suspected of having osteomalacia, bone metastases or Paget's disease, and in characterising lesions at joints and/or entheses in SpAs, including PsA. Myeloma (p. 966) should be screened for with an FBC, measurement of CRP, and plasma and urinary protein electrophoresis. If these results are positive, a radiological skeletal survey should be obtained. Routine biochemistry, vitamin D and parathyroid hormone (PTH) should be measured if osteomalacia is suspected. In Paget's disease, ALP may be elevated but can be normal in localised disease. Any persistently elevated ESR, CRP, angiotensin-converting enzyme (ACE), immunoglobulins, C3/C4 or platelets invariably indicates inflammatory disease. Laboratory investigations are normal in patients with FM alone and in hEDS.

Management

Management should be directed towards the underlying cause. Chronic pain of unknown cause and that associated with FM respond poorly to analgesics and NSAIDs, but may respond partially to antineuropathic agents, such as amitriptyline, duloxetine, gabapentin and pregabalin.

Back pain

Back pain is a common symptom that affects 60–80% of people at some time in their lives. Although the prevalence has not increased, reported disability from back pain has risen significantly in the last 30 years. In Western countries, back pain is the most common cause of sickness-related work absence. In the UK, 7% of adults consult their GP each year with back pain. Globally, low back pain is thought to affect about 9% of the population. The most important causes are summarised in Box 24.17.

Clinical assessment

The main purpose of clinical assessment is to differentiate the self-limiting disorder of acute mechanical back pain from serious spinal pathology, as summarised in Figure 24.11. Mechanical back pain is the most common cause of acute back pain in people aged 20–55. This accounts for more than 90% of episodes, and is usually acute and associated with lifting or bending. It is exacerbated by activity and is generally relieved by rest (Box 24.18). It is usually confined to the lumbar–sacral region, buttock or thigh, is asymmetrical and does not radiate beyond the knee (which would imply nerve root irritation). On examination, there may be asymmetric local paraspinal muscle spasm and tenderness, and painful restriction of some, but not all, movements. Low back pain is more common in manual workers, particularly those in occupations that involve heavy lifting and twisting. The prognosis

is generally good. After 2 days, 30% are better and 90% have recovered by 6 weeks. Recurrences of pain may occur and about 10–15% of patients go on to develop chronic back pain that may be difficult to treat. Psychological elements, such as job dissatisfaction, depression and anxiety, are important risk factors for the transition to chronic pain and disability.

Back pain secondary to serious spinal pathology has different characteristics (Box 24.19). If there is clinical evidence of spinal cord or nerve root compression, sepsis including tuberculosis, or a cauda equina lesion (Box 24.20), urgent investigation is needed. Spinal stenosis presents insidiously with leg discomfort on walking that is relieved by rest, bending forwards or walking uphill. Patients may adopt a characteristic simian posture, with a forward stoop and slight flexion at hips and knees. The most common cause is the gradual development of coexisting contributing lesions such as facet joint arthritis, ligament flavum thickening or degenerative spondylolisthesis.

Degenerative disc disease is a common cause of chronic low back pain in middle-aged adults. Prolapse of an intervertebral disc presents when discs are still well hydrated (in young and early middle age) with nerve root pain, which can be accompanied by a sensory deficit, motor weakness and asymmetrical reflexes. Examination may reveal a positive sciatic or femoral stretch test. About 70% of patients improve by 4 weeks. Inflammatory back pain (IBP) due to axial spondyloarthritis (axSpA) or PsA has a gradual onset and almost always occurs before the age of 40. It is associated with morning stiffness and improves with movement. Spondylolisthesis (p. 1059) may cause back pain that

24.17 Causes of low back pain

- Mechanical (soft-tissue lesion) back pain
- Intervertebral disc lesions (e.g. prolapse, disc degeneration)
- Facet joint disease (osteoarthritis, psoriatic arthritis)
- Vertebral fracture (p. 994)
- Paget's disease
- Axial spondyloarthritis
- Spondylodiscitis
- Bone metastases
- Spondylolisthesis (p. 1059)
- Scheuermann's disease (p. 1055)

24.18 Features of mechanical low back pain

- Pain varies with physical activity (improved with rest)
- Onset often sudden and precipitated by lifting or bending
- Recurrent episodes
- Pain limited to back or upper leg
- No clear-cut nerve root distribution
- No systemic features
- Prognosis good (90% recovery at 6 weeks)

24.19 Red flags for possible spinal pathology

History

- Age: presentation <20 years or >55 years
- Character: constant, progressive pain unrelieved by rest
- Location: thoracic pain
- Past medical history: carcinoma, tuberculosis, HIV, systemic glucocorticoid use, osteoporosis
- Constitutional: systemic upset, sweats, weight loss
- Major trauma

Examination

- Painful spinal deformity
- Severe/symmetrical spinal deformity
- Saddle anaesthesia
- Progressive neurological signs/muscle-wasting
- Multiple levels of root signs

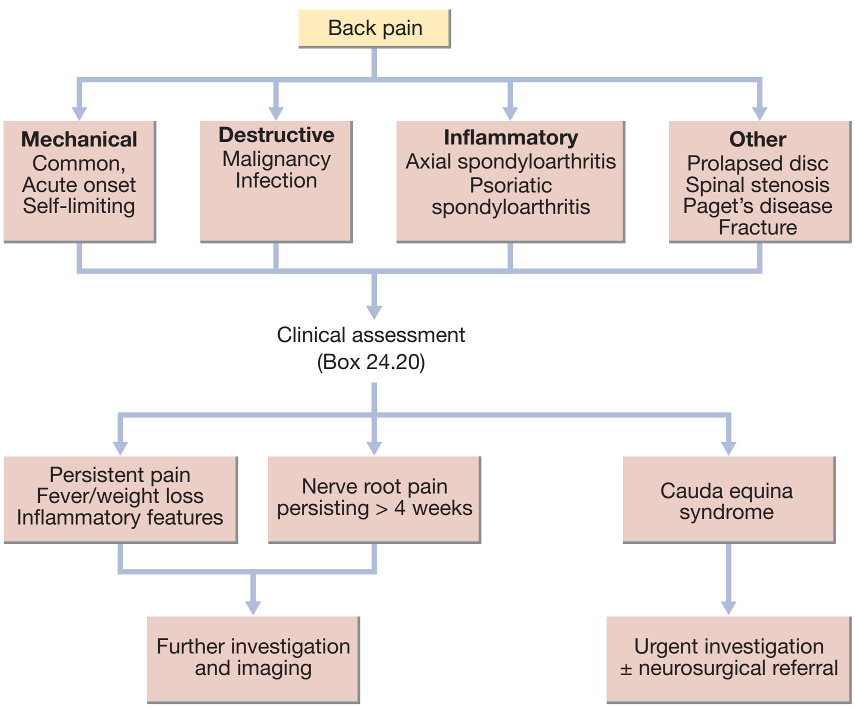

Fig. 24.11 Initial triage assessment of back pain.

i 24.20 Clinical features of radicular pain

Nerve root pain

- Unilateral leg pain worse than low back pain
- Pain radiates beyond knee
- Paraesthesia in same distribution
- Nerve irritation signs (reduced straight leg raising that reproduces leg pain)
- Motor, sensory or reflex signs (limited to one or adjacent nerve roots)
- Prognosis reasonable (50% recovery at 6 weeks)

Cauda equina syndrome

- Difficulty with micturition
- Loss of anal sphincter tone or faecal incontinence
- Saddle anaesthesia
- Gait disturbance
- Pain, numbness or weakness affecting one or both legs

is typically aggravated by standing and walking. Occasionally, diffuse idiopathic skeletal hyperostosis (DISH; p. 1058) can cause back pain but it is usually asymptomatic. Arachnoiditis is a rare cause of chronic severe low back pain. It is caused by chronic inflammation of the nerve root sheaths in the spinal canal and can complicate meningitis, spinal surgery or myelography with oil-based contrast agents.

Investigations

Investigations are not required in patients with acute mechanical back pain. Those with persistent pain (>6 weeks) or red flags (see Box 24.19) should undergo further investigation. MRI is the investigation of choice because it can demonstrate spinal stenosis, cord compression or nerve root compression, as well as inflammatory changes in axSpA, malignancy and sepsis. Plain X-rays can be of value in patients suspected of having vertebral compression fractures, OA and degenerative disc disease. If metastatic disease is suspected, bone scintigraphy should be considered. Additional investigations that may be required include routine biochemistry and haematology, ESR and CRP (to screen for sepsis and inflammatory disease), protein and urinary electrophoresis (for myeloma), human leucocyte antigen (HLA)-B27 status in IBP and prostate-specific antigen (for prostate carcinoma).

Management

Education is important in patients with mechanical back pain. It should emphasise the self-limiting nature of the condition and the fact that exercise is helpful rather than damaging. Regular analgesia and/or NSAIDs may be required to improve mobility and facilitate exercise. Return to work and normal activity should take place as soon as possible. Bed rest is not helpful and may increase the risk of chronic disability. Referral for physical therapy should be considered if a return to normal activities has not been achieved by 6 weeks. Low-dose tricyclic antidepressant drugs may help pain, sleep and mood.

Other treatment modalities that are occasionally used include epidural and facet joint injection, traction and lumbar supports, though there is limited randomised controlled trial evidence to support their use. Malignant disease, osteoporosis, Paget's disease and SpAs require specific treatment of the underlying condition.

Surgery is required in less than 1% of patients with low back pain but may be needed in progressive spinal stenosis, in spinal cord compression and in some patients with nerve root compression.

Regional musculoskeletal pain

Regional musculoskeletal pain is a common presenting complaint, usually occurring as the result of age-related degenerative disease of tendons and ligaments, OA and trauma.

Neck pain

Neck pain is a common symptom that can occur following an injury or falling asleep in an awkward position, as a result of stress or in association with OA of the spine. The causes are shown in Box 24.21. Most cases resolve spontaneously or with a short course of NSAIDs or analgesics and some exercise therapy. Patients with persistent pain that follows a nerve root distribution and those with upper or lower limb neurological signs should be investigated by MRI and, if necessary, referred for a neurosurgical opinion.

i 24.21 Typical causes of neck pain

Mechanical	
• Postural • Whiplash injury	• Facet joint • Cervical spondylosis
Inflammatory	
• Infections • Axial spondyloarthritis • Psoriatic arthritis	• Rheumatoid arthritis • Polymyalgia rheumatica • Discitis
Metabolic	
• Axial calcium pyrophosphate dihydrate disease	• Fibrous dysplasia • Paget's disease
Neoplastic	
• Metastases • Myeloma	• Lymphoma • Intrathecal tumours
Other	
• Fibromyalgia	• Torticollis
Referred	
• Pharynx • Cervical lymph nodes • Teeth • Angina pectoris	• Aortic aneurysm • Pancoast tumour • Diaphragm

Shoulder pain

Shoulder pain is a common complaint over the age of 40 (Box 24.22). Varying pain patterns associated with common lesions are shown in Figure 24.12. For most shoulder lesions, general management is with analgesics, NSAIDs, local glucocorticoid injections and physiotherapy aimed at restoring normal movement and function. Surgery may be required in patients who have debilitating or persistent symptoms in association with rotator cuff lesions or severe acromioclavicular joint arthritis. If there is subacromial impingement, without evidence of a rotator cuff tear on MRI, subacromial glucocorticoid injection and physiotherapy constitute a reasonable first step. Calcific supraspinatus tendonitis unresponsive to glucocorticoid injection can be treated with barbotage (needle disruption of deposit under ultrasound guidance). Complete rotator cuff tears in people under 40 years of age may respond well to full surgical repair but results are

24.22 Clinical findings in shoulder pain

Rotator cuff and subacromial lesions

- Pain reproduced by resisted active movement:
  - Abduction: supraspinatus
  - External rotation: infraspinatus, teres minor
  - Internal rotation: subscapularis

Acromioclavicular joint

- Pain on full abduction and adduction (at 90° of forward elevation)

Bicipital (long head) tendinitis

- Tenderness over bicipital groove
- Pain reproduced by resisted active wrist supination or elbow flexion

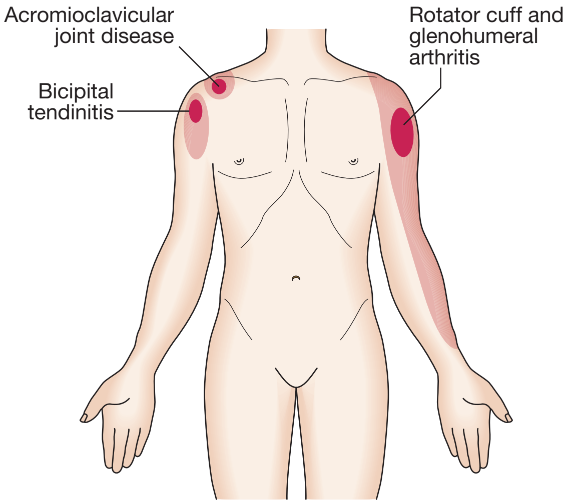

Fig. 24.12 Pain patterns around the shoulder. The dark shading indicates sites of maximum pain.

less good in older people. Adhesive capsulitis (frozen shoulder) presents with pain associated with marked restriction of elevation and external rotation. Adhesive capsulitis is commonly associated with diabetes mellitus and neck/radicular lesions. Treatment in the early stage is with analgesia, intra- and extracapsular glucocorticoid injection, and regular 'pendulum' exercises of the arm to mobilise. Complete recovery sometimes takes up to 2 years. For severe or persistent symptoms, joint distension and manipulation under anaesthesia are surgical options.

Elbow pain

The most common causes are repetitive trauma causing lateral epicondylitis (tennis elbow) and medial epicondylitis (golfer's elbow) (Box 24.23). SpAs, including psoriatic disease, can present with the same symptoms (tendon insertion enthesitis). Management is by rest, analgesics and topical or systemic NSAIDs. Local glucocorticoid injections may be required in resistant cases. Olecranon bursitis can also follow local repetitive trauma but other causes include infections and gout.

Hand and wrist pain

Pain from hand or wrist joints is well localised to the affected joint, except for pain from the first carpometacarpal (CMC) joint, commonly targeted by OA or PsA; although maximal at the thumb base, the pain often radiates down the thumb and to the radial aspect of the wrist. Non-articular causes of hand pain include:

24.23 Typical local causes of elbow pain

Lesion	Pain	Examination findings
Lateral humeral epicondylitis (e.g. traumatic 'tennis elbow' or SpA-related enthesitis)	Lateral epicondyle Radiation to extensor forearm	Tenderness over epicondyle Pain reproduced by resisted active wrist extension
Medial humeral epicondylitis (e.g. traumatic 'golfer's elbow' or SpA-related enthesitis)	Medial epicondyle Radiation to flexor forearm	Tenderness over epicondyle Pain reproduced by resisted active wrist flexion
Olecranon bursitis (e.g. gout, rheumatoid arthritis or infective, as in tuberculosis)	Olecranon	Tender swelling

(SpA = spondyloarthritis)

- *Tenosynovitis*: affects flexor or extensor digital tendons. Pain and tenderness are well localised to the tendon lesions. There is often early-morning 'claw-like' digit stiffness. De Quervain's tenosynovitis involves the tendon sheaths of abductor pollicis longus and extensor pollicis brevis. It produces pain maximal over the radial aspect of the distal forearm and wrist and marked pain on forced ulnar deviation of the wrist with the thumb held across the patient's palm (Finkelstein's sign). This test is not specific for this lesion alone.
- *Raynaud's phenomenon*: digital vasospasm triggered mostly by cold (p. 1035).
- *C6, C7 or C8 radiculopathy*.
- *Carpal tunnel syndrome*: hand position-dependent and/or nocturnal pain, numbness and paraesthesia of thumb and second to fourth digits.

Hip pain

Pain from the hip joint is usually felt deep in the groin, with variable radiation to the buttock, anterolateral thigh or knee (Fig. 24.13). Patients who report 'hip pain' sometimes point to greater trochanter or buttock areas. Greater trochanter pain syndrome is usually due to either gluteus medius insertional tendonitis/enthesitis, trochanteric bursitis or referred pain (Box 24.24). Pain at this site may also be referred from the lumbosacral spine. A differential diagnosis of hip joint conditions (groin pain) is symphysitis (SpAs, including psoriasis disease, need ruling out). Other less common causes of pain in the hip/groin area include inguinal hernia, adductor tendonitis and enthesitis of anterior superior/inferior iliac spines.

Knee pain

In middle and older age, the most common cause of knee pain is OA, the features of which are described on page 1008. Pain that is associated with locking of the knee (sudden painful inability to extend fully) is usually due to a meniscal tear or osteochondritis dissecans. Referred pain from the hip may present at the knee and is reproduced by hip, not knee, movement. Pain from periarticular lesions is well localised to the involved structure (Box 24.25). Anterior knee pain may be due to patellar ligament or retinacular lesions (enthesitis, tendonitis, fat-pad syndrome) occurring typically

i 24.24 Local causes of hip pain

Lesion	Pain	Examination findings
Gluteus medius enthesitis	Upper lateral thigh, worse on lying on that side at night	Tenderness over greater trochanter
Trochanteric bursitis	As above	As above
Adductor tendinitis (usually an SpA-enthesitis or sports-related trauma lesion)	Upper inner thigh	Tenderness over adductor origin/tendon/muscle Pain reproduced by resisted active hip adduction
Ischiogluteal enthesitis/bursitis	Buttock, worse on sitting	Tenderness over ischial prominence
Pubic symphysitis (can mimic intra-articular hip lesions)	Medial groin pain, can radiate to inner or even outer upper thighs	Tenderness over symphysis joint If pain is worse on trunk curl/rectus activation under symphysis-resting hand, it may be insertional rectus enthesitis (SpAs)
(SpA = spondyloarthritis)		

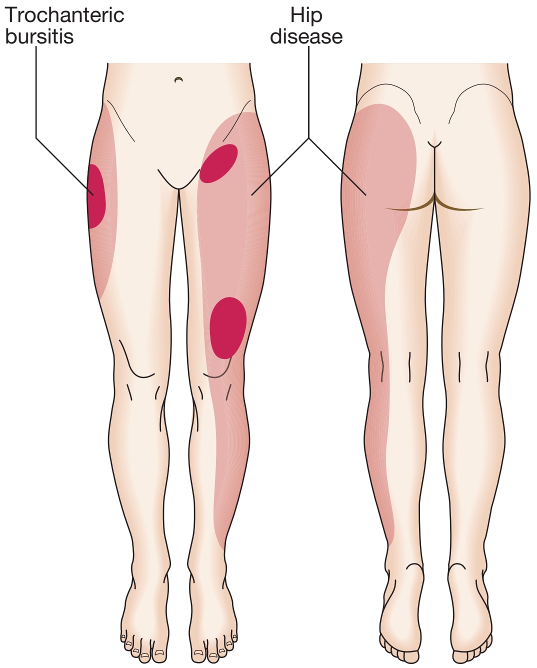

Fig. 24.13 Pain patterns of hip disease and trochanteric pain syndrome. The dark shading indicates sites of maximum pain.

i 24.25 Local causes of knee pain

Lesion	Pain	Examination findings
Pre-patellar bursitis	Over patella	Tender fluctuant swelling in front of patella
Superficial and deep infrapatellar bursitis and fat-pad syndrome	Anterior knee, inferior to patella	Tenderness in front of (superficial) or behind (deep) patellar tendon Pain on full flexion
Anserine bursitis/ enthesitis	Upper medial tibia	Tenderness (± swelling) over upper medial tibia
Medial collateral ligament lesions (e.g. enthesitis)	Upper medial tibia	Localised tenderness of upper medial tibia Pain reproduced by valgus stress on partly flexed knee
Popliteal cyst (Baker's cyst)	Popliteal fossa	Tender swelling of popliteal fossa
Patellar ligament enthesopathy	Anterior upper tibia	Tenderness over tibial tubercle
Osteochondritis of patellar ligament (Osgood–Schlatter disease)	Anterior upper tibia	Adolescents are affected Pain on resisted active knee extension

from overuse and/or an SpA condition. Anterior knee pain is relatively common in adolescents and may be the result of patellar articular cartilage or ligament insertion osteochondritis.

Ankle and foot pain

Pain from the ankle (tibiotalar) joint due to OA or osteochondral defect is felt between the malleoli and is worse on weight-bearing. Pain from the subtalar joint (from the same lesions) is also worse on weight-bearing. Inflammatory arthritis of either of these joints (RA, PsA, CPPD arthritis or gout) often worsens and swells with rest. These diagnoses can be associated with hindfoot tenosynovitis (peroneal or posterior tibial). Pain under the heel is typically due to plantar fasciitis. This can occur as the result of overuse, which case it may respond to rest, padded footwear and local glucocorticoid injections, but can also arise in SpA as a manifestation of enthesitis. Pain affecting the back of the heel may be due to Achilles tendinitis or enthesitis. The MTP joints of the feet are commonly involved symmetrically in RA. The presentation is with pain on walking felt below the metatarsal heads, often described as 'walking on marbles'. Patients with active inflammation of the MTP joints have pain when the forefoot is squeezed (p. 982). Involvement of the first MTP joint is common in OA or PsA and is associated, respectively, with hallux valgus and dactylitis. The hallux also a classical target in acute gout. Morton's neuroma is a neuropathy of an interdigital nerve and is usually located between the third and fourth metatarsal heads. Women are most commonly affected (tight shoes can be to blame). Local sensory loss and a palpable tender swelling between the metatarsal heads may be detected. Footwear adjustment, with or without a local glucocorticoid injection, often helps but surgical decompression may be required if symptoms persist.

Muscle pain and weakness

Muscle pain and weakness can arise from a variety of causes. It is important to distinguish between a subjective feeling of generalised weakness occurring with fatigue, and an objective weakness with loss of muscle power and function. The former is a non-specific manifestation of many systemic conditions.

Clinical assessment

Proximal muscle weakness suggests the presence of a myopathy or myositis, which typically causes difficulty with standing from a seated position, walking up steps, squatting and lifting overhead. The causes are shown in Box 24.26. Worsening of symptoms on exercise and post-exertional cramps suggest a metabolic myopathy, such as glycogen storage disease (p. 370). A strong family history and onset in childhood or early adulthood suggest muscular dystrophy (p. 1143). Alcohol excess can cause an inflammatory myositis and atrophy of type 2 muscle fibres. Proximal myopathy may be a complication of glucocorticoid therapy, prolonged/severe hypercalcaemia and osteomalacia. Myopathy and myositis can also occur in association with many drugs (see 'Further information', p. 1060) and viral infections, including HIV; in the latter case, it may be due to HIV itself or to treatment with zidovudine. Polymyositis and dermatomyositis (p. 1039) are associated with coexisting/co-presenting malignancy, especially gonadal tumours. Clinical examination should document the presence, pattern and severity of muscle weakness (p. 1081), assessed using the Medical Research Council (MRC) scale (no power (0) to full power (5)).

Investigations

Investigations should include routine biochemistry and haematology, ESR, CRP, creatine kinase, serum 25(OH)-vitamin D, PTH, parvovirus, hepatitis B/C, HIV and streptococcus serology, serum and urine protein electrophoresis, serum ACE, ANAs/ENAs, RF, complement and myositis-specific autoantibodies such as Jo-1. Open muscle biopsy (site guided by MRI detection of abnormal muscle) and electromyography (EMG) are usually required to make the diagnosis. The initial imaging screening for malignancy is usually a CT scan of the chest, abdomen and pelvis; upper gastrointestinal endoscopy and colonoscopy may also be considered.

i 24.26 Causes of proximal muscle pain or weakness

Inflammatory	
• Polymyositis • Dermatomyositis • Other autoimmune connective tissue disease	• Inclusion body myositis • Sarcoid • Myasthenia gravis
Endocrine (Ch. 18)	
• Hypothyroidism • Hyperthyroidism	• Cushing's syndrome • Addison's disease
Metabolic (Ch. 14)	
• Myophosphorylase deficiency • Phosphofructokinase deficiency • Hypokalaemia	• Carnitine deficiency • Osteomalacia (p. 1049) • Hypercalcaemia
Genetic	
• Muscular dystrophy (various; p. 1143)	
Drugs/toxins	
• Alcohol • Cocaine • Glucocorticoids • Statins and fibrates	• Tumour necrosis factor inhibitors • Zidovudine
Infections (Ch. 11)	
• Viral (HIV, cytomegalovirus, rubella, Epstein–Barr, echo) • Parasitic (schistosomiasis, cysticercosis, toxoplasmosis)	• Bacterial (*Clostridium perfringens*, staphylococci, tuberculosis, *Mycoplasma*)

Management

Management is determined by the cause but all patients with muscle disease should benefit from physiotherapy and graded exercises to maximise muscle function after the initial inflammation is controlled.

Principles of management

The management of rheumatological disorders should be tailored to the underlying diagnosis. Certain aspects are common to many disorders, however, and the general principles are discussed here. The therapeutic aims are:

- to educate patients about their disease
- to control pain, if it is present
- to optimise function
- to modify the disease process where this is possible
- to identify and treat comorbidity.

These aims are interrelated and success in one area often benefits others. Successful management requires careful assessment of the person as a whole. The management plan should be individualised and patient-centred, should involve relevant members of the multidisciplinary team, and should be agreed and understood by both the patient and all the practitioners that are involved. It must also take into account:

- the patient's activity requirements and occupational and recreational aspirations
- risk factors that may influence the disease
- the patient's perceptions and knowledge of the condition
- medications and coping strategies that have already been tried
- comorbid disease and its therapy
- the availability, costs and logistics of appropriate evidence-based interventions.

The simplest and safest interventions should be tried first. Symptoms and signs may change with time, so the management plan for most patients will require regular review and re-adjustment.

Core interventions that should be considered for everyone with a painful musculoskeletal condition are listed in Box 24.27. There are also other non-pharmacological and drug options, the choice of which depends on the nature and severity of the diagnosis.

Education and lifestyle interventions

Education

Patients must always be informed about the nature of their condition and its investigation, treatment and prognosis, since education can improve outcome. Information and therapist contact can reduce pain and disability, improve self-efficacy and reduce the health-care costs of many musculoskeletal conditions, including OA and RA. The mechanisms are unclear but in part may result from improved adherence. Benefits are modest but potentially long-lasting, safe and cost-effective. Education can be provided through one-to-one discussion, written literature,

i 24.27 Interventions for patients with rheumatic diseases

Core interventions	
• Education • Aerobic conditioning • Muscle strengthening • Simple analgesics • Disease-modifying therapy	• Reduction of adverse mechanical factors • Pacing of activities • Appropriate footwear • Weight reduction if obese
Other options	
• Other analgesic drugs: Oral non-steroidal anti-inflammatory drugs Topical agents Opioid analgesics Amitriptyline Gabapentin/pregabalin	• Local glucocorticoid injections • Physical treatments: Heat, cold, aids, appliances • Surgery • Coping strategies (see Box 24.28)

patient-led group education classes and interactive computer programs. Inclusion of the patient's partner or carer is often appropriate; this is essential for childhood conditions but also helps in many chronic adult conditions, such as RA and FM.

For children and adolescents with chronic diseases such as JIA, education and support of the whole family, schooling and psychological support is essential and best delivered through a multidisciplinary team.

Exercise

Several types of exercise can be prescribed:

- *Aerobic fitness training* can produce long-term reduction in pain and disability. It improves well-being, encourages restorative sleep and benefits common comorbidity, such as obesity, diabetes, chronic heart failure and hypertension.
- *Local strengthening exercise* for muscles that act over compromised joints also reduces pain and disability, with improvements in the reduced muscle strength, proprioception, coordination and balance that associate with chronic arthritis. 'Small amounts often' of strengthening exercise are better than protracted sessions performed infrequently.
- *Weight-bearing exercise* is of value in osteoporosis, where it can result in modest increases in bone density and slow bone loss.

Joint protection

Excessive impact-loading and adverse repetitive use of a compromised joint or periarticular tissue can worsen symptoms in patients with arthritis. This can be mitigated by cessation of contact sports and by pacing of activities by dividing physical tasks into shorter segments with brief breaks in between. Other strategies include adaptations to machinery or tools at the workplace; the use of shock-absorbing footwear with thick soft soles, which can reduce impact-loading through feet, knees, hips and back; and the use of a walking stick on the contralateral side to a painful hip, knee or foot.

Non-pharmacological interventions

Physical and occupational therapy

Local heat, ice packs, wax baths and other local external applications can induce muscle relaxation and provide temporary relief of symptoms in a range of rheumatic diseases.

Hydrotherapy induces muscle relaxation and facilitates enhanced movement in a warm, pain-relieving environment without the restraints of gravity and normal load-bearing. Various manipulative techniques may also help improve restricted movement. The combination of these with education and therapist contact enhances their benefits.

Splints can give temporary rest and support for painful joints and periarticular tissues, and can prevent harmful involuntary postures during sleep. Prolonged rest must be avoided, however. Orthoses are more permanent appliances used to reduce instability and excessive abnormal movement. They include working wrist splints, knee orthoses, and iron and T-straps to control ankle instability. Orthoses are particularly suited to severely disabled patients in whom a surgical option is inappropriate and often need to be custom-made for the individual.

Aids and appliances can provide dignity and independence for patients with respect to activities of daily living. Common examples are a raised toilet seat, raised chair height, extended handles on taps, a shower instead of a bath, thick-handled cutlery, and extended 'hands' to pull on tights and socks. Full assessment and advice from an occupational therapist maximise the benefits of these (Box 24.27).

Self-help and coping strategies

These help patients to cope better with, and adjust to, chronic pain and disability. They may be useful at any stage but are particularly so for patients with incurable problems, who have tried all available treatment options. The aim is to increase self-management through self-assessment and problem-solving, so that patients can recognise negative but potentially remediable aspects of their mood (stress, frustration, anger or low self-esteem) and their situation (physical, social, financial). These may then be addressed by changes in attitude and behaviour, as shown in Box 24.28.

Involvement of the spouse or partner in mutual goal-setting can improve partnership adjustment. Such approaches are often an element of group education classes and pain clinics but may require more formal clinical psychological input.

Tailored multidisciplinary approaches are required for patients with JIA and other chronic childhood diseases, dependent on age and maturity. Adolescents and young adults have specific demands, different to those of young children and adults, which are influenced by many issues in their lives impinging on the disease process, its impact and their ability to cope with it.

Weight control

Obesity aggravates pain at most sites through increased mechanical strain and is a risk factor for progression of joint damage in patients with OA and other types of arthritis. This should be explained to obese patients and strategies offered

i 24.28 Self-help and coping strategies

- Yoga and relaxation techniques to reduce stress
- Avoidance of negative situations or activities that produce stress and increase in pleasant activities that give satisfaction
- Information and discussion to alter beliefs about and perspectives on disease
- Reduction or avoidance of catastrophising and maladaptive pain behaviour
- Imagery and distraction techniques for pain
- Expansion of social contact and better use of social services

on how to lose and maintain an appropriate weight (p. 700). Excessive weight loss can be counterproductive and adults with a BMI of <20 kg/m^2 are at increased risk of fractures. Patients should therefore be advised to maintain BMI within the 20–25 g/m^2 range.

Surgery

A variety of surgical interventions can relieve pain and conserve or restore function in patients with bone, joint and periarticular disease (Box 24.29). Soft tissue release and tenosynovectomy can reduce inflammatory symptoms, improve function and prevent or retard tendon damage for variable periods, sometimes indefinitely. Synovectomy does not prevent disease progression but may be indicated for pain relief when drugs, physical therapy and intra-articular injections have provided insufficient relief. The main approaches for damaged joints are osteotomy (cutting bone to alter joint mechanics and load transmission), excision arthroplasty (removing part or all of the joint), joint replacement (insertion of prosthesis in place of the excised joint) and arthrodesis (joint fusion). Surgical fixation of fractures is frequently required in patients with osteoporosis and other bone diseases.

The main aims of surgery are to provide pain relief and improve function and quality of life. If surgery is to be successful, the aims and consequences of each operation should be considered as part of an integrated programme of management and rehabilitation by multidisciplinary teams of surgeons, allied health professionals and physicians, and carefully explained to the patient. Assessment of motivation, social support and environment is no less important than careful consideration of patients' general health, their risks for major surgery, the extent of disease in other joints, and their ability to mobilise following surgery. For some severely compromised people, pain relief and functional independence are better served by provision of a suitable wheelchair, home adjustments and social services than by surgery that is technically successful but following which the patient cannot mobilise.

i 24.29 Surgical procedures in rheumatology and bone disease

Procedure	Indication
Soft tissue release	
Carpal tunnel	Median nerve compression
Tarsal tunnel	Posterior tibial nerve entrapment
Flexor tenosynovectomy	Relief of 'trigger' fingers
Ulnar nerve transposition	Ulnar nerve entrapment at elbow
Fasciotomy	Severe Dupuytren's contracture
Tendon repairs and transfers	
Hand extensor tendons	Extensor tendon rupture
Thumb and finger flexor tendons	Flexor tendon rupture
Synovectomy	
Wrist and extensor tendon sheath (+ excision of radial head)	Pain relief and prevention of extensor tendon rupture in RA, resistant inflammatory synovitis
Knee synovectomy	Resistant inflammatory synovitis
Osteotomy	
Femoral osteotomy	Early OA of hip
Tibial osteotomy	Unicompartmental knee OA Deformed tibia in OA or Paget's disease
Excision arthroplasty	
First metatarsophalangeal joint (Keller's procedure)	Painful hallux valgus
Radial head	Painful distal radio-ulnar joint
Lateral end of clavicle	Painful acromioclavicular joint
Metatarsal head	Painful subluxed metatarsophalangeal joints
Joint replacement arthroplasty	
Knee, hip, shoulder, elbow	Painful damaged joints in OA and RA
Arthrodesis	
Wrist	Damaged joint: pain relief, improvement of grip
Ankle/subtalar joints	Damaged joint: pain relief, stabilisation of hindfoot
Fracture repair	
Hip arthroplasty	Fractured neck of femur
External fixation	Multiple fractures, open fractures
Intramedullary nailing	Tibial and femur fractures
Screw, plating and wiring	Wrist and other fractures
Other procedures	
Nerve root decompression	Spinal stenosis, nerve entrapment
Kyphoplasty	Painful vertebral fracture (evidence base poor)
Vertebroplasty	Painful vertebral fracture (evidence base poor)

Pharmacological treatment

Analgesics

Paracetamol (1 g up to 4 times daily) is the oral analgesic of first choice for mild to moderate pain. It is thought to work by inhibiting prostaglandin synthesis in the brain while having little effect on peripheral prostaglandin production. It is well tolerated and has few adverse effects and drug interactions. An increased risk of gastrointestinal events and cardiovascular disease has been reported with chronic usage in observational studies, but this may be due to channelling of patients at higher risk of these events for treatment with paracetamol rather than NSAID. Paracetamol can be combined with codeine (co-codamol) or dihydrocodeine (co-dydramol). These compound analgesics are more effective than paracetamol but have more side-effects, including constipation, headache and delirium, especially in the elderly. The centrally acting opioid analgesics tramadol and meptazinol may be useful for temporary control of severe pain unresponsive to other measures but can cause nausea, bowel upset, dizziness and somnolence, and withdrawal symptoms after chronic use. The non-opioid analgesic nefopam (30–90 mg 3 times daily) can help moderate pain, though side-effects (nausea, anxiety, dry mouth) often limit its use. Patients with severe or intractable pain may require strong opioid analgesics, such as oxycodone and morphine.

Non-steroidal anti-inflammatory drugs

NSAIDs are among the most widely prescribed drugs but their use has declined over recent years because long-term prescription is associated with an increased risk of cardiovascular disease. Oral NSAIDs are useful in the treatment of a range of rheumatic diseases with an inflammatory component. There is variability in response and patients who do not gain benefit from one NSAID may well do so with another. They inhibit the cyclo-oxygenase (COX) and prostaglandin H synthase enzymes, which convert arachidonic acid, derived from membrane phospholipids, to prostaglandins and leukotrienes by the COX and 5-lipoxygenase pathways, respectively (Fig. 24.14). There are two COX isoforms,

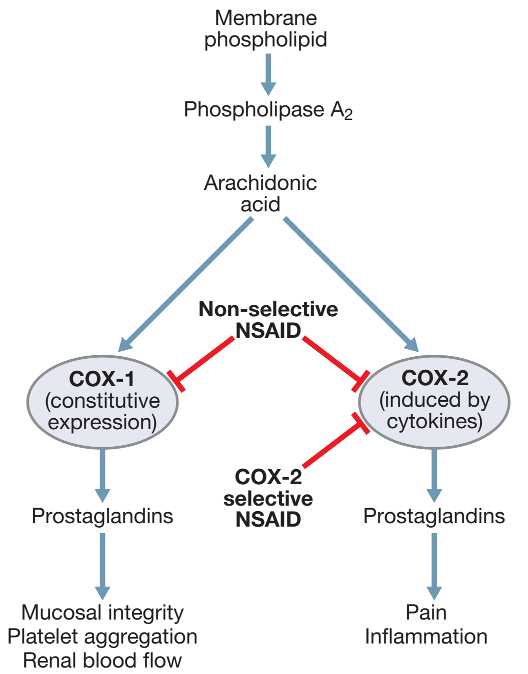

Fig. 24.14 Mechanism of action of non-steroidal anti-inflammatory drugs.

encoded by different genes. The COX-1 enzyme is constitutively expressed in gastric mucosa, platelets and kidneys, and production of prostaglandins at these sites protects against mucosal damage and regulates platelet aggregation and renal blood flow. The COX-2 enzyme is induced at sites of inflammation, producing prostaglandins that cause local pain and swelling. Inflammation also up-regulates COX-2 in the spinal cord, where it modulates pain perception. Ibuprofen, diclofenac and naproxen are non-selective drugs that inhibit both COX enzymes, whereas celecoxib and etoricoxib are selective inhibitors of COX-2. While NSAIDs have anti-inflammatory activity, they are not thought to have a disease-modifying effect in either OA or inflammatory rheumatic diseases.

Non-selective NSAIDs can damage the gastric and duodenal mucosal barrier and are associated with an increased risk of upper gastrointestinal ulceration, bleeding and perforation. The adjusted increased risk (odds ratio) of bleeding or perforation from non-selective NSAIDs is 4–5, though differences exist between NSAIDs (Box 24.30). Dyspepsia is a poor guide to the presence of NSAID-associated ulceration and bleeding, and the principal risk factors are shown in Box 24.31. Co-prescription of a proton pump inhibitor (PPI) or misoprostol (200 μg twice or 3 times daily) reduces the risk of NSAID-induced ulceration and bleeding but H_2-antagonists in standard doses are ineffective. The COX-2 selective NSAIDs are much less likely to cause gastrointestinal toxicity but benefit is attenuated in patients on low-dose aspirin. The National Institute for Health and Care Excellence (NICE) guidelines advise that a PPI should be co-prescribed with all NSAIDs, including COX-2-selective NSAIDs, even though the risk of gastrointestinal events with these is low. Since chronic PPI therapy is associated with an increased risk of hip fracture, the merits of giving PPI therapy with a COX-2-selective drug need to be weighed up carefully.

Other side-effects of NSAIDs include fluid retention and renal impairment due to inhibition of renal prostaglandin production, non-ulcer-associated dyspepsia, abdominal pain and altered bowel habit, and rashes. Interstitial nephritis, asthma and anaphylaxis can also occur but are rare. Recommendations for NSAID prescribing are summarised in Box 24.32. Because of the risk of adverse effects, NSAIDs should be used with great care in the elderly (Box 24.33).

Topical agents

Topical NSAID creams and gels and capsaicin cream (chilli extract; 0.025%) can help in the treatment of OA and superficial periarticular lesions affecting hands, elbows and knees. They may be used as monotherapy or as an adjunct to oral analgesics. Topical NSAIDs can penetrate superficial tissues and even

24.30 Commonly used NSAIDs and their risk of gastrointestinal bleeding and perforation

Drug	Daily adult dose	Doses/ day	Idiosyncratic side-effects, comments
Low risk			
Celecoxib	100–200 mg	1–2	Selective COX-2 inhibitor
Etoricoxib	60–120 mg	1	Selective COX-2 inhibitor
Medium risk			
Ibuprofen	1600–2400 mg	3–4	Gastrointestinal adverse effects more likely than with COX-2 inhibitors, even with PPI therapy
Naproxen	500–1000 mg	1–2	
Diclofenac	75–150 mg	2–3	
High risk			
Indometacin	50–200 mg	3–4	High incidence of dyspepsia and CNS side-effects
Ketoprofen	100–200 mg	2–4	
Piroxicam	20–30 mg	1–2	Restricted use in those > 60 years

(CNS = central nervous system; COX = cyclo-oxygenase; PPI = proton pump inhibitor)

24.31 Risk factors for NSAID-induced ulcers

- Age > 60 years*
- Past history of peptic ulcer*
- Past history of adverse event with NSAID
- Concomitant glucocorticoid use
- High-dose or multiple NSAIDs
- High-risk NSAID (see Box 24.30)

*The most important risk factors.

24.32 Recommendations for the use of NSAIDs

- Use the lowest dose for the shortest time possible to control symptoms
- Avoid NSAIDs in patients on warfarin
- Allow 2–3 weeks to assess efficacy. If response is inadequate, consider a trial of another NSAID
- Never prescribe more than one NSAID at a time
- Co-prescribe a proton pump inhibitor for patients with risk factors for gastrointestinal adverse effects (see Box 24.31)
- Avoid in patients with vascular disease

reach the joint capsule, though intrasynovial levels mainly reflect blood-borne drug delivery. Capsaicin selectively binds to the protein transient receptor potential vanilloid type 1 (TRPV1), which is a heat-activated calcium channel on the surface of peripheral type C nociceptor fibres. Initial application causes a burning sensation but continued use depletes presynaptic substance P, with subsequent pain reduction that is optimal after a period of 1–2 weeks.

Disease-modifying antirheumatic drugs

Disease-modifying antirheumatic drugs (DMARDs) are a group of small-molecule inhibitors of the immune response. They are employed in a range of inflammatory rheumatic diseases, as well as in other chronic inflammatory conditions. The most common indications are summarised in Box 24.34. Most of these drugs have the potential to cause bone marrow suppression or liver dysfunction and they require regular blood monitoring. Monitoring requirements for commonly used DMARDs are also summarised in Box 24.34. If toxicity occurs, treatment may need to be stopped temporarily and resumed at a lower dose. If toxicity is severe, therapy may have to be withdrawn completely and another drug substituted.

24.33 Use of oral NSAIDs in old age

- **Gastrointestinal complications**: age is a strong risk factor for bleeding and perforation, and for peptic ulceration. Elderly patients are more likely to die if they suffer NSAID-associated bleeding or perforation.
- **Cardiovascular disease**: use NSAIDs with caution in patients with cardiovascular disease. Therapy with NSAIDs may exacerbate hypertension and heart failure.
- **Renal disease**: use of NSAIDs may cause renal impairment.

Methotrexate

Methotrexate (MTX) is the core DMARD in RA, JIA and PsA. It inhibits folic acid reductase, preventing formation of tetrahydrofolate, which is necessary for DNA synthesis in leucocytes and other cells. It is given orally in a starting dose of 10–15 mg weekly and escalated in 2.5 mg increments every 2–4 weeks to a maximum of 25 mg weekly until benefit or toxicity occurs. Folic acid (5 mg/week) should be co-prescribed to be taken the day after MTX since it reduces adverse effects without impairing efficacy. Benefit is usually observed after 4–8 weeks but treatment should continue for 3 weeks before the conclusion is reached that MTX has been ineffective. The most common adverse effects are nausea, vomiting and malaise, which usually occur one 1–2 days after the weekly dose. Individuals who experience these effects can sometimes be successfully treated with subcutaneous MTX. Patients should be warned of drug interaction with sulphonamides and the importance of avoiding excess alcohol, which enhances MTX hepatotoxicity. Acute pulmonary toxicity (pneumonitis) is rare but can occur at any time during treatment, and patients should be warned to stop therapy and seek advice if they develop any new respiratory symptoms. If pneumonitis occurs, treatment should be withdrawn and high-dose glucocorticoids given. MTX must be co-prescribed with robust contraception in women of child-bearing potential and treatment must be stopped for 3 months in advance of planning a pregnancy.

Sulfasalazine

Sulfasalazine (SSZ) can be used alone and or combination with MTX and another DMARD. Its mechanism of action is incompletely understood. Nausea and gastrointestinal intolerance are the main adverse effects but leucopenia, abnormal LFTs and rashes may also occur. The usual starting dose is 500 mg daily, escalating in 500 mg increments every 2 weeks to a maintenance dose of 2–4 g daily until benefit or toxicity occurs. Benefit may be

24.34 Disease-modifying antirheumatic drugs

		Monitoring*			
Drug	**Maintenance dose**	**FBC**	**LFTs**	**Other**	**Indications**
Methotrexate	10–25 mg weekly orally	✓	✓		RA, PsA, AxSpA, JIA
Sulfasalazine	2–4 g daily orally	✓	✓		RA, PsA, AxSpA, JIA
Hydroxychloroquine	200–400 mg daily orally	–	–	Visual function	RA, SLE
Leflunomide	10–20 mg daily orally	✓	✓	BP	RA, JIA, PsA
Azathioprine	1–2.5 mg/kg daily orally	✓	✓		SLE, SV
Apremilast	30 mg twice daily orally	–	–	–	PsA
Tofacitinib	5 mg twice daily orally	✓	✓	Infection	RA
Baricitinib	2–4 mg daily orally	✓	✓	Infection	RA
Cyclophosphamide	2 mg/kg daily orally 15 mg/kg IV	✓	✓	eGFR	SLE, SV
Mycophenolate mofetil (MMF)	2–4 g daily orally	✓	✓	–	SLE, SV
Gold (myocrisin)	50 mg 4-weekly IM	✓	–	Urinalysis	RA
Penicillamine	500–1500 mg daily orally	✓	✓	Urinalysis	RA
Ciclosporin A	3–5 mg/kg daily orally	–	–	BP, eGFR	RA, PsA

*Monitoring tests are usually done every 2 weeks on initiation of treatment for 6 weeks, then monthly for 3 months, then 3-monthly.
(AxSpA = axial spondyloarthritis; BP = blood pressure; eGFR = estimated glomerular filtration rate; FBC = full blood count; IM = intramuscular; IV = intravenous; JIA = juvenile idiopathic arthritis; LFTs = liver function tests; PsA = psoriatic arthritis; RA = rheumatoid arthritis; SLE = systemic lupus erythematosus; SV = systemic vasculitis)

observed after 4–8 weeks but treatment should be continued for 3 months before the conclusion is reached that it has been ineffective. Orange staining of urine and contact lenses may occur.

Hydroxychloroquine

Hydroxychloroquine (HCQ) is used in the treatment of RA and SLE in a dose of 200–400 mg daily. Its mechanism of action is incompletely understood. A wide range of side-effects can potentially occur but HCQ is usually well tolerated in practice. With long-term use, there is a risk of ocular toxicity due to accumulation in the retina, although this is uncommon. It is usual to check visual function before starting treatment and to repeat this periodically while treatment is continued. HCQ is generally considered to be safe during pregnancy

Leflunomide

Leflunomide can be used alone or in combination with other drugs in a dose of 10–20 mg/day. It works by inhibiting dihydro-orotate dehydrogenase, an enzyme used by activated lymphocytes to synthesise pyrimidines necessary for DNA synthesis. It has low marrow toxicity but may cause liver dysfunction, hypertension and hirsutism. It must be co-prescribed with robust contraception in women of child-bearing potential. Treatment must be stopped for a period of 2 years in advance of planning a pregnancy.

Azathioprine

Azathioprine is most commonly used in vasculitis and SLE. It is metabolised to 6-mercaptopurine (6-MP), which blocks lymphocyte proliferation by inhibiting DNA synthesis. The typical starting dose is 1 mg/kg body weight per day, increasing to 2.5 mg/kg until a response is observed or toxicity occurs. Bone marrow suppression is the most important side-effect but nausea may also occur. Genetic polymorphisms in the enzyme thiopurine S-methyltransferase (TPMT) influence catabolism of 6-MP and sometimes genetic testing for TPMT variants is done to guide dosages. Allopurinol inhibits catabolism of azathioprine, necessitating a 75% reduction in azathioprine dose.

Apremilast

Apremilast is used in the treatment of PsA. It works by inhibiting phosphodiesterase D4 in leucocytes, which in turn suppresses production of pro-inflammatory cytokines, thereby reducing inflammation. Apremilast is given orally in a dose of 30 mg twice daily. The main adverse effects are gastrointestinal upset, weight loss and an increased risk of depression.

Janus-activated kinase inhibitors

Janus-activated kinase (JAK) inhibitors work by inhibiting JAK enzymes, which are a family of intracellular signalling molecules that play a key role in transducing the effects of several pro-inflammatory cytokines. They are indicated for patients with RA who have responded inadequately to standard DMARDs and provide an alternative to biologic treatments. Two JAK inhibitors are currently available: tofacitinib, which is given orally in a dose of 5 mg twice daily, and baricitinib, which is given orally in a dose of 2–4 mg once daily. The main adverse effects are an increased risk of opportunistic infections, hepatotoxicity and haematological toxicity.

Cyclophosphamide

Cyclophosphamide is a cytotoxic alkylating agent that cross-links DNA and halts cell division, causing immunosuppression. It is mainly used to induce remission in life-threatening systemic vasculitis and SLE. It can be given orally in a dose of 2 mg/kg/day for 3–6 months or intravenously in a dose of 15 mg/kg every 3–4 weeks on 6–8 occasions. Adverse effects include nausea, anorexia, vomiting, bone marrow suppression, cardiac toxicity, alopecia and haemorrhagic cystitis. The risk of cystitis can be mitigated by co-administration of mesna (2-mercaptoethane sulfonate, which binds its urotoxic metabolites) and a high fluid intake.

Mycophenolate mofetil

Mycophenolate mofetil (MMF) works by inhibiting inosine monophosphate dehydrogenase, a rate-limiting enzyme in the synthesis of guanosine nucleotides in lymphocytes. MMF is frequently used in SLE and vasculitis in doses of 2–4 g daily orally. Haematological toxicity is the main adverse effect.

Other DMARDs

Gold, penicillamine and ciclosporin A have been superseded by more effective alternatives but are still occasionally used. Gold (sodium aurothiomalate, myocrisin) is indicated for RA. Its mechanism of action is unknown. It is given by intramuscular injection of 50 mg weekly after an initial test dose of 10 mg. Treatment is continued for up to 6 months until there is clinical benefit or adverse effects occur. If there is benefit, the frequency of injections is reduced to two-weekly and then monthly, providing that the response is maintained. Penicillamine is indicated for RA but is poorly tolerated. It is given in a starting dose of 125–250 mg daily on an empty stomach, and increased in 125 mg increments every 6 weeks to a maximum dose of 1500 mg daily until there is clinical benefit or adverse effects occur. Ciclosporin A is a calcineurin inhibitor that inhibits lymphocyte activation. It is occasionally used in RA at a dose of 2.5–4 mg/kg/day orally.

Glucocorticoids

Glucocorticoids have powerful anti-inflammatory and immunosuppressive effects. They promote apoptosis of many immune cells and activation of a wide range of pro-inflammatory signalling pathways. They are used orally, intravenously, intramuscularly and by intra-articular injection in the treatment of a wide range of inflammatory rheumatic diseases, as well as by local injection in patients with soft tissue rheumatism (p. 1026).

Systemic glucocorticoids

Systemic glucocorticoids are widely used in moderate to high doses to induce remission in early RA and in systemic and polyarticular JIA. They are also used at lower doses for maintenance therapy and in the treatment of flares in RA, PsA and axSpA with peripheral joint involvement. Glucocorticoids should be used with caution in PsA because of a rebound increase in activity of psoriasis when the effects wear off. Glucocorticoids are also used to induce remission and to maintain disease control in giant cell arteritis, polymyalgia rheumatica, vasculitis and SLE.

Intra-articular and intramuscular glucocorticoids

Intra-articular glucocorticoids are employed in the treatment of a wide range of inflammatory arthritides and are primarily indicated when there are one or two problem joints with persistent synovitis despite good general control of the disease. Methylprednisolone is one of the most widely used, typically in doses of 40–80 mg. Intramuscular methylprednisolone (80–120 mg) is a useful way of controlling inflammatory arthritis while waiting for the effects of a newly introduced DMARD to take effect, and is also helpful

in patients with stable disease who have a disease flare where a major change in DMARD strategy is not thought to be necessary.

Biologics

The term 'biologic' refers to a group of medications that includes monoclonal antibodies, fusion proteins and decoy receptors, which are used in the treatment of several inflammatory rheumatic diseases. They are targeted towards specific cytokines, receptors and other cell-surface molecules regulating the immune response (Fig. 24.15). The main adverse effect of the biologics used in inflammatory diseases is an increased risk of infections. Biologics are not carcinogenic, but patients who develop cancer while on treatment may exhibit accelerated progression of the tumour due to suppression of the immune response. Treatment costs are much higher than with DMARDs and many countries have set guidelines restricting their use to patients who have active disease despite having had an adequate trial of standard therapies. Their mechanisms of action, dosages and indications are summarised in Box 24.35.

Anti-TNF therapy

A variety of inhibitors of the pro-inflammatory cytokine TNF have been developed. Most are monoclonal antibodies that bind to and neutralise TNF, but etanercept is a decoy receptor that prevents TNF binding to its receptor. Anti-TNF therapy has traditionally been used as the first-line biological drug in RA when DMARD therapy has been incompletely effective. It has also traditionally been used as the first-line biologic in PsA and AxSpA, but anti IL-17A therapy (see below) has emerged as an equally effective alternative. Anti-TNF therapy is usually co-prescribed with MTX in RA and PsA as this increases efficacy, but TNF inhibitors are also effective as monotherapy. They are usually given as monotherapy in AxSpA unless there is peripheral joint involvement. Anti-TNF therapy is contraindicated in patients with active infections such as untreated tuberculosis and those with indwelling catheters, due to the high risk of infection. Other contraindications are severe heart failure and multiple sclerosis, both of which may be worsened by treatment.

Rituximab

Rituximab is an antibody directed against the CD20 receptor, which is expressed on B lymphocytes and immature plasma cells. It causes profound B-cell lymphopenia for several months due to complement-mediated lysis of cells that express CD20. Rituximab is indicated in patients with RA who have not responded adequately to first-line therapy but is typically employed as a third-line treatment when TNF inhibitors have been ineffective. It is also used in place of cyclophosphamide to induce remission in patients with ANCA-positive vasculitis. In RA, the treatment can be repeated when signs of improvement are wearing off (anything from 6 months to 1 year or longer). In ANCA-positive vasculitis, a single cycle of treatment may last for up to 18 months. Rituximab is sometimes used off-label in SLE, even though clinical trials did not show efficacy. Adverse effects include hypogammaglobulinaemia, infusion reactions, an increased risk of infections and, rarely, progressive multifocal leucoencephalopathy (PML; p. 1123), a serious and potentially fatal infection of the CNS caused by reactivation of JC virus.

Belimumab

Belimumab is indicated in SLE. It is a monoclonal antibody that blocks the effects of the cytokine B-cell-activating factor of the TNF family (BAFF), which is required for B-cell survival and function. It is usually given when patients have had an inadequate response to glucocorticoids and hydroxychloroquine. The main

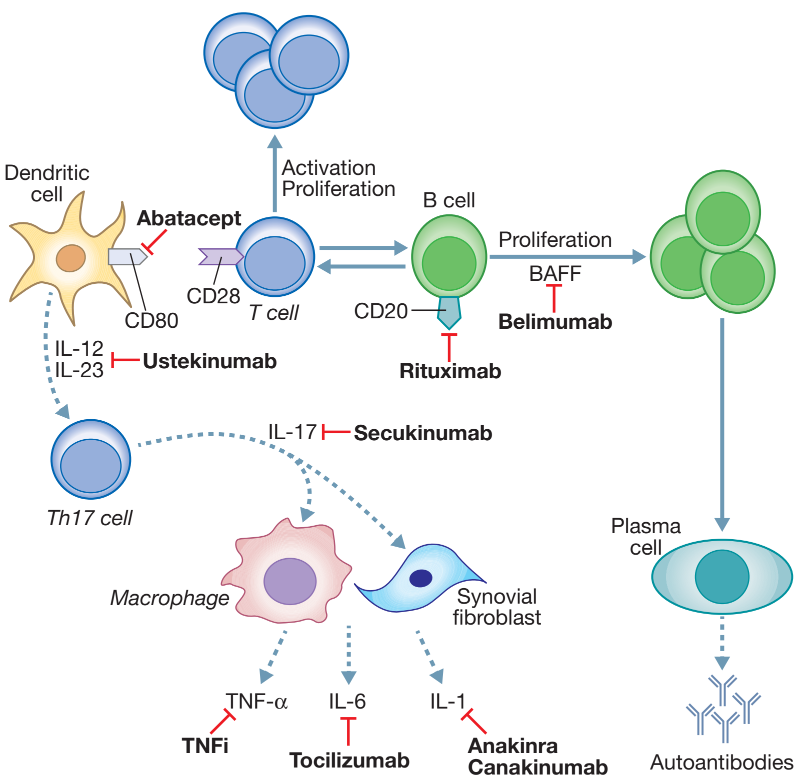

Fig. 24.15 Targets for biologic therapies in inflammatory rheumatic diseases. Biologic treatments for inflammatory rheumatic diseases work by targeting key cytokines and other molecules involved in regulating the immune response. See page 64 for more details. (BAFF = B-cell-activating factor of the TNF family; CD = cluster of differentiation; IL = interleukin; TNF-α = tumour necrosis factor alpha; TNFi = inhibitor of tumour necrosis factor)

24.35 Biological drugs for inflammatory rheumatic disease

Drug	Maintenance dose	Mechanism of action	Indications
Etanercept	50 mg weekly SC	Decoy receptor for TNF-α	RA, PsA, AxSpA, JIA
Infliximab	3–5 mg/kg 8-weekly IV	Antibody to TNF-α	RA, PsA, AxSpA, JIA
Adalimumab	40 mg 2-weekly SC		
Certolizumab	200 mg 2-weekly SC		
Golimumab	50 mg 4-weekly SC		
Rituximab	2×1 g 2 weeks apart IV	Antibody to CD20; destroys B cells	RA, vasculitis
Belimumab	10 mg/kg 4-weekly IV	Antibody to BAFF; inhibits B-cell activation	SLE
Abatacept	125 mg weekly SC *or* 10 mg/kg 4-weekly IV	Inhibits T-cell activation	RA
Tocilizumab	162 mg weekly SC *or* 8 mg/kg 8-weekly IV	Blocks IL-6 receptor	RA, JIA
Ustekinumab	45 mg 12-weekly SC	Antibody to IL-12 and IL-23	PsA
Secukinumab	150 mg 4-weekly SC	Antibody to IL-17A	PsA, AxSpA
Anakinra	100 mg daily SC	Decoy receptor for IL-1	RA, CAPS, AOSD
Canakinumab	150 mg *or* 2 mg/kg 8-weekly SC	Antibody to IL-1β	CAPS, sJIA, AOSD, gout

(AOSD = adult-onset Still's disease; AxSpA = axial spondyloarthritis; BAFF = B-cell-activating factor of the TNF family; CAPS = cryopyrin-associated periodic syndromes; CD = cluster of differentiation; IL = interleukin; IV = intravenous; JIA = juvenile idiopathic arthritis; PsA = psoriatic arthritis; RA = rheumatoid arthritis; SC = subcutaneous; sJIA = systemic juvenile inflammatory arthritis; SLE = systemic lupus erythematosus; TNF-α = tumour necrosis factor alpha)

adverse effects are an increased risk of infection, leucopenia and infusion reactions.

Abatacept

Abatacept is a fusion protein in which the Fc domain of IgG has been combined with the extracellular domain of CTLA4, which blocks T-cell activation by acting as a decoy for CD28, a co-stimulatory molecule necessary for T-cell activation (p. 69). It is indicated in patients with RA who have not responded adequately to first-line therapy but is typically employed as a third-line treatment when TNF inhibitors have been ineffective. The main adverse effect is an increased risk of infections.

Tocilizumab

Tocilizumab is a monoclonal antibody to the IL-6 receptor. It is indicated in patients with RA who have not responded adequately to first-line therapy or to TNF inhibitors. It is sometimes employed as a third-line treatment when TNF inhibitors have been ineffective. An exception is when patients are MTX-intolerant, in which case it is often used as a first-line therapy, based on a randomised trial in which it showed greater efficacy than the TNF inhibitor adalimumab. Adverse effects include leucopenia, abnormal LFTs, hypercholesterolaemia, hypersensitivity reactions and an increase risk of diverticulitis.

Ustekinumab

Ustekinumab is an antibody to the p40 protein, which is a subunit of IL-23 and IL-12. It is indicated in patients with PsA who have not responded adequately to first-line therapy with other biologics. Adverse effects include an increased risk of infections, hypersensitivity reactions and an exfoliative dermatitis.

Secukinumab

Secukinumab is a monoclonal antibody to IL-17A. It is indicated in patients with PsA and axSpA, including ankylosing spondylitis, and who have not responded adequately to first-line therapy. Adverse effects include an increased risk of infections, nasopharyngitis and headache.

Anakinra

Anakinra is a decoy receptor for IL-1. It is occasionally used in RA but is less effective than other biological drugs. A more frequent indication is for the treatment of adult-onset Still's disease (p. 1040) and in cryopirin-associated periodic syndromes (p. 81). Adverse effects include an increased risk of infections, hypersensitivity reactions and neutropenia.

Canakinumab

Canakinumab is indicated for the treatment of systemic JIA (Still's disease), adult-onset Still's disease, familial fever syndromes and acute flares of gout resistant to other treatments. It is a monoclonal antibody directed against the pro-inflammatory cytokine IL-1β. The usual maintenance dose in adults is 150–300 mg SC every 8 weeks. Adverse effects include an increased risk of infections, hypersensitivity reactions and neutropenia.

Osteoarthritis

Osteoarthritis (OA) is by far the most common form of arthritis and is a major cause of pain and disability in older people. It is characterised by focal loss of articular cartilage, subchondral osteosclerosis, osteophyte formation at the joint margin, and remodelling of joint contour with enlargement of affected joints. 24

Epidemiology

The prevalence rises progressively with age and it has been estimated that 45% of all people develop knee OA and 25% hip OA at some point during life. Although some are asymptomatic, the lifetime risk of having a total hip or knee replacement for OA in someone aged 50 is about 11% for women and 8% for men in the UK. There are major ethnic differences in susceptibility: the prevalence of hip OA is lower in Africa, China, Japan and the Indian subcontinent than in European countries, and that of knee OA is higher.

Pathophysiology

OA is a complex disorder with both genetic and environmental components (Box 24.36). Genetic factors are recognised as playing a key role in the pathogenesis of OA. Family-based studies have estimated that the heritability of OA ranges from about 43% at the knee to between 60% and 65% at the hip and

i 24.36 Risk factors for osteoarthritis

Genetics
- Skeletal dysplasias
- Polygenic inheritance

Developmental abnormalities
- Developmental dysplasia of the hip
- Slipped femoral epiphysis

Repetitive loading
- Farmers
- Miners
- Elite athletes

Adverse biomechanics
- Meniscectomy
- Ligament rupture
- Paget's disease

Obesity

Trauma

Hormonal
- Oestrogen deficiency
- Aromatase inhibitors

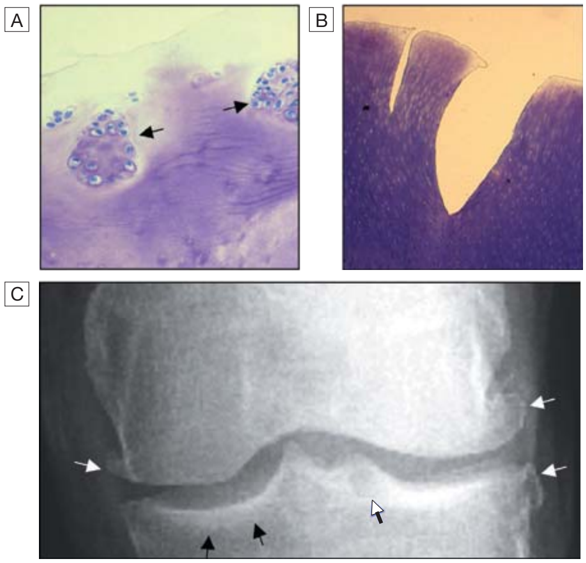

Fig. 24.16 Pathological changes in osteoarthritis. **A** Abnormal nests of proliferating chondrocytes (arrows) interspersed with matrix devoid of normal chondrocytes. **B** Fibrillation of cartilage in OA. **C** X-ray of knee joint affected by OA, showing osteophytes at joint margin (white arrows), subchondral sclerosis (black arrows) and a subchondral cyst (open arrow).

hand, respectively. In most cases, the inheritance is polygenic and mediated by several genetic variants of small effect. OA can, however, be a component of multiple epiphyseal dysplasias, which are caused by mutations in the genes that encode components of cartilage matrix. Structural abnormalities, such as slipped femoral epiphysis and developmental dysplasia of the hip, are also associated with a high risk of OA, presumably due to abnormal load distribution across the joint. Similar mechanisms probably explain the increased risk of OA in patients with limb deformity secondary to Paget's disease of bone. Biomechanical factors play an important role in OA related to certain occupations, such as farmers (hip OA), miners (knee OA) and elite or professional athletes (knee and ankle OA). It has been speculated that the higher prevalence of knee OA in the Indian subcontinent and East Asia might be accounted for by squatting. There is also a high risk of OA in people who have had destabilising injuries, such as cruciate ligament rupture, and those who have had meniscetomy. For most individuals, however, participation in recreational sport does not appear to increase the risk significantly. There is a strong association between obesity and OA, particularly of the hip. This is thought to be due partly to biomechanical factors but it has also been speculated that cytokines released from adipose tissue may play a role. Oestrogen appears to play a role; lower rates of OA have been observed in women who use hormone replacement therapy (HRT), and women who receive aromatase inhibitor therapy for breast cancer often experience a flare in symptoms of OA.

Degeneration of articular cartilage is the defining feature of OA. Under normal circumstances, chondrocytes are terminally differentiated cells but in OA they start dividing to produce nests of metabolically active cells (Fig. 24.16A). Initially, matrix components are produced by these cells at an increased rate, but at the same time there is accelerated degradation of the major structural components of cartilage matrix, including aggrecan and type II collagen (see Fig. 24.5, p. 987). Eventually, the concentration of aggrecan in cartilage matrix falls and makes the cartilage vulnerable to load-bearing injury. Fissuring of the cartilage surface ('fibrillation') then occurs, leading to the development of deep vertical clefts (Fig. 24.16B), localised chondrocyte death and decreased cartilage thickness. This is initially focal, mainly targeting the maximum load-bearing part of the joint, but eventually large parts of the cartilage surface are damaged. Calcium pyrophosphate and basic calcium phosphate crystals often become deposited in the abnormal cartilage.

OA is also accompanied by abnormalities in subchondral bone, which becomes sclerotic and the site of subchondral cysts (Fig. 24.16C). Fibrocartilage is produced at the joint margin, which undergoes endochondral ossification to form osteophytes. Bone remodelling and cartilage thinning slowly alter the shape of the OA joint, increasing its surface area. It is almost as though there is a homeostatic mechanism operative in OA that causes enlargement of the failing joint to spread the mechanical load over a greater surface area.

Patients with OA also have higher BMD values at sites distant from the joint and this is particularly associated with osteophyte formation. This is in keeping with observations made in epidemiological studies that show that patients with OA are partially protected from developing osteoporosis and vice versa. This is likely to be due to the fact that the genetic factors that predispose to osteoporosis might be protective for OA.

The synovium in OA is often hyperplastic and may be the site of inflammatory change, but to a much lesser extent than in RA and other inflammatory arthropathies. Osteochondral bodies commonly occur within the synovium, reflecting chondroid metaplasia or secondary uptake and growth of damaged cartilage fragments. The outer capsule also thickens and contracts, usually retaining the stability of the remodelling joint. The muscles surrounding affected joints commonly show evidence of wasting and non-specific type II fibre atrophy.

Clinical features

OA has a characteristic distribution, mainly targeting the hips, knees, PIP and DIP joints of the hands, neck and lumbar spine (see Fig. 24.10). The main presenting symptoms are pain and functional restriction. The causes of pain in OA are not completely understood but may relate to increased pressure in subchondral bone (mainly causing night pain), trabecular microfractures, capsular distension and low-grade synovitis. Pain may also result from bursitis and enthesopathy secondary to altered joint mechanics. Typical OA pain has the characteristics listed in Box 24.37. For many people, functional restriction of the hands, knees or hips is an equal, if not greater, problem than pain. The clinical findings vary according to severity but are principally those of joint damage.

i 24.37 Symptoms and signs of osteoarthritis

Pain

- Insidious onset over months or years
- Variable or intermittent nature over time ('good days, bad days')
- Mainly related to movement and weight-bearing, relieved by rest
- Only brief (<15 mins) morning stiffness and brief (<5 mins) 'gelling' after rest
- Usually only one or a few joints painful

Clinical signs

- Restricted movement due to capsular thickening or blocking by osteophyte
- Palpable, sometimes audible, coarse crepitus due to rough articular surfaces
- Bony swelling around joint margins
- Deformity, usually without instability
- Joint-line or periarticular tenderness
- Muscle weakness and wasting
- Mild or absent synovitis

i 24.38 Characteristics of generalised nodal osteoarthritis

- Polyarticular finger interphalangeal joint osteoarthritis
- Heberden's (± Bouchard's) nodes
- Marked female preponderance
- Peak onset in middle age
- Good functional outcome for hands
- Predisposition to osteoarthritis at other joints, especially knees
- Strong genetic predisposition

The correlation between the presence of structural change, as assessed by imaging, and symptoms such as pain and disability varies markedly according to site. It is stronger at the hip than at the knee, and poor at most small joints. This suggests that the risk factors for pain and disability may differ from those for structural change. At the knee, for example, reduced quadriceps muscle strength and adverse psychosocial factors (anxiety, depression) correlate more strongly with pain and disability than the degree of radiographic change.

Radiological evidence of OA is very common in middle-aged and older people, and the disease may coexist with other conditions, so it is important to remember that pain in a patient with OA may be due to another cause.

Generalised nodal OA

Characteristics of this common form of OA are shown in Box 24.38. Some patients are asymptomatic whereas others develop pain, stiffness and swelling of one or more PIP and DIP joints of the hands from the age of about 40 years onwards. Gradually, these develop posterolateral swellings on each side of the extensor tendon, which slowly enlarge and harden to become Heberden's (DIP) and Bouchard's (PIP) nodes (Fig. 24.17). Typically, each joint goes through a phase of episodic symptoms (1–5 years) while the node evolves and OA develops. Once OA is fully established, symptoms may subside and hand function often remains good. Affected joints are enlarged as a result of osteophyte formation and often show characteristic lateral deviation, reflecting the asymmetric focal cartilage loss of OA (Fig. 24.18). Involvement of the first CMC joint is also common, leading to pain on trying to open bottles and jars, and functional

Fig. 24.17 Nodal osteoarthritis. Heberden's nodes and lateral (radial/ulnar) deviation of distal interphalangeal joints, with mild Bouchard's nodes at the proximal interphalangeal joints.

Fig. 24.18 X-ray appearances in hand osteoarthritis. There is joint space narrowing affecting the proximal interphalangeal (PIP) and distal interphalangeal (DIP) joints in both hands. There are typical articular subchondral and 'gullwing' appearances to some osteoarthritis-affected joints, as well as osteophyte formation that is most marked at the second DIP joints bilaterally and the first PIP joint on the right hand (arrows).

impairment. Clinically, it may be detected by the presence of crepitus on joint movement, and squaring of the thumb base.

Generalised nodal OA has a very strong genetic component: the daughter of an affected mother has a 1 in 3 chance of developing nodal OA herself. People with nodal OA are also at increased risk of OA at other sites, especially the knee.

Knee OA

At the knee, OA principally targets the patello-femoral and medial tibio-femoral compartments but eventually spreads to affect the whole of the joint (Fig. 24.19). It may be isolated or occur as part of generalised nodal OA. Most patients have bilateral and symmetrical involvement. In men, trauma is often a more important risk factor and may result in unilateral OA.

The pain is usually localised to the anterior or medial aspect of the knee and upper tibia. Patello-femoral pain is usually worse going up and down stairs or inclines. Posterior knee pain suggests the presence of a complicating popliteal cyst (Baker's cyst). Prolonged walking, rising from a chair, getting in or out of

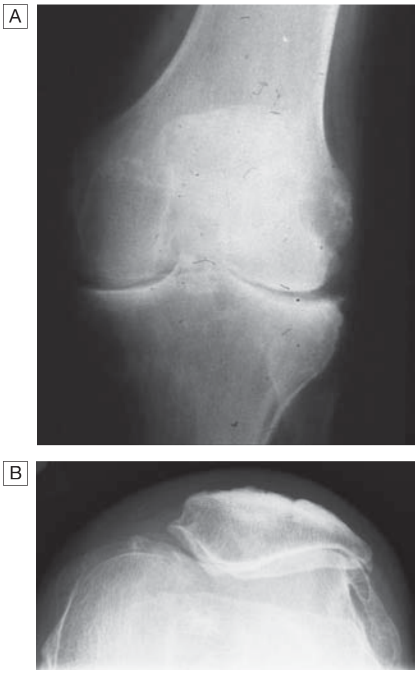

Fig. 24.19 X-ray appearances in knee osteoarthritis. A Advanced osteoarthritis showing almost complete loss of joint space affecting both compartments and sclerosis of subchondral bone. B Skyline view of the patella femoral joint in a patient with severe patello-femoral osteoarthritis. There is almost complete loss of joint space and lateral displacement of the patella.

Fig. 24.20 Typical varus knee deformity resulting from marked medial tibio-femoral osteoarthritis.

a car, or bending to put on shoes and socks may be difficult. Local examination findings may include:

- a jerky, asymmetric (antalgic) gait with less time weight-bearing on the painful side
- a varus (Fig. 24.20) or, less commonly, valgus and/or a fixed flexion deformity
- joint-line and/or periarticular tenderness (secondary anserine bursitis and medial ligament enthesopathy (see Box 24.25), causing tenderness of the upper medial tibia)
- weakness and wasting of the quadriceps muscle
- restricted flexion and extension with coarse crepitus
- bony swelling around the joint line.

CPPD crystal deposition in association with OA is common at the knee. This may result in a more overt inflammatory component (stiffness, effusions) and super-added acute attacks of synovitis ('pseudogout'; p. 1016), which may be associated with more rapid radiographic and clinical progression.

Hip OA

Hip OA most commonly targets the superior aspect of the joint (Fig. 24.21). It is often unilateral at presentation, frequently progresses with superolateral migration of the femoral head, and has a poor prognosis. The less common central (medial) OA shows more central cartilage loss and is largely confined to women. It is often bilateral at presentation and can be associated with generalised nodal OA. It has a better prognosis than superior hip OA and progression to axial migration of the femoral head is uncommon.

The hip shows the best correlation between symptoms and radiographic change. Hip pain is usually maximal deep in the anterior groin, with variable radiation to the buttock, anterolateral thigh, knee or shin. Lateral hip pain, worse on lying on that side with tenderness over the greater trochanter, suggests secondary trochanteric bursitis. Common functional difficulties are the same as for knee OA; in addition, restricted hip abduction in women may cause pain during sexual intercourse. Examination may reveal:

- an antalgic gait
- weakness and wasting of quadriceps and gluteal muscles
- pain and restriction of internal rotation with the hip flexed – the earliest and most sensitive sign of hip OA; other movements may subsequently be restricted and painful
- anterior groin tenderness just lateral to the femoral pulse
- fixed flexion, external rotation deformity of the hip
- ipsilateral leg shortening with severe joint attrition and superior femoral migration.

Obesity is associated with more rapid progression of hip OA.

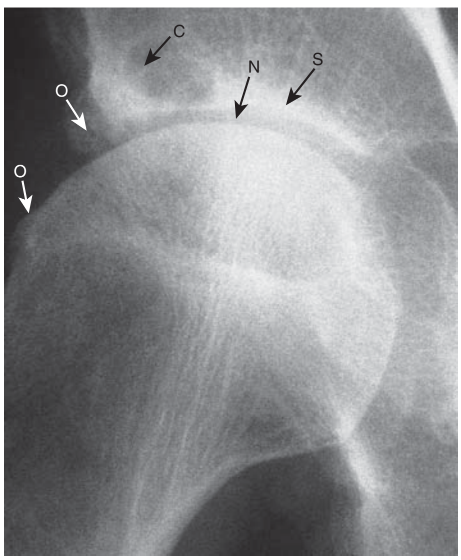

Fig. 24.21 X-ray of hip showing changes of osteoarthritis. Note the superior joint space narrowing (N), subchondral sclerosis (S), marginal osteophytes (O) and cysts (C).

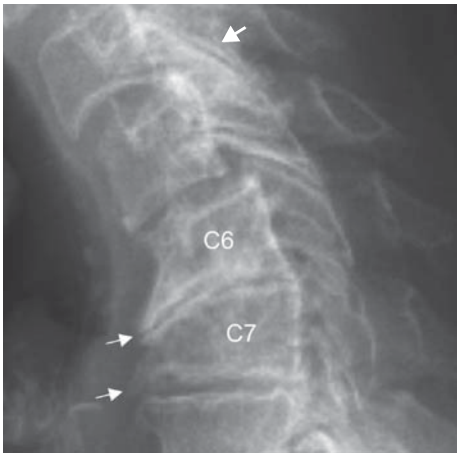

Fig. 24.22 X-ray of spine showing typical changes of osteoarthritis. Cervical spondylosis showing disc space narrowing between C6 and C7, osteophytes at the anterior vertebral body margins (thin arrows) and osteosclerosis at the apophyseal joints (thick arrow).

Spine OA

The cervical and lumbar spine are the sites most often targeted by OA, where it is referred to as cervical spondylosis and lumbar spondylosis, respectively (Fig. 24.22). Spine OA may occur in isolation or as part of generalised OA. The typical presentation is with pain localised to the low back region or the neck, although radiation of pain to the arms, buttocks and legs may also occur due to nerve root compression. The pain is typically relieved by rest and worse on movement. On physical examination, the range of movement may be limited and loss of lumbar lordosis is typical. The straight leg-raising test or femoral stretch test may be positive and neurological signs may be seen in the legs where there is complicating spinal stenosis or nerve root compression.

Early-onset OA

Unusually, typical symptoms and signs of OA may present before the age of 45. In most cases, a single joint is affected and there is a clear history of previous trauma. However, specific causes of OA need to be considered in people with early-onset disease affecting several joints, especially those not normally targeted by OA, in which case rare causes need to be considered (Box 24.39). Kashin–Beck disease is a rare form of OA that occurs in children, typically between the ages of 7 and 13, in some regions of China. The cause is unknown but suggested predisposing factors are selenium deficiency and contamination of cereals with mycotoxin-producing fungi.

24.39 Causes of early-onset osteoarthritis

Monoarticular

- Previous trauma, localised instability

Pauciarticular or polyarticular

- Juvenile idiopathic arthritis (p. 1026)
- Metabolic or endocrine disease:
  - Haemochromatosis (p. 895)
  - Ochronosis
  - Acromegaly (p. 685)
- Spondylo-epiphyseal dysplasia
- Late avascular necrosis
- Neuropathic joint
- Kashin–Beck disease

Erosive OA

This term is used to describe an unusual group of patients with hand OA who have a more prolonged symptom phase, more overt inflammation, more disability and worse outcome than those with nodal OA. Distinguishing features include preferential targeting of PIP joints, subchondral erosions on X-rays, occasional ankylosis of affected joints and lack of association with OA elsewhere. It is unclear whether erosive OA is part of the spectrum of hand OA or a discrete subset.

Investigations

A plain X-ray of the affected joint should be performed and often this will show one or more of the typical features of OA (see Figs 24.18–24.22). In addition to providing diagnostic information, X-rays are of value in assessing the severity of structural change, which is helpful if joint replacement surgery is being considered. Non-weight-bearing postero-anterior views of the pelvis are adequate for assessing hip OA. Patients with suspected knee OA should have standing anteroposterior X-rays taken to assess tibio-femoral cartilage loss, and a flexed skyline view to assess patello-femoral involvement. Spine OA can often be diagnosed on a plain X-ray, which typically shows evidence of disc space narrowing and osteophytes. If nerve root compression or spinal stenosis is suspected, MRI should be performed.

Routine biochemistry, haematology and autoantibody tests are usually normal, though OA is associated with a moderate acute phase response. Synovial fluid aspirated from an affected joint is viscous with a low cell count.

Unexplained early-onset OA requires additional investigation, guided by the suspected underlying condition. X-rays may show typical features of dysplasia or avascular necrosis, widening of joint spaces in acromegaly, multiple cysts, chondrocalcinosis and MCP joint involvement in haemochromatosis (p. 895), or disorganised architecture in neuropathic joints.

Management

Treatment follows the principles outlined on pages 1000–1007. Measures that are pertinent in older people are summarised in Box 24.40.

Education

It is important to explain the nature of the condition fully, outlining the role of relevant risk factors such as obesity, heredity and

24.40 Osteoarthritis in old age

- **Pain and disability**: osteoarthritis is the principal cause in old age.
- **Calcium phosphate deposition disease**: may cause acute attacks of synovitis (pseudogout) on a background of chronic osteoarthritis.
- **Falls**: reduced muscle strength and pain associated with lower limb osteoarthritis increase the risk.
- **Muscle-strengthening exercises**: safely reduce the pain and disability of knee osteoarthritis with accompanying improvements in balance and reduced tendency to fall.
- **Oral paracetamol and topical non-steroidal anti-inflammatory drugs**: safe in older people, with no important drug interactions or contraindications.
- **Intra-articular injection of glucocorticoid**: a very safe and often effective treatment, particularly useful for tiding a patient over a special event.
- **Total joint replacement**: an excellent cost-effective treatment for severe disabling knee or hip osteoarthritis in older people. There is no age limit for joint replacement surgery.

trauma. The patent should be informed that established structural changes are permanent and that, although a cure is not possible at present, pain and function can often be improved. The prognosis should also be discussed, mentioning that it is generally good for nodal hand OA and better for knee than hip OA.

Lifestyle advice

Weight loss has a substantial beneficial effect on symptoms if the patient is obese and is probably one of the most effective treatments available for OA of the lower limbs. Strengthening and aerobic exercises also have beneficial effects in OA and should be advised, preferably with reinforcement by a physiotherapist (see Box 24.27). Quadriceps strengthening exercises are particularly beneficial in knee OA. Shock-absorbing footwear, pacing of activities, use of a walking stick for painful knee or hip OA, and provision of built-up shoes to equalise leg lengths can all improve symptoms.

Non-pharmacological therapy

Acupuncture and transcutaneous electrical nerve stimulation (TENS) have been shown to be effective in knee OA. Local physical therapies, such as heat or cold, can sometimes give temporary relief.

Pharmacological therapy

If symptoms do not respond to non-pharmacological measures, paracetamol should be tried. Addition of a topical NSAID, and then capsaicin, for knee and hand OA can also be helpful. Oral NSAIDs should be considered in patients who remain symptomatic. These drugs are significantly more effective than paracetamol and can be successfully combined with paracetamol or compound analgesics if the pain is severe. Strong opiates may occasionally be required. Antineuropathic drugs, such as amitriptyline, gabapentin and pregabalin, are sometimes used in patients with symptoms that are difficult to control but the evidence base for their use is poor. Neutralising antibodies to nerve growth factor have been developed and are a highly effective treatment for pain in OA but they are not yet licensed for routine clinical use.

Intra-articular injections

Intra-articular glucocorticoid injections are effective in the treatment of knee OA and are also used for symptomatic relief in the treatment of OA at the first CMC joint. The duration of effect is usually short but trials of serial glucocorticoid injections every 3 months in knee OA have shown efficacy for up to 1 year. Intra-articular injections of hyaluronic acid are effective in knee OA but the treatment is expensive and the effect short-lived. In the UK they have not been considered to be cost-effective by NICE.

Neutraceuticals

Chondroitin sulphate and glucosamine sulphate have been used alone and in combination for the treatment of knee OA. There is evidence from randomised controlled trials that these agents can improve knee pain to a small extent (3–5%) compared with placebo.

Surgery

Surgery should be considered for patients with OA whose symptoms and functional impairment impact significantly on their quality of life despite optimal medical therapy and lifestyle advice. Total joint replacement surgery is by far the most common surgical procedure for patients with OA. It can transform the quality of life for people with severe knee or hip OA and is indicated when there is significant structural damage on X-ray. Although surgery should not be undertaken at an early stage during the development of OA, it is important to consider it before functional limitation has become advanced since this may compromise outcome. Patient-specific factors, such as age, gender, smoking and presence of obesity, should not be barriers to referral for joint replacement.

Only a small proportion of patients with OA progress to the extent that total joint replacement is required but OA is by far the most frequent indication for this. Over 95% of joint replacements continue to function well into the second decade after surgery and most provide life-long, pain-free function. Up to 20% of patients are not satisfied with the outcome, however, and a few experience little or no improvement in pain. Other surgical procedures are performed much less frequently. Osteotomy is occasionally carried out to prolong the life of malaligned joints and to relieve pain by reducing intraosseous pressure. Cartilage repair is sometimes performed to treat focal cartilage defects resulting from joint injury.

Crystal-induced arthritis

A variety of crystals can deposit in and around joints and cause an acute inflammatory arthritis, as well as a more chronic arthritis associated with progressive joint damage (Box 24.41). Crystals can be the primary pathogenic agent, as in gout, or an accessory factor, as in calcium pyrophosphate deposition disease, in which crystals are deposited in joints that are already abnormal. Several factors influence crystal formation (Fig. 24.23). There must be sufficient concentration of the chemical components (ionic product), but whether a crystal then forms depends on the balance of tissue factors that promote and inhibit crystal nucleation and growth. The inflammatory potential of crystals resides in their physical irregularity and high negative surface charge, which can induce inflammation and damage cell membranes. Crystals may also cause mechanical damage to tissues and act as wear particles at the joint surface. They can reside in cartilage or tendon for years without causing inflammation or symptoms, and it is only when they are released that they trigger inflammation. This may occur spontaneously but can also result from local trauma, rapid changes in the concentration of the components that form crystals, or in association with an acute phase response triggered by intercurrent illness or surgery. In the longer term, a reduction in concentrations of the solutes that form crystals causes dissolution of crystals and remission of the arthritis.

Gout

Gout is the most common inflammatory arthritis in men and in older women. It is caused by deposition of monosodium urate monohydrate crystals in and around synovial joints.

Epidemiology

The prevalence of gout is approximately 1–2%, with a greater than 5 : 1 male preponderance. Gout has become progressively more common over recent years in affluent societies due to the increased prevalence of obesity and metabolic syndrome (p. 730), of which hyperuricaemia is an integral component. The risk of developing gout increases with age and with serum uric acid (SUA) levels. These are normally distributed in the general population and hyperuricaemia is defined as an SUA of more than 2 standard deviations above the mean for the

24.41 Crystal-associated arthritis and deposition in connective tissue

Crystal	Associations
Common	
Monosodium urate monohydrate	Acute gout Chronic tophaceous gout

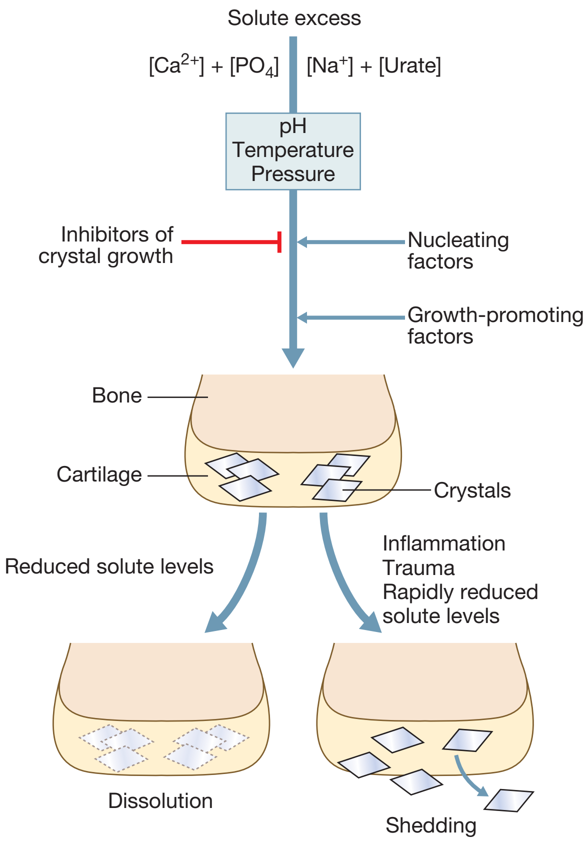

Fig. 24.23 Mechanisms of crystal formation.

population. SUA levels are higher in men, increase with age and are positively associated with body weight. Levels are higher in some ethnic groups (such as Maoris and Pacific islanders). Although hyperuricaemia is strong risk factor for gout, only a minority of hyperuricaemic individuals actually develop gout.

Pathophysiology

About one-third of the body uric acid pool is derived from dietary sources and two-thirds from endogenous purine metabolism (Fig. 24.24). The concentration of uric acid in body fluids depends on the balance between endogenous synthesis, and elimination by the kidneys (two-thirds) and gut (one-third). Purine nucleotide synthesis and degradation are regulated by a network of enzyme pathways, but xanthine oxidase plays a pivotal role in catalysing the conversion of hypoxanthine to xanthine and xanthine to uric acid.

The causes of hyperuricaemia are shown in Box 24.42. In over 90% of patients, the main abnormality is reduced uric acid

24.42 Causes of hyperuricaemia and gout

Diminished renal excretion	
• Increased renal tubular reabsorption* • Renal failure • Lead toxicity • Lactic acidosis • Alcohol	• Drugs: Thiazide and loop diuretics Low-dose aspirin Ciclosporin Pyrazinamide
Increased intake	
• Game • Seafood	• Offal • Red meat
Increased production	
• Myeloproliferative and lymphoproliferative disease • Psoriasis • High fructose intake • Glycogen storage disease (p. 370)	• Inherited disorders: Lesch–Nyhan syndrome (HPRT mutations) Phosphoribosyl pyrophosphate synthetase 1 mutations

*Usually genetically determined (see text).
(HPRT = hypoxanthine guanine phosphoribosyl transferase)

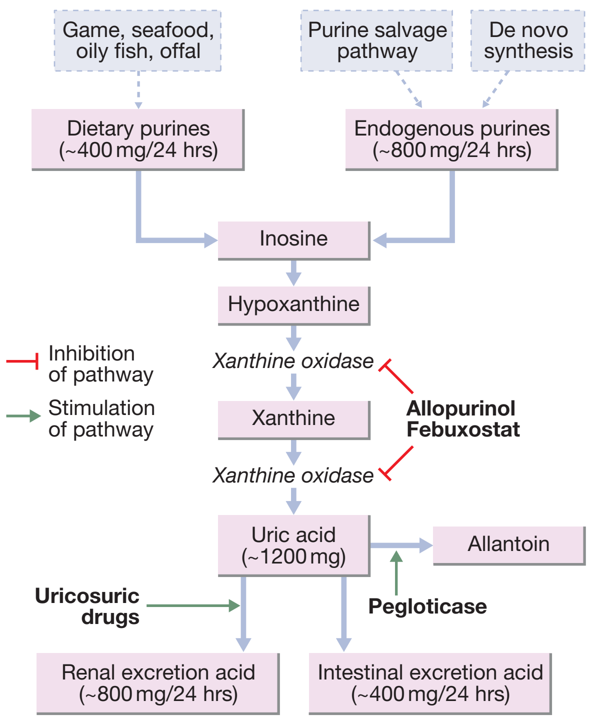

Fig. 24.24 Uric acid metabolism. The main pathways for uric acid production and elimination are shown, along with the site of action for urate-lowering therapies.

excretion by the kidney, which is genetically determined. Impaired renal excretion of urate also accounts for the occurrence of hyperuricaemia in chronic renal failure, and for hyperuricaemia associated with thiazide diuretic therapy.

Other risk factors for gout include metabolic syndrome, high alcohol intake (predominantly beer, which contains guanosine), generalised OA, and a diet relatively high in game, offal, seafood, red meat and fructose, or low in vitamin C. Lead poisoning may cause gout (saturnine gout). The association between OA and gout is thought to be due to a reduction in levels of proteoglycan and other inhibitors of crystal formation in osteoarthritic cartilage, predisposing to crystal formation.

Some patients develop gout because they over-produce uric acid. The mechanisms are poorly understood, except in the case of a few single gene disorders where there are mutations in genes that regulate purine metabolism (Box 24.42). Lesch–Nyhan syndrome is an X-linked recessive form of gout that is also associated with mental retardation, self-mutilation and choreoathetosis. An inherited cause should be suspected if other clinical features are present or there is an early age at onset with a positive family history. Severe hyperuricaemia can also occur in patients with haematological and other cancers who are undergoing chemotherapy due to increased purine turnover (tumour lysis syndrome). This is seldom connected with gout but can be associated with acute kidney injury (p. 411).

Clinical features

The classical presentation is with an acute monoarthritis, which affects the first MTP joint in over 50% of cases (Fig. 24.25). Other common sites are the ankle, midfoot, knee, small joints of hands, wrist and elbow. The axial skeleton and large proximal joints are rarely involved. Typical features include:

- rapid onset, reaching maximum severity in 2–6 hours, and often waking the patient in the early morning
- severe pain, often described as the 'worst pain ever'
- extreme tenderness, such that the patient is unable to wear a sock or to let bedding rest on the joint
- marked swelling with overlying red, shiny skin
- self-limiting over 5–14 days, with complete resolution.

During the attack, the joint shows signs of marked synovitis, swelling and erythema. There may be accompanying fever, malaise and even delirium, especially if a large joint such as the knee is involved. As the attack subsides, pruritus and desquamation of overlying skin are common. The main differential diagnosis is septic arthritis, infective cellulitis or reactive arthritis. Acute attacks may also manifest as bursitis, tenosynovitis or cellulitis, which have the same clinical characteristics. Many patients describe milder episodes lasting just a few days. Some have attacks in more than one joint. Others have further attacks in other joints a few days later (cluster attacks), the first possibly acting as a trigger. Simultaneous polyarticular attacks are unusual.

Some people never have a second episode and in others several years may elapse before the next one. In many, however, a second attack occurs within 1 year and may progress to chronic gout, with chronic pain and joint damage, and occasionally severe deformity and functional impairment. Patients with uncontrolled hyperuricaemia who suffer multiple attacks of acute gout may also progress to chronic gout.

The presentation of gout in the elderly may be atypical with chronic symptoms rather than acute attacks (Box 24.43).

Crystals may be deposited in the joints and soft tissues to produce irregular firm nodules called tophi. These have a predilection for the extensor surfaces of fingers, hands, forearm, elbows, Achilles tendons and sometimes the helix of the ear. Tophi have a white colour (Fig. 24.26), differentiating them from rheumatoid nodules. Tophi can ulcerate, discharging white gritty material, become infected or induce a local inflammatory response, with erythema and pus in the absence of secondary infection. They are usually a feature of long-standing gout but can sometimes develop within 12 months in patients with chronic renal failure. Occasionally, tophi may develop in the absence of previous acute attacks, especially in patients on thiazide therapy who have coexisting OA.

In addition to causing musculoskeletal disease, chronic hyperuricaemia may be complicated by renal stone formation (p. 431) and, if severe, renal impairment due to the development of interstitial nephritis as a result of urate deposition in the kidney. This is particularly common in patients with chronic tophaceous gout who are on diuretic therapy.

Investigations

The diagnosis of gout can be confirmed by the identification of urate crystals in the aspirate from a joint, bursa or tophus (see Fig. 24.6A, p. 988). In acute gout, the synovial fluid may be

Fig. 24.25 Podagra. Acute gout causing swelling, erythema and extreme pain and tenderness of the first metatarsophalangeal joint.

24.43 Gout in old age

- **Aetiology**: a higher proportion of older patients have gout secondary to diuretic use and chronic kidney disease. Gout is often associated with osteoarthritis.
- **Presentation**: may be atypical, with painful tophi and chronic symptoms, rather than acute attacks. Joints of the upper limbs are more frequently affected.
- **Management**: acute attacks are best treated by aspiration and intra-articular injection of glucocorticoids, followed by early mobilisation. Non-steroidal anti-inflammatory drugs and colchicine should be used with caution because of increased risk of toxicity. Low doses of allopurinol (50 mg/day) should be given and increased gradually to avoid toxicity.

Fig. 24.26 Tophus with white monosodium urate monohydrate crystals visible beneath the skin. Diuretic-induced gout in a patient with pre-existing nodal osteoarthritis.

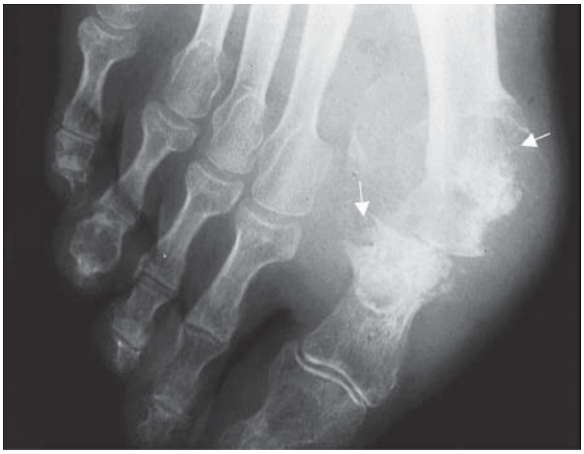

Fig. 24.27 Erosive arthritis in chronic gout. Punched-out ('Lulworth Cove') erosions (arrows) in association with a destructive arthritis affecting the first metatarsophalangeal joint.

turbid due to an elevated neutrophil count. In chronic gout, the appearance is more variable but occasionally the fluid appears white due to the presence of urate crystals. Between attacks, aspiration of an asymptomatic first MTP joint or knee may still reveal crystals.

A biochemical screen, including renal function, uric acid, glucose and lipid profile, should be performed because of the association with metabolic syndrome. Hyperuricaemia is usually present in gout but levels may be normal during an attack because serum urate falls during inflammation. Acute gout is characterised by an elevated ESR and CRP and with a neutrophilia, all of which return to normal as the attack subsides. Tophaceous gout may be accompanied by a modest but chronic elevation in ESR and CRP.

X-rays are usually normal in acute gout but well-demarcated erosions may be seen in patients with chronic or tophaceous gout (Fig. 24.27). Tophi may also be visible on X-rays as soft tissue swellings. In late disease, destructive changes may occur that are similar to those in other forms of advanced inflammatory arthritis.

Management

Management should focus on first dealing with the acute attack and then giving prophylaxis to lower SUA and prevent further attacks.

Acute gout

Oral colchicine given in doses of 0.5 mg twice or 3 times daily is the treatment of first choice in acute gout. It works by inhibiting microtubule assembly in neutrophils. The most common adverse effects are nausea, vomiting and diarrhoea. Oral NSAIDs are also effective but are used less commonly since many patients affected by acute gout have coexisting cardiovascular, cerebrovascular or chronic kidney disease. Oral prednisolone (15–20 mg daily) or intramuscular methylprednisolone (80–120 mg daily) for 2–3 days are highly effective and are a good choice in elderly patients where there is an increased risk of toxicity with colchicine and NSAID (Box 24.43). The IL-1β inhibitor canakinumab (see Box 24.35) is effective but extremely expensive and so seldom given. Local ice packs can also be used for symptomatic relief. Patients with recurrent episodes can keep a supply of an NSAID, colchicine or prednisolone and take it as soon as the first symptoms occur, continuing until the attack resolves. Joint aspiration can give pain relief, particularly if a large joint is affected, and may be combined with an intra-articular glucocorticoid injection if the diagnosis is clear and infection can be excluded.

Prophylaxis

Patients who have had a single attack of gout do not necessarily need to be given urate-lowering therapy, but individuals who have more than one acute attack within 12 months and those with complications such as tophi or erosions should be offered it (Box 24.44). The long-term therapeutic aim is to prevent attacks occurring by bringing uric acid levels below the level at which monosodium urate monohydrate crystals form. A therapeutic target of 360 μmol/L (6 mg/dL) is recommended in the British Society of Rheumatology guidelines, whereas the European League Against Rheumatism guidelines recommend a threshold of 300 μmol/L (5 mg/dL).

Allopurinol is the drug of first choice. It inhibits xanthine oxidase, which reduces the conversion of hypoxanthine and xanthine to uric acid. The recommended starting dose is 100 mg daily, or 50 mg in older patients and in renal impairment. The dose of allopurinol should be increased by 100 mg every 4 weeks (50 mg in the elderly and those with renal impairment) until the target uric acid level is achieved, side-effects occur or the maximum recommended dose is reached (900 mg/day). Acute flares of gout often follow initiation of urate-lowering therapy. The patient should be warned about this and told to continue therapy, even if an attack occurs. The risk of flares can be reduced by prophylaxis with oral colchicine (0.5 mg twice daily) or an NSAID for the first few months. Alternatively, patients can be given a supply of colchicine, an NSAID or prednisolone to be taken at the first

i 24.44 Indications for urate-lowering drugs

- Recurrent attacks of acute gout
- Evidence of bone or joint damage
- Tophi
- Renal impairment
- Nephrolithiasis

24

sign of an acute attack. In the longer term, annual monitoring of uric acid levels is recommended. In most patients, urate-lowering therapy needs to be continued indefinitely.

Febuxostat also inhibits xanthine oxidase. It is typically used in patients with an inadequate response to allopurinol, and when allopurinol is contraindicated or causes adverse effects. Febuxostat undergoes hepatic metabolism and no dose adjustment is required for renal impairment. It is more effective than allopurinol but commonly provokes acute attacks when therapy is initiated. The usual starting dose is 80 mg daily, increasing to 120 mg daily in patients with an inadequate response. Prophylaxis against acute attacks should be given on initiating therapy, as described for allopurinol.

Uricosuric drugs, such as probenecid, sulfinpyrazone and benzbromarone, lower urate levels but are seldom used in routine clinical practice. They are contraindicated in over-producers and those with renal impairment or urolithiasis and require patients to maintain a high fluid intake to avoid uric acid crystallisation in the renal tubules.

Pegloticase is a biological treatment in which the enzyme uricase (oxidises uric acid to 5-hydroxyisourate, which is then converted to allantoin) has been conjugated to monomethoxypolyethylene glycol. It is indicated for the treatment of tophaceous gout resistant to standard therapy and is administered as an intravenous infusion every 2 weeks for up to 6 months. It is highly effective at controlling hyperuricaemia and can cause regression of tophi. The main adverse effects are infusion reactions (which can be treated with antihistamines or glucocorticoids) and flares of gout during the first 3 months of therapy. A limiting factor for longer-term treatment is the development of antibodies to pegloticase, which occur in a high proportion of cases and are associated with an impaired therapeutic response.

Lifestyle measures are equally important as drug therapy in the treatment of gout. Patients should be advised to lose weight where appropriate and to reduce excessive alcohol intake, especially beer. Several antihypertensive drugs, including thiazides, β-blockers and ACE inhibitors, increase uric acid levels, whereas losartan has a uricosuric effect and should be substituted for other drugs if possible. Patients should be advised to avoid large amounts of seafood and offal, which have a high purine content, but a highly restrictive diet is not necessary.

Calcium pyrophosphate dihydrate crystal deposition disease

This condition is associated with deposition of calcium pyrophosphate dihydrate (CPPD) crystals within articular and hyaline cartilage and is often referred to as 'pseudogout'. It is rare under the age of 55 years but occurs in 10–15% of people between 65 and 75 and 30–60% of those over 85. The knee (hyaline cartilage and menisci) is by far the most common site, followed by the wrist (triangular fibrocartilage) and pelvis (symphysis pubis). Risk factors are shown in Box 24.45. In many patients, chondrocalcinosis is asymptomatic and an incidental finding on X-ray. A proportion of patients present with an acute inflammatory arthritis (pseudogout) or a chronic inflammatory arthropathy superimposed on a background of OA, especially at the knee (Fig. 24.28), associated with joint damage and functional limitation.

Pathophysiology

The underlying mechanisms of crystal deposition are poorly understood. Clinical studies have shown that pyrophosphate levels are raised in patients with CPPD crystal deposition disease, possibly due to over-production, but why this happens is unclear. In hypophosphatasia (see Box 24.75, p. 1050), the predisposing factor is thought to be impaired degradation of pyrophosphate due to deficiency of ALP. In OA, it is thought that a reduction in the amounts of proteoglycan and other natural inhibitors of crystal formation in the abnormal cartilage also predispose to crystal deposition (see Fig. 24.23).

Clinical features

The typical presentation is with a swollen tender joint that is warm and erythematous with a large effusion. Fever is common and the patient may appear confused and ill. The knee is most commonly affected, followed by the wrist, shoulder, ankle and elbow. Trigger factors include trauma, intercurrent illness, dehydration and surgery. Septic arthritis and gout are the main differential diagnoses.

Chronic arthropathy may also occur in association with CPPD crystal deposition disease, affecting the same joints that are involved in acute pseudogout. The presentation is with chronic pain, early morning stiffness, inactivity gelling and functional impairment. Acute attacks of pseudogout may be superimposed. Affected joints usually show features of OA, with varying degrees of synovitis. Effusion and synovial thickening are usually most apparent at knees and wrists. Wrist involvement may result in carpal tunnel syndrome and second and third MCP joints can be

24.45 Risk factors for chondrocalcinosis

affected. Inflammatory features may be sufficiently pronounced to suggest RA. Inflammatory changes can occur at entheses and may involve tendons and the ligamentum flavum. Inflammation around the odontoid may occur secondary to CPPD deposition, leading to crowned dens syndrome; this presents clinically with neck pain. Severe damage and instability of knees or shoulders can mimic a neuropathic joint but no neurological abnormalities will be found.

Investigations

The pivotal investigation is joint aspiration, followed by examination of synovial fluid using compensated polarised microscopy to demonstrate CPPD crystals (see Fig. 24.6B, p. 988) and to permit distinction from gout. The aspirated fluid is often turbid and may be uniformly blood-stained, reflecting the severity of inflammation. Since sepsis and pseudogout can coexist, Gram stain and culture of the fluid should be performed to exclude sepsis, even if CPPD crystals are identified in synovial fluid.

X-rays of the affected joint may show evidence of calcification in hyaline cartilage and/or fibrocartilage, although absence of calcification does not exclude the diagnosis. Signs of OA are frequently present. Screening for secondary causes (Box 24.45) should be undertaken, especially in patients who present under the age of 25 and those with polyarticular disease.

Management

Joint aspiration can sometimes provide symptomatic relief in pseudogout and in a few patients no further treatment is required. People with persistent symptoms can be treated with intra-articular glucocorticoids, colchicine or an NSAID. Since most patients with pseudogout are elderly, NSAIDs and colchicine must be used with caution. Early active mobilisation is also important. Chronic pyrophosphate-induced arthropathy should be managed as for OA (p. 1011).

Basic calcium phosphate deposition disease

Basic calcium phosphate (BCP) deposition disease is caused by the deposition of hydroxyapatite or apatite crystals and other basic calcium phosphate salts (octacalcium phosphate, tricalcium phosphate) in soft tissues. The main affected sites are tendons, ligaments and hyaline cartilage in patients with degenerative disease, and skeletal muscle and subcutaneous tissues in connective tissue diseases.

Pathophysiology

Under normal circumstances, inhibitors of mineralisation, such as pyrophosphate and proteoglycans, prevent calcification of soft tissues. When these protective mechanisms break down, abnormal calcification occurs. There are many causes (Box 24.46). In most situations calcification is of no consequence, but when the crystals are released an inflammatory reaction may be initiated, causing local pain and inflammation.

Calcific periarthritis

This occurs as the result of deposition of BCP in tendons, which provokes an acute inflammatory response. The most commonly affected site is the supraspinatus tendon (Fig. 24.29) but other sites may also be involved, including the tendons around the hip, feet and hands. The presentation is with acute pain, swelling and local tenderness that develops rapidly over 4–6 hours. The overlying skin may be hot and red, raising the possibility of infection. Attacks sometimes occur spontaneously but can also be triggered by trauma. Modest systemic upset

i 24.46 Rheumatic diseases associated with basic calcium phosphate deposition

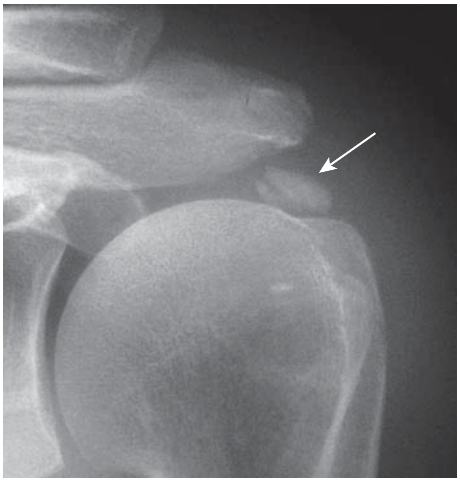

Fig. 24.29 Shoulder X-ray showing supraspinatus tendon calcification (arrow).

and fever are common. Tendon calcification may be seen on X-ray. If the affected joint or bursa is aspirated, inflammatory fluid containing many calcium-staining (alizarin red S) aggregates may be obtained. During an acute attack, there may be a neutrophilia with an elevation in ESR and CRP. Routine biochemistry is normal. Treatment is with analgesics and NSAIDs. Attacks may also respond to a local injection of glucocorticoid. The condition usually resolves spontaneously over 1–3 weeks and this is often accompanied by dispersal and disappearance of calcific deposits on X-ray. Large deposits sometimes accumulate, causing limitation of joint movement, and may require surgical removal.

Acute inflammatory arthritis

Deposition of BCP occurs commonly in OA, both alone and in combination with CPPD crystals, in which case it is referred to as mixed crystal deposition disease. It may present with pseudogout or be an incidental finding.

Milwaukee shoulder syndrome

This is a rare syndrome, in which extensive deposition of BCP crystals in large joints is associated with progressive joint destruction. It is more common in women than in men. The onset is gradual with joint pain, sometimes precipitated by injury

or overuse. The disease progresses over a few months to cause severe pain and disability, associated with joint destruction. X-rays show joint space narrowing, osteophytes and calcification. Aspiration yields large volumes of relatively non-inflammatory fluid containing abundant BCP aggregates and often cartilage fragments. The differential diagnosis is end-stage avascular necrosis, chronic sepsis or neuropathic joint. There is no acute phase response and synovial fluid cultures are negative.

Treatment is with analgesics, intra-articular injection of glucocorticoids, local physical treatments and physiotherapy. The clinical outcome is poor, however, and most patients require joint replacement. The cause is incompletely understood but it has been speculated that deposition of BCP crystals activates collagenase and other proteases in articular cells, which are responsible for the tissue damage.

Autoimmune connective tissue disease

Deposition of BCP may occur in the subcutaneous tissues and muscle of patients with systemic sclerosis and other autoimmune connective tissue diseases. Usually, the deposits are asymptomatic but they may be associated with pain and local ulceration. The mechanism by which this occurs is unclear and there is no specific treatment.

Fibromyalgia

Fibromyalgia (FM) is a condition of generalised pain and consequent disability. It is frequently associated with medically unexplained symptoms in other systems (p. 1187). The prevalence in the UK and US is about 2–3%. Although FM can occur at any age, including adolescence, it increases in prevalence with age, to reach a peak of 7% in women aged over 70. There is a strong female predominance of around 10:1. Risk factors include life events that cause (unresolved) psychosocial distress relating to previous abuse, marital disharmony, alcoholism or illness in the family, poor sleep health, previous injury or assault, and low income. FM arises in a variety of races and cultures.

Pathophysiology

The cause of FM is poorly understood but two abnormalities that may be interrelated (Fig. 24.30) and have been consistently reported in affected patients are disturbed, non-restorative sleep and pain sensitisation, probably caused by abnormal central pain processing.

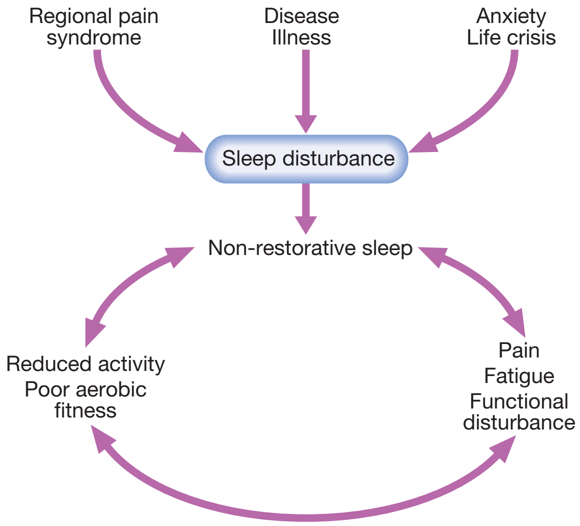

Fig. 24.30 Possible causative mechanisms in fibromyalgia.

Clinical features

The main presenting feature is widespread pain, which is often worst in the neck and back (Box 24.47). It is characteristically diffuse and unresponsive to analgesics and NSAIDs. Physiotherapy often makes FM pain worse. Fatiguability, most prominent in the morning, is another major problem and disability is often marked. Although people can usually dress, feed and groom themselves, they may be unable to perform tasks such as shopping or housework. They may have experienced major difficulties at work or may even retire because of pain and fatigue.

Examination is unremarkable, apart from the presence of hyperalgesia on moderate digital pressure (enough just to whiten the nail) over multiple sites (Fig. 24.31).

24.47 The spectrum of symptoms in fibromyalgia

Usual symptoms

- Widespread pain
- Fatiguability
- Disability
- Broken, non-restorative sleep
- Low affect, irritability, poor concentration

Variable locomotor symptoms

- Early-morning stiffness
- Feeling of swelling in hands
- Distal finger tingling

Additional, variable, non-locomotor symptoms

- Non-throbbing bifrontal headache (tension headache)
- Colicky abdominal pain, bloating, variable bowel habit (irritable bowel syndrome)
- Bladder fullness, nocturnal frequency (irritable bladder)
- Hyperacusis, dyspareunia, discomfort when touched (allodynia)
- Frequent side-effects with drugs (chemical sensitivity)

Investigations and management

There are no abnormalities on routine blood tests or imaging but it is important to screen for other conditions that could account for all or some of the patient's symptoms (Box 24.48). Extensive imaging is not recommended but bone scintigraphy can identify many conditions that can contribute to widespread pain and is a useful 'negative' test.

The aims of management are to educate the patient about the condition, address unresolved psychological issues, achieve pain control and improve sleep. Wherever possible, education should include the spouse, family or carer. It should be acknowledged that the cause of FM is not fully understood but the widespread pain does not reflect inflammation, tissue damage or disease. The model of a self-perpetuating cycle of poor sleep and pain (see Fig. 24.30) is a useful framework for problem-based management. Understanding the diagnosis can often help the patient come to terms with the symptoms. Repeat or drawn-out investigation may reinforce beliefs in occult serious pathology and should be avoided.

Low-dose amitriptyline (10–75 mg at night), with or without fluoxetine, may help by encouraging delta sleep and reducing

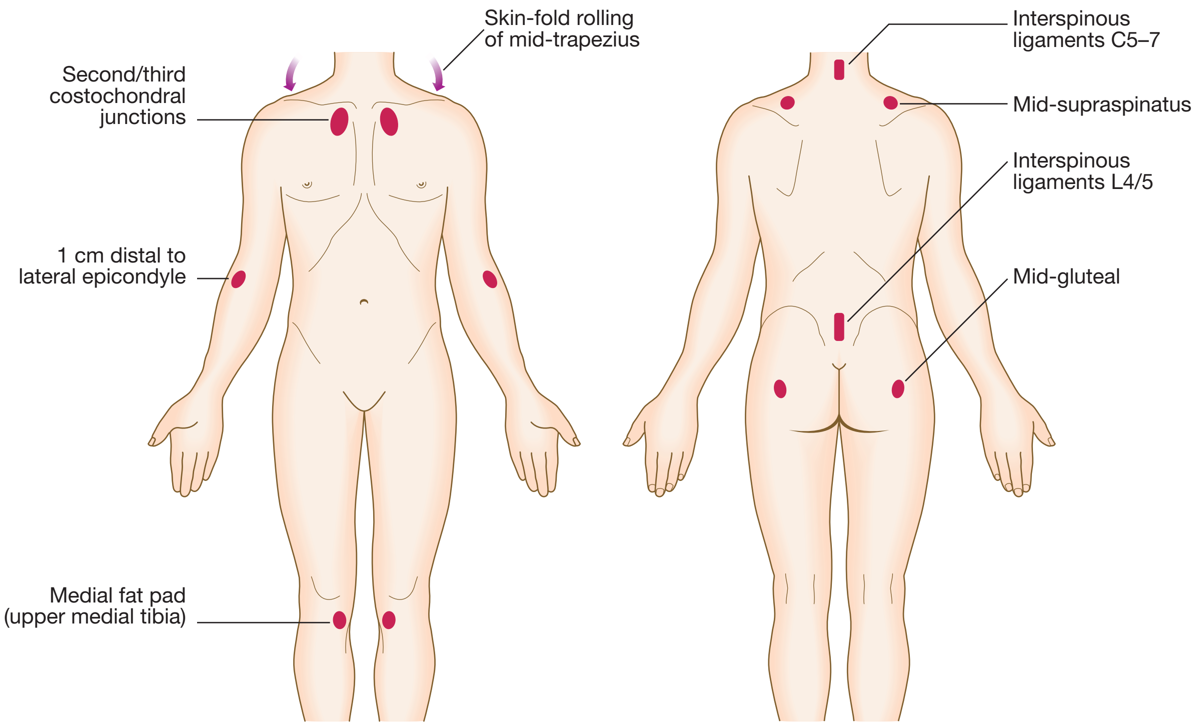

Fig. 24.31 Typical tender points in fibromyalgia.

i 24.48 Laboratory investigations recommended before finalising a diagnosis of fibromyalgia

Test	Condition screened for
Full blood count, liver and renal function tests	General disease indicators
Erythrocyte sedimentation rate, C-reactive protein, serum amyloid A, immunoglobulins	Inflammatory disease
Thyroid function	Hypo-/hyperthyroidism
Calcium, albumin, phosphate, alkaline phosphatase, parathyroid hormone, 25-hydroxyvitamin-D, serum angiotensin-converting enzyme	Hyperparathyroidism, osteomalacia, sarcoid
Antinuclear antibodies, extractable nuclear antigens, rheumatoid factor, anti-cyclic citrullinated peptide antibodies, complement C3 and C4, lupus anticoagulant, anti-cardiolipin antibodies, streptococcal antibodies	Autoinflammatory and autoimmune diseases

spinal cord wind-up. Many people with FM, however, are intolerant of even small doses of amitriptyline. There is limited evidence for the use of tramadol, serotonin–noradrenaline (norepinephrine) re-uptake inhibitors (SNRIs) such as duloxetine, and the anticonvulsants pregabalin and gabapentin. A graded increase in aerobic exercise can improve well-being and sleep quality. The use of self-help strategies and a cognitive behavioural approach with relaxation techniques should be encouraged. Sublimated anxiety relating to distressing life events should be specifically explored with appropriate counselling. There are patient organisations that provide additional information and support. Although treatment may improve quality of life and ability to cope, most people remain symptomatic for many years.

Bone and joint infections

Septic arthritis

Septic arthritis is the most rapid and destructive joint disease. The incidence is 2–10 per 100 000 in the general population and 30–70 per 100 000 in those with pre-existing joint disease or joint replacement. Septic arthritis is associated with significant morbidity and still has a mortality of about 10% despite advances in antimicrobial therapy. The most important risk factor for mortality is increasing age.

Pathogenesis

Septic arthritis usually occurs as a result of haematogenous spread from infections of the skin or upper respiratory tract; infection from direct puncture wounds or secondary to joint aspiration is uncommon. Risk factors include increasing age, pre-existing joint disease (principally RA), diabetes mellitus, immunosuppression (by drugs or disease) and intravenous drug misuse. In RA, the skin is a frequent portal of entry because of maceration of skin between the toes due to joint deformity and difficulties with foot hygiene caused by hand deformity. Box 24.49 describes the particular considerations in old age.

Clinical features

The usual presentation is with acute or subacute monoarthritis and fever. The joint is usually swollen, hot and red, with pain at rest and on movement. Although any joint can be affected, lower limb joints, such as the knee and hip, are most commonly

24.49 Joint and bone infection in old age

- **Vertebral infection**: more common. Recognition may be delayed, as symptoms may be attributed to compression fractures caused by osteoporosis.
- **Peripheral vascular disease**: leads to more frequent involvement of the bones of the feet, and diabetic foot ulcers are also commonly complicated by osteomyelitis.
- **Prosthetic joint infections**: now more common because of the increased frequency of prosthetic joint insertion in older people.
- **Gram-negative bacilli**: more frequent pathogens than in younger people.
- **Cephalosporins:** contraindicated due to the high risk of *Clostridium difficile*.
- **Septic arthritis:** mortality is high in elderly patients.

targeted. Patients with pre-existing arthritis may present with multiple joint involvement.

In adults, the most likely organism is *Staphylococcus aureus*, particularly in patients with RA and diabetes. In young, sexually active adults, gonococcus may be responsible. Disseminated gonococcal infection occurs in up to 3% of patients with untreated gonorrhoea. This usually presents with migratory arthralgia, low-grade fever and tenosynovitis, which may precede the development of an oligo- or monoarthritis. Painful pustular skin lesions may also be present. Gram-negative bacilli or group B, C and G streptococci are important causes among the elderly and intravenous drug users. Less commonly, septic arthritis may be caused by group A streptococci, pneumococci, meningococci and *Haemophilus influenzae*.

Investigations

The pivotal investigation is joint aspiration but blood cultures should also be taken. The synovial fluid is usually turbid or blood-stained but may appear normal. If the joint is not readily accessible, aspiration should be performed under imaging guidance or in theatre. Prosthetic joints should only be aspirated in theatre.

Synovial fluid should be sent for Gram stain and culture; cultures are positive in around 90% of cases but the Gram stain is positive in only 50%. In contrast, synovial fluid culture is positive in only 30% of gonococcal infections, making it important to obtain concurrent cultures from the genital tract (positive in 70–90% of cases). There is a leucocytosis with raised ESR and CRP in most patients, but these features may be absent in elderly or immunocompromised patients, or early in the disease course. Serial measurements of CRP and ESR are useful in following the response to treatment.

Management

The principles of management are summarised in Box 24.50. The patient should be admitted to hospital for pain relief and administration of parenteral antibiotics. Flucloxacillin (2 g IV 4 times daily) is the antibiotic of first choice pending the results of cultures, since it will cover most staphylococcal and streptococcal infections. If there is reason to suspect meticillin-resistant *Staphylococcus aureus* (such as a known carrier), vancomycin should be used instead while awaiting cultures. If a Gram-negative infection is suspected, gentamicin or vancomycin should be considered as first-line treatments. Cephalosporins are a potential alternative for Gram-negative infections but carry a high risk of *Clostridium difficile* infection in those aged over 65. Whatever antibiotic is chosen, the regimen may need to be changed,

24.50 Emergency management of suspected septic arthritis

Admit patient to hospital

Perform urgent investigations

- Aspirate joint:
  - Send synovial fluid for Gram stain and culture
  - Use imaging guidance if required
- Send blood for culture, routine biochemistry and haematology, including erythrocyte sedimentation rate and C-reactive protein
- Consider sending other samples (sputum, urine, wound swab) for culture, depending on patient history, to determine primary source of infection

Commence intravenous antibiotic*

- Flucloxacillin (2 g 4 times daily)
- If penicillin-allergic:
  - Clindamycin (450–600 mg 4 times daily in younger patients)
  - Intravenous vancomycin (1 g twice daily if age >65 years)
- If high risk of Gram-negative sepsis (recurrent urinary tract infection):
  - Intravenous gentamicin (5 mg/kg once daily) or vancomycin (750–1000 mg twice daily)

Relieve pain

- Oral and/or intravenous analgesics
- Consider local ice-packs

Aspirate joint

- Perform serial needle aspiration to dryness (1–3 times daily or as required)
- Consider arthroscopic drainage if needle aspiration difficult

Arrange physiotherapy

- Early regular passive movement, progressing to active movements once pain controlled and effusion not re-accumulating

*The evidence base for choice of antibiotic selection is poor. Local guidelines should be followed where available.

depending on the organism that is isolated. Microbiology advice should always be sought in complicated situations, such as when treating intravenous drug users, patients in intensive care and those who might be colonised by resistant organisms. It is traditional to continue intravenous antibiotics for 2 weeks and to follow this with oral treatment for another 4 weeks, but there is no evidence to support the optimal duration of treatment. Joint aspiration should be performed using a large-bore needle once or twice daily. If this is not possible, arthroscopic or open surgical drainage may be needed performed. Regular passive movement should be undertaken from the outset, and active movements encouraged once the condition has stabilised. Infected prosthetic joints require management by the orthopaedic team, but prolonged antibiotic treatment on its own is often ineffective and removal of the prosthesis is required for eradication of the infection.

Arthritis may be a feature of Lyme disease caused by members of the *Borrelia* species of microorganisms (p. 255). It is generally a late manifestation, which usually affects large joints. Brucellosis presents with an acute febrile illness, followed in some cases by the development of localised infection, which can result in arthritis, bursitis, osteomyelitis, sacroiliitis and paravertebral or psoas abscesses. These conditions are discussed on pages 254 and 255.

Viral arthritis

The usual presentation is with acute polyarthritis following a febrile illness, which may be accompanied by a rash. Most cases of

24.51 Musculoskeletal manifestations of HIV

Condition	Comment
Non-specific arthralgia	Most common; intermittent and polyarticular
Reactive arthritis Psoriatic arthritis Idiopathic lower limb inflammatory arthritis	Especially in men who have sex with men
Osteonecrosis Myositis Vasculitis Sjögren's-like disease	Unclear if related to HIV, its treatment or intercurrent disease

viral arthritis are self-limiting and settle down within 4–6 weeks. Human parvovirus arthropathy (mainly B19; p. 237) is the most common in Europe; adults may not have the characteristic 'slapped cheek' facial rash seen in children. The diagnosis can be confirmed by a rise in specific IgM. Polyarthritis may also occur rarely with hepatitis B and C, rubella (including rubella vaccination) and HIV infection. A variety of mosquito-borne viruses may cause epidemics of acute polyarthritis, including Ross River (Australia, Pacific), Chikungunya and O'nyong-nyong (Asia, Africa), and Mayaro viruses (South America). A wide variety of articular symptoms have been associated with HIV, mainly in the later stages of infection (Box 24.51). Management is symptomatic, with NSAIDs and analgesics.

Osteomyelitis

In osteomyelitis, the primary sites of infection are bone and bone marrow. Any part of a bone may be involved but there is preferential targeting of the juxta-epiphyseal regions of long bones adjacent to joints. The risk of osteomyelitis increases with age; the incidence is about 8.8 cases per 100 000 person-years in those under 18, rising to 40.8 cases in those aged 60–69 and 88.3 cases in those above the age of 80.

Pathogenesis

Haematogenous spread is the most common cause in children but contiguous spread of infection from adjacent soft tissues or as the result of surgery is more important in adults. Diabetes is a particularly important risk factor, accounting for about 30% of cases in recent series. Other risk factors include immunosuppressive therapy, HIV infection and sickle-cell disease, which particularly increases the risk of *Salmonella* infection. The organisms most frequently implicated are *Staph. aureus*, *Staph. epidermidis* and streptococci. The infection often results in a florid inflammatory response, with a greatly increased intraosseous pressure. If untreated, the condition may cause localised areas of osteonecrosis, leading to the development of a fragment of necrotic bone that is called a sequestrum. Eventual perforation of the cortex by pus stimulates local new bone formation (involucrum) in the periosteum, often leading to the development of sinuses that discharge through the skin.

Clinical features

The presentation is with localised bone pain and tenderness, often accompanied by malaise, night sweats and pyrexia. The adjacent joint may be painful to move and may develop a sterile effusion or secondary septic arthritis.

Investigations

Patients suspected of having osteomyelitis should have an MRI, which is more sensitive than X-ray for detecting early changes. Where possible, cultures should be obtained by open or imaging-guided biopsy of the lesion. Evidence of osteopenia, localised osteolysis and osteonecrosis may be seen on X-ray. Blood cultures should be taken, which may also reveal the causative organism. Routine bloods typically show evidence of an acute phase response with a neutrophilia and raised ESR and CRP.

Management

Early recognition is critical as once osteomyelitis becomes established and chronic, it may prove very hard to eradicate with antibiotics alone. The principles are those followed for septic arthritis, with parenteral antibiotics for 2 weeks, followed by oral antibiotics for at least 4 weeks. An exception is in localised osteomyelitis of the toes and fingers, which can often be treated successfully with a prolonged course of oral antibiotics. Resection of the infected bone and subsequent reconstruction may be required. Complications of chronic osteomyelitis include secondary amyloidosis (p. 81) and skin malignancy at the margin of a discharging sinus (Marjolin's ulcer).

Discitis

Discitis is an unusual condition in which there is infection of the intervertebral disc, often extending into the epidural space or paravertebral soft tissues. *Staph. aureus* is the most common pathogen. Risk factors include diabetes mellitus, immunodeficiency or immunosuppressive therapy, and intravenous drug use. The presentation is with back pain accompanied by fever, and an acute phase response with high ESR and CRP and a neutrophilia. If the diagnosis is suspected, an MRI should be performed and blood cultures taken. If blood cultures are negative, open or imaging-guided biopsy of the lesion should be performed to try to identify the organism responsible. Management is with supportive care and parenteral antibiotics followed by oral antibiotics, as described for osteomyelitis.

Tuberculosis

Tuberculosis can affect the musculoskeletal system, usually targeting the spine (Pott's disease) or large joints such as the hip, knee or ankle. The presentation is with pain, swelling and fever. The X-ray changes are non-specific and mycobacteria are seldom identified in the synovial fluid, so tissue biopsy is required for a definitive diagnosis. Medical management is described on page 592. In some cases, surgical débridement may be required for extensive joint disease, and spinal involvement may require surgical stabilisation and decompression.

24

Rheumatoid arthritis

Rheumatoid arthritis (RA) is a common form of inflammatory arthritis, occurring throughout the world and in all ethnic groups. The prevalence of RA is approximately 0.8–1.0% in Europe and the Indian subcontinent, with a female-to-male ratio of 3 : 1. The prevalence is lower in South-east Asia (0.4%). The highest prevalence in the world is in Pima Indians (5%). It is a chronic disease characterised by a clinical course of exacerbations and remissions.

Pathophysiology

RA is a complex disease with both genetic and environmental components. The importance of genetic factors is demonstrated by higher concordance of RA in monozygotic (12–15%) compared with dizygotic twins (3%), and an increased frequency of disease in first-degree relatives of patients. Genome-wide association studies have detected nearly 100 loci that are associated with the risk of developing RA. The strongest association is with variants in the HLA region. Recent studies have shown that the association with HLA is determined by variations in three amino acids in the HLA-DRβ1 molecule (positions 11, 71 and 74) and single variants HLA-B (at position 9) and HLA-DPβ1 (at position 9). The non-HLA loci generally lie within or close to genes involved in regulating the immune response. It is currently believed that RA occurs when an environmental stimulus, such as infection, triggers autoimmunity in a genetically susceptible host by modifying host proteins through processes like citrullination so that they become immunogenic. However, no single specific pathogen has been identified as a cause. An important environmental risk factor is cigarette smoking, which is also associated with more severe disease and reduced responsiveness to treatment. Remission may occur during pregnancy and sometimes RA first presents post-partum. This is likely to be due to suppression of the immune response during pregnancy but hormonal changes may also play a role.

The disease is characterised by infiltration of the synovial membrane with lymphocytes, plasma cells, dendritic cells and macrophages. There is evidence that $CD4^+$ T lymphocytes and B cells play important roles in the pathogenesis of RA by interacting with other cells in the synovium, as illustrated in Figure 24.32. Lymphoid follicles form within the synovial membrane in which T- and B-cell interactions occur, causing activation of T cells to produce cytokines and activation of B cells to produce autoantibodies, including RF and ACPA. Synovial macrophages are activated by TNF and interferon gamma (IFN-γ), produced by T cells. The macrophages produce several pro-inflammatory cytokines, including TNF, IL-1 and IL-6, which act on synovial fibroblasts to produce further cytokines, setting up a positive feedback loop. The synovial fibroblasts proliferate, causing synovial hypertrophy and producing matrix metalloproteinases and the proteinase ADAMTS-5, which degrade soft tissues and cartilage. Prostaglandins and nitric oxide produced within the inflamed synovium cause vasodilatation, resulting in swelling and pain. Systemic release of IL-6 triggers production of acute phase proteins by the liver. At the joint margin, the inflamed synovium (pannus) directly invades bone and cartilage to cause joint erosions. A key pathogenic factor in bone erosions and periarticular osteoporosis is osteoclast activation, stimulated by the production of M-CSF by synovial cells and RANKL by activated T cells (Fig. 24.32). New blood-vessel formation (angiogenesis) occurs, causing the inflamed synovium to become highly vascular.

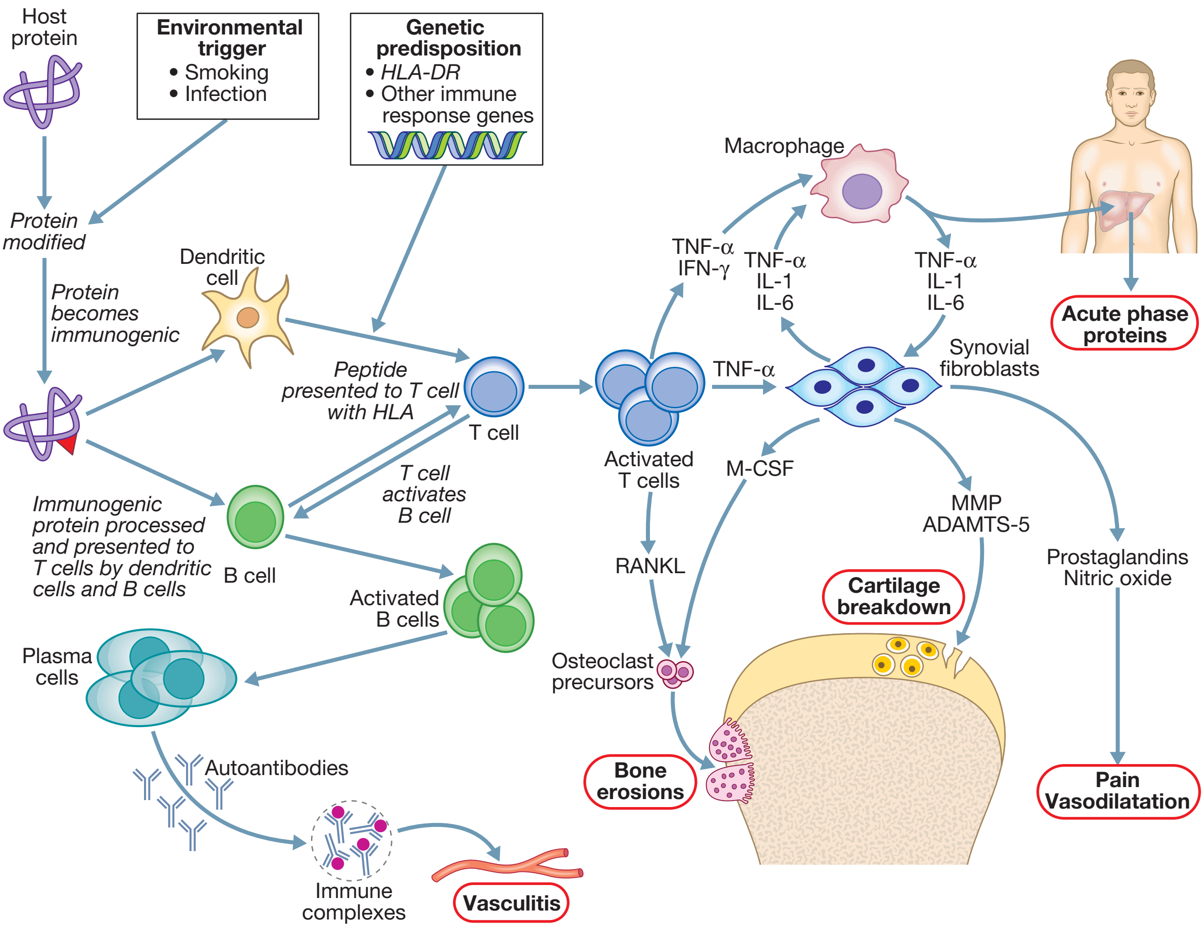

Fig. 24.32 Pathophysiology of rheumatoid arthritis. Some of the cytokines and cellular interactions believed to be important in rheumatoid arthritis are shown. (ADAMTS5 = aggrecanase; IL = interleukin; M-CSF = macrophage colony-stimulating factor; MMP = matrix metalloproteinase; RANKL = receptor activator of nuclear factor kappa B ligand; TNF = tumour necrosis factor)

i 24.52 Criteria for diagnosis of rheumatoid arthritis*

Criterion	Score
Joints affected	
1 large joint	0
2–10 large joints	1
1–3 small joints	2
4–10 small joints	3
>10 joints (at least 1 small joint)	5
Serology	
Negative RF and ACPA	0
Low positive RF or ACPA	2
High positive RF or ACPA	3
Duration of symptoms	
<6 weeks	0
>6 weeks	1
Acute phase reactants	
Normal CRP and ESR	0
Abnormal CRP or ESR	1
Patients with a score ≥6 are considered to have definite RA.	

*European League Against Rheumatism/American College of Rheumatology 2010 criteria.
(ACPA = anti-citrullinated peptide antibody; CRP = C-reactive protein; ESR = erythrocyte sedimentation rate; RF = rheumatoid factor)

Within these blood vessels, pro-inflammatory cytokines activate endothelial cells, which support recruitment of yet more leucocytes to perpetuate the inflammatory process.

Later, fibrous or bony ankylosis may occur. Muscles adjacent to inflamed joints atrophy and may be infiltrated with lymphocytes. This leads to progressive biomechanical dysfunction and may further amplify destruction.

Rheumatoid nodules occur in patients who are RF- or ACPA-positive and primarily affect extensor tendons. They consist of a central area of fibrinoid material surrounded by a palisade of proliferating mononuclear cells. Granulomatous lesions may occur in the pleura, lung, pericardium and sclera.

Clinical features

The typical presentation is with pain, joint swelling and stiffness affecting the small joints of the hands, feet and wrists in a symmetrical fashion. Large joint involvement, systemic symptoms and extra-articular features may also occur. Clinical criteria for the diagnosis of RA are shown in Box 24.52.

Sometimes RA has an acute onset, with severe early morning stiffness, polyarthritis and pitting oedema. This occurs more commonly in old age. Another presentation is with proximal muscle stiffness mimicking polymyalgia rheumatica (p. 1042). Occasionally, the onset is palindromic, with relapsing and remitting episodes of pain, stiffness and swelling that last for only a few hours or days.

Examination typically reveals swelling and tenderness of the affected joints. Erythema is unusual and its presence suggests coexistent sepsis. Characteristic deformities may develop with long-standing uncontrolled disease, although these have become less common over recent years with more aggressive management. They include ulnar deviation of the fingers, 'swan neck' deformity, the boutonnière or 'button hole' deformity, and a Z deformity of the thumb (Fig. 24.33). Dorsal subluxation of the ulna at the distal radio-ulnar joint may occur and contribute to rupture of the fourth and fifth extensor tendons. Triggering of fingers may occur because of nodules in the flexor tendon

Fig. 24.33 The hand in rheumatoid arthritis. **A** Ulnar deviation of the fingers with wasting of the small muscles of the hands and synovial swelling at the wrists, the extensor tendon sheaths, the metacarpophalangeal and proximal interphalangeal joints. **B** 'Swan neck' deformity of the fingers.

sheaths. Subluxation of the MTP joints of the feet may result in 'cock-up' toe deformities, causing pain on weight-bearing on the exposed MTP heads and the development of secondary adventitious bursae and callosities. In the hindfoot, a valgus deformity of the calcaneus may be observed as the result of damage to the ankle and subtalar joints. This is often associated with loss of the longitudinal arch (flat foot) due to rupture of the tibialis posterior tendon. Popliteal (Baker's) cysts may occur in patients with knee synovitis, in which synovial fluid communicates with the cyst but is prevented from returning to the joint by a valve-like mechanism; this is not specific to RA. Rupture may be induced by knee flexion, leading to calf pain and swelling that may mimic a deep venous thrombosis (DVT). These joint deformities tend to be observed in older patients with long-standing disease but are becoming much less common with more aggressive treatment of RA in its early stages.

Systemic features

Anorexia, weight loss and fatigue may occur throughout the disease course. Osteoporosis is a common complication (p. 1044) and muscle-wasting may occur as the result of systemic inflammation and reduced activity. Extra-articular features are most common in patients with long-standing seropositive erosive disease but may occasionally occur at presentation, especially in men. Most are due to serositis, granuloma and nodule formation or vasculitis (Box 24.53).

Nodules

Rheumatoid nodules occur almost exclusively in RF- or ACPA-positive patients, usually in extensor tendons (Fig. 24.34). They

i 24.53 Extra-articular manifestations of rheumatoid disease

Systemic
- Fever

- Mononeuritis multiplex

Amyloidosis (p. 81)

Fig. 24.34 Rheumatoid nodules and olecranon bursitis. Nodules were palpable within, as well as outside, the bursa.

are frequently asymptomatic but some may be complicated by ulceration and secondary infection.

Vasculitis

This is uncommon but may occur in seropositive patients. The presentation is with systemic symptoms, such as fatigue and fever and nail-fold infarcts. Rarely, cutaneous ulceration, skin necrosis and mesenteric, renal or coronary artery occlusion may occur.

Ocular involvement

The most common symptom is dry eyes (keratoconjunctivitis sicca) due to secondary Sjögren's syndrome (p. 1038). Scleritis and peripheral ulcerative keratitis are uncommon but more serious and potentially sight-threatening complications that usually present with pain and redness. Clinical features and management are discussed in more detail on page 1172.

Serositis

Serositis is usually asymptomatic but may present with pleural or pericardial pain and breathlessness. Pericardial effusion and constrictive pericarditis may rarely occur.

Cardiac involvement

Heart block, cardiomyopathy, coronary artery occlusion and aortic regurgitation have all been reported but are rare. The risk of cardiovascular disease is increased due to a combination of conventional risk factors, such as high cholesterol, smoking, hypertension, reduced physical activity, NSAIDs, glucocorticoids and the effects of inflammatory cytokines on vascular endothelium.

Pulmonary involvement

Pulmonary fibrosis may occur but is often asymptomatic. There is some evidence that the risk of pulmonary fibrosis is increased by anti-TNF therapy, although its uncertain whether this is causal or a marker of more severe disease in patients who require anti-TNF treatment.

Peripheral neuropathy

Entrapment neuropathies may result from compression by hypertrophied synovium or by joint subluxation. Median nerve compression is the most common and bilateral carpal tunnel syndrome can occur as a presenting feature of RA. Other syndromes include ulnar nerve compression at the elbow or wrist, compression of the lateral popliteal nerve at the head of the fibula, and tarsal tunnel syndrome (entrapment of the posterior tibial nerve in the flexor retinaculum), which causes burning, tingling and numbness in the distal sole and toes. Diffuse symmetrical peripheral neuropathy and mononeuritis multiplex may occur in patients with rheumatoid vasculitis.

Spinal cord compression

This rare complication is caused by compression of the spinal cord from subluxation of the cervical spine at the atlanto-axial joint or at a subaxial level (Fig. 24.35). Atlanto-axial subluxation is due to erosion of the transverse ligament posterior to the odontoid peg. It can lead to cord compression or sudden death following minor trauma or manipulation. It should be suspected in any RA patient who describes new onset of occipital headache, particularly if symptoms of paraesthesia or electric shock are present in the arms. The onset is often insidious, with subtle loss of function that may initially be attributed to active disease. Reflexes and power can be difficult to assess in patients with extensive joint disease and therefore sensory or upper motor signs are most important. Patients with evidence of spinal cord compression require urgent neurosurgical referral for stabilisation and fixation.

Other complications

Amyloidosis is a rare complication of long-standing disease that usually presents with nephrotic syndrome. Microcytic anaemia can occur due to iron deficiency resulting from NSAID-induced gastrointestinal blood loss, whereas normochromic, normocytic anaemia with thrombocytosis occurs in patients

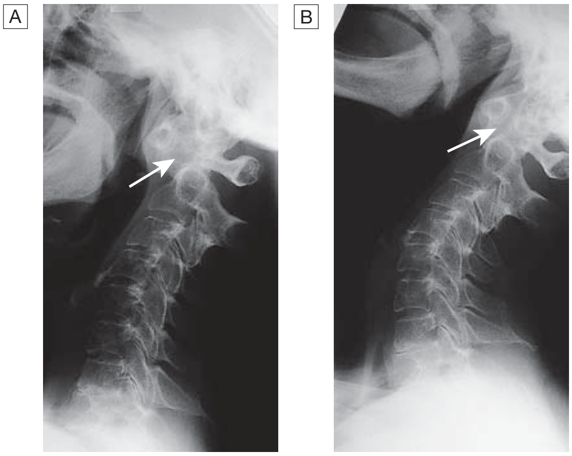

Fig. 24.35 Subluxation of cervical spine. A Flexion, showing widening of the space (arrow) between the odontoid peg of the axis (behind) and the anterior arch of the atlas (in front). B Extension, showing reduction in this space.

24.54 Felty's syndrome

Risk factors

- Age of onset 50–70 years
- Female > male
- Caucasians > blacks
- Long-standing rheumatoid arthritis
- Deforming but inactive disease
- Seropositive for rheumatoid factor

Common clinical features

- Splenomegaly
- Lymphadenopathy
- Weight loss
- Skin pigmentation
- Keratoconjunctivitis sicca
- Vasculitis, leg ulcers
- Recurrent infections
- Nodules

Laboratory findings

- Normochromic, normocytic anaemia
- Neutropenia
- Abnormal liver function
- Thrombocytopenia
- Impaired T- and B-cell immunity

with active disease. Felty's syndrome is a rare complication of seropositive RA in which splenomegaly occurs in combination with neutropenia and thrombocytopenia (Box 24.54). Localised or generalised lymphadenopathy can occur in patients with active disease but persistent lymphadenopathy may indicate the development of lymphoma, which is more common in patients with long-standing RA.

Investigations

The diagnosis of RA is essentially clinical but investigations are useful in confirming the diagnosis and assessing disease activity (Box 24.55). The ESR and CRP are usually raised but normal results do not exclude the diagnosis, especially if only a few joints are involved. Tests for ACPA are positive in about 70% of cases and are highly specific for RA, occurring in many patients before clinical onset of the disease. Similarly, RF is also positive in about 70% of cases, most of whom also test positive for ACPA. RF is less specific than ACPA, however, and positive tests can occur in other diseases (p. 991).

Ultrasound examination and MRI are not routinely required but can be value in patients with symptoms suggestive of RA where there is clinical uncertainty about the presence of synovitis. Plain X-rays of the hands, wrist and feet are usually normal in early RA but periarticular osteoporosis and marginal joint erosions may be observed with more advanced disease. The main indication for an X-ray is in the assessment of patients with painful joints to determine whether significant structural damage has occurred. Patients who are suspected of having atlanto-axial disease should have lateral X-rays taken in flexion and extension, and an MRI. In those with suspected Baker's cyst, ultrasound may be required to establish the diagnosis.

DAS28 is widely used to assess disease activity, response to treatment and need for biological therapy. It involves counting the number of swollen and tender joints in the upper limbs and knees, and combining this with the ESR and the patient's assessment of the activity of their arthritis on a visual analogue scale, where 0 indicates no symptoms and 100 the worst symptoms possible. This data are entered into a calculator to generate a numerical score. The higher the value, the more active the disease (Fig. 24.36).

24.55 Investigations and monitoring of rheumatoid arthritis

To establish diagnosis

- Clinical criteria
- Erythrocyte sedimentation rate and C-reactive protein
- Ultrasound or magnetic resonance imaging
- Rheumatoid factor and anti-citrullinated peptide antibodies

To monitor disease activity and drug efficacy

- Pain (visual analogue scale)
- Early morning stiffness (minutes)
- Joint tenderness
- Joint swelling
- DAS28 score (see Fig. 24.36)
- Erythrocyte sedimentation rate and C-reactive protein

To monitor disease damage

- X-rays
- Functional assessment

To monitor drug safety

- Urinalysis
- Full blood count
- Chest X-ray
- Urea and creatinine
- Liver function tests

Management

The treatment goal is to suppress inflammation, control symptoms and prevent joint damage. This involves a combination of pharmacological and non-pharmacological therapies. When RA occurs in women of child-bearing age, additional considerations need to be taken into account and these are summarised in Box 24.56.

Pharmacological therapy

DMARD therapy should be introduced in all patients as this improves outcome. A typical algorithm is shown in Figure 24.37. On first diagnosis, prednisolone should be started in a dose of 30 mg daily gradually reducing in 5 mg increments every 2 weeks until therapy is withdrawn after about 12 weeks. At the same time, methotrexate should be started in an initial dose of 15 mg weekly, along with folic acid 5 mg weekly, and escalated up to a maximum of 25 mg weekly, depending on the response. If the patient fails to respond adequately or dose-limiting toxicity occurs, then an additional DMARD should be commenced in combination with MTX. The most common combination is triple therapy, in which

24

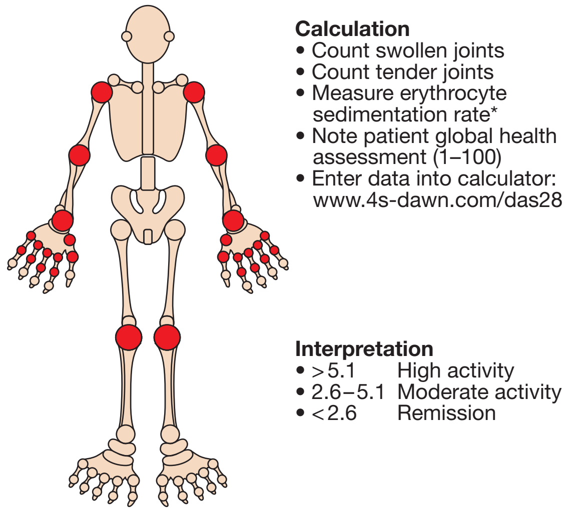

Fig. 24.36 Calculation of the Disease Activity Score 28 (DAS28). *Erythrocyte sedimentation rate or C-reactive protein can be used for the calculation.

24.56 Rheumatoid arthritis in pregnancy

- **Immunological changes in pregnancy**: many patients with rheumatoid arthritis go into remission during pregnancy.
- **Conception**: methotrexate should be discontinued for at least 3 months and leflunomide discontinued for at least 24 months before trying to conceive.
- **Paracetamol**: the oral analgesic of choice during pregnancy.
- **Oral non-steroidal anti-inflammatory drugs and selective cyclo-oxygenase 2 (COX-2) inhibitors**: can be used from implantation to 20 weeks' gestation.
- **Glucocorticoids**: may be used to control disease flares; the main maternal risks are hypertension, glucose intolerance and osteoporosis.
- **Disease-modifying antirheumatic drugs (DMARDs) that may be used**: sulfasalazine, hydroxychloroquine and azathioprine if required to control inflammation.
- **DMARDs that must be avoided**: methotrexate, leflunomide, cyclophosphamide, mycophenolate and gold.
- **Biologic therapies**: experience is limited but they may be relatively safe during pregnancy. The main theoretical risk is immunosuppression in the neonate, except for certolizumab, which does cross the placenta in negligible amounts.
- **Breastfeeding**: methotrexate, leflunomide and cyclophosphamide are contraindicated.

methotrexate, sulfasalazine and hydroxychloroquine are combined (Fig. 24.37). Other DMARDs can be substituted or added, along with a low-dose glucocorticoid such as prednisolone (5–10 mg daily) if the patient fails to respond fully. If disease activity remains high (DAS28 >5.1) despite triple therapy, however, it is usual to progress to biologic therapy. The most commonly used first-line biologics in RA are TNF inhibitors, although several other options are available (p. 1006). When the patient has been stabilised on biologic treatment for 12 months or more, a reduction in dose should be considered, since it is possible to reduce the dose in up to 50% of patients without loss of therapeutic effect. The JAK inhibitors tofacitinib and baricitinib have efficacy in patients who fail to respond adequately to other DMARDs and provide an alternative to biologic therapies.

RA is a chronic disease and flares can occur even in patients who are established on DMARD and biologic therapy. Transient

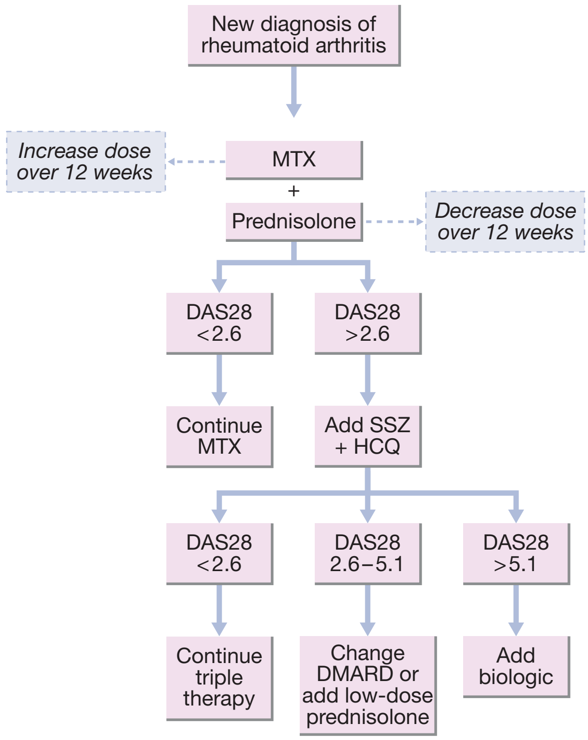

Fig. 24.37 Algorithm for the management of rheumatoid arthritis. (DAS28 = Disease Activity Score 28; DMARD = disease-modifying antirheumatic drug; HCQ = hydroxychloroquine; MTX = methotrexate; SSZ = sulfasalazine)

flares can be dealt with by intra-articular glucocorticoid injections or a short course of oral glucocorticoids, but if a sustained flare occurs, a change in systemic DMARD and/or biologic therapy may need to be considered.

Non-pharmacological therapy

Physical and occupational therapy play important roles and it is vital for all patients to be assessed by an occupational therapist and physiotherapist and the appropriate advice and treatment provided.

Surgery

Synovectomy can be helpful in joints that have failed to respond adequately to systemic therapy and intra-articular injections. Joint replacement surgery may be required but the need for this has diminished over recent years, presumably as the result of more aggressive medical management. Other surgical procedures that can be helpful are excision of the metatarsal heads in patients with subluxation of the MTP joints; neurosurgery in patients with atlanto-axial subluxation; and fusion or the wrist or ankle in patients with joint damage (see Box 24.29, p. 1002).

Juvenile idiopathic arthritis

Juvenile idiopathic arthritis (JIA) is the term, accepted by the international community, for several forms of arthritis defined by the International League of Associations for Rheumatology 2001 criteria (Box 24.57). This includes juvenile forms of psoriatic arthritis (JPsA), rheumatoid arthritis (JRA) and more undifferentiated forms of inflammatory arthritis. The majority of patients with JIA have a phenotype that is distinct from adult inflammatory arthritis

24.57 Clinical features of juvenile idiopathic arthritis

Subtype	Frequency	Clinical features	Immunology
Systemic juvenile idiopathic arthritis	5%	Fever, rash, arthralgia, hepatosplenomegaly	Autoantibody-negative
Oligoarthritis (≤4 joints)	60%	Large-joint arthritis, uveitis	ANA-positive
Polyarthritis (≥5 joints)	20%	Polyarthritis; may be extended form of oligoarthritis	ANA-positive
Enthesis-related	5%	Sacroiliitis, enthesopathy	HLA-B27-positive
RF-positive	5%	Polyarthritis, similar to RA	RF-positive, ACPA-positive
Psoriatic arthritis	5%	Same as adult disease (p. 1032)	Autoantibody-negative

(ACPA = anti-citrullinated peptide antibody; ANA = antinuclear antibody; HLA = human leucocyte antigen; RA = rheumatoid arthritis; RF = rheumatoid factor)

and includes a strong association with uveitis. JIA affects about 1 : 1000 children and young people up to 16 years of age – similar to the prevalence of diabetes (1 : 700). The annual incidence is approximately 1 per 10 000 children and young people.

Whereas joint restriction is attributed to damage in adults, in children it indicates inflammatory activity. Arthritis in children affects limb growth and has a negative effect on height and weight attainment. In young children, effective disease control can repair joint damage before puberty.

Oligoarthritis is the most common form of JIA, accounting for about 60% of cases. It is more common in females and tends to affect large joints in an asymmetrical pattern. There is an association with uveitis and many patients are ANA-positive. Polyarticular JIA is heterogeneous: some patients are RF- and/or ACPA-positive, while others are negative for autoantibodies.

Systemic juvenile idiopathic arthritis (sJIA, formerly known as Still's disease) is characterised by fever, rash, arthritis, hepatosplenomegaly and serositis in association with anaemia and a raised ESR and CRP. Autoantibody tests are negative. This form of JIA is associated with haemophagocytic syndrome.

Many cases of enthesitis-related arthritis (ERA) are likely to be self-limiting forms of spondyloarthritis. ERA can progress over time into a more obviously defined spondyloarthropathy.

Investigations

ESR and CRP do not correlate well with the extent or severity of inflammation and may be normal. A very high ESR may indicate the presence of inflammatory bowel disease or (very rarely) leukaemia. Low haemoglobin is likely to be due to anaemia of chronic disease rather than iron deficiency. A positive ANA occurs in 40–75% of cases of JIA and indicates an increased risk of eye disease. Ultrasound is the radiological investigation of choice to confirm synovitis or tenosynovitis. The false-negative rate is higher in foot and ankle disease than in other joints. Arthroscopy should be avoided unless a biopsy is required. Synovial fluid aspiration, but not arthroscopy, is essential when considering sepsis and tuberculosis.

Management

The key approach is to gain early rapid control of inflammation, minimise the adverse effects of treatment and support the general physical and mental health of the patient, which requires full multidisciplinary team input. The standard immunotherapy is methotrexate (subcutaneous methotrexate is typically used in the young child). Alternative treatment includes leflunomide, sulfasalazine and hydroxychloroquine. Azathioprine and ciclosporin can be used to treat JIA with uveitis. Mycophenolate and tacrolimus are considered to have a specific role in treating

24.58 Juvenile idiopathic arthritis in adolescence

- **Uveitis**: may be clinically silent and persist into adulthood. All (not just those who are ANA-positive) need ophthalmic screening for eye involvement.
- **Persistence into adulthood**: occurs in 50% of cases, especially in systemic disease. Specific supportive management through transition from adolescence to adulthood should be planned.
- **Reduced peak bone mass**: common in polyarthritis and systemic juvenile idiopathic arthritis but there are few data on fracture risk and the evidence base for treatment is poor.
- **Therapy**: methotrexate is standard treatment, used after NSAIDs alone are insufficient. Anti-TNF therapy is effective in all forms of juvenile idiopathic arthritis but long-term safety remains unclear.

(ANA = antinuclear antibody; NSAIDs = non-steroidal anti-inflammatory drugs; TNF = tumour necrosis factor)

uveitis alone. Drug combinations are not well studied in JIA. Biologic therapies, including anti-TNF, are effective in JIA and are now a standard treatment in the presence of refractory disease or intolerance of methotrexate or other non-biologic immunotherapies. Tocilizumab is also effective in sJIA, and has been approved by NICE for use in the UK.

Prognosis

Suboptimal outcomes are associated with delayed diagnosis and referral to the specialist multidisciplinary team, inadequate disease control, presentation with uveitis, sJIA in males and poor engagement with services. Psychological support of affected children and their families is associated with improved outcome. Oligo-JIA often resolves at puberty. Polyarticular disease and sJIA remain active into adulthood in about 50% of cases. Common issues around the transition of adolescent patients into adulthood are shown in Box 24.58.

Spondyloarthropathies

Spondyloarthropathies (SpAs) comprise a group of related inflammatory musculoskeletal diseases that show overlap in their clinical features and have a shared immunogenetic association with HLA-B27 (Box 24.59). They include:

- axial spondyloarthritis
- ankylosing spondylitis
- reactive arthritis
- psoriatic arthritis

- arthritis with inflammatory bowel disease (enteropathic spondyloarthritis).

In axial spondylitis and ankylosing spondylitis, the axial skeleton (i.e. the central core skeleton) is predominantly affected. In contrast to RA, in the SpAs there are frequent and notable non-synovial musculoskeletal lesions – mainly inflammatory in nature – of ligaments, tendons, periosteum and other bone lesions. A hallmark lesion of all SpAs is enthesitis, which is inflammation at the site of a ligament or tendon insertion into bone. Dactylitis, inflammation of a whole finger or toe, may also occur (see Fig. 24.43).

It has been estimated that about 1% of the adult population in the USA may have an SpA (about 2.7 million). There is a striking association with HLA-B27, particularly for ankylosing spondylitis (>95%). Additionally, SpAs are thought to arise as the result of an aberrant host response to infection and abnormal mucosal immunity mediated through changes in the IL-12, IL-23 and Th17 axis (p. 65). In some situations, a triggering organism can be identified, as in reactive arthritis following bacterial dysentery or chlamydial urethritis, but in others the environmental trigger remains obscure. Familial clustering not only is common to the specific condition occurring in the proband, but also may extend to other diseases in the spondyloarthropathy group.

i 24.59 Features common to spondyloarthropathies

- Asymmetrical inflammatory oligoarthritis (lower > upper limb)
- History of inflammatory back pain
- Sacroiliitis and spinal osteitis
- Enthesitis (e.g. gluteus medius insertion, plantar fascia origin)
- Tendency for familial aggregation
- HLA-B27 association
- Psoriasis (of skin and/or nails)
- Uveitis
- Sterile urethritis and/or prostatitis
- Inflammatory bowel disease
- Aortic root lesions (aortic incompetence, conduction defects)

(HLA = human leucocyte antigen)

Axial spondyloarthropathy

Axial spondyloarthropathy includes classical ankylosing spondylitis (AS) as well as axial spondyloarthritis (axSpA). Inflammatory changes in the entire axial skeleton are characteristic of axSpA and can be visualised by MRI; structural alterations, such as new bone formation with syndesmophytes and ankylosis, develop later in the course of the disease. Accordingly, the criteria for diagnosing AS (Box 24.60), which require evidence of sacroiliitis on X-ray, are often only able to be applied many years after a patient's symptoms started. Not all patients with axSpA will go on to develop AS.

Pathophysiology

Axial SpA and AS arise from an interaction between environmental pathogens and the host immune system in genetically susceptible individuals. Increased faecal carriage of *Klebsiella aerogenes* has been reported in patients with established AS and may relate to exacerbation of both joint and eye disease. There is increasing evidence that axSpA and AS are due to an abnormal host response to the intestinal microbiota with involvement of Th17 cells, which have a key role in mucosal immunity. This leads to production of various inflammatory cytokines, including IL-12, IL-23, IL-17 and TNF-α, which play vital roles in the pathogenesis of enthesitis and other inflammatory lesions (Fig. 24.38).

There a strong association between axial spondyloarthropathy and carriage of the major histocompatibility complex (MHC)

i 24.60 Comparison of diagnostic criteria for axial spondyloarthritis (ASAS) and ankylosing spondylitis (modified New York)

	Axial spondyloarthritis	Ankylosing spondylitis
Imaging	Sacroiliitis on MRI only	Bilateral sacroiliitis on X-ray, even if changes are mild Unilateral sacroiliitis on X-ray if changes are definite
History	Back pain >3 months that has four of the following characteristics: 1. improved by exercise 2. not relieved by rest 3. insidious onset 4. night pain 5. age at onset < 45 Good response of back pain to NSAID Family history of spondyloarthritis History of inflammatory bowel disease	Low back pain >3 months improved by exercise and not relieved by rest
Clinical examination	Arthritis Enthesitis Uveitis Dactylitis Psoriasis	Limitation of lumbar spine movement in sagittal and frontal planes Chest expansion reduced
Investigations	HLA-B27-positive Elevated CRP	

Axial spondyloarthritis is diagnosed from: sacroiliitis on MRI + one other feature on history, clinical examination or investigation.
The diagnosis can also be made in HLA-B27-positive patients with >1 clinical feature in the absence of sacroiliitis
Ankylosing spondylitis can be diagnosed on X-ray evidence of sacroiliitis with one other feature on history or examination

(ASAS = Assessment of Spondylitis International Society; CRP = C-reactive protein; HLA = human leucocyte antigen; MRI = magnetic resonance imaging; NSAID = non-steroidal anti-inflammatory drug)

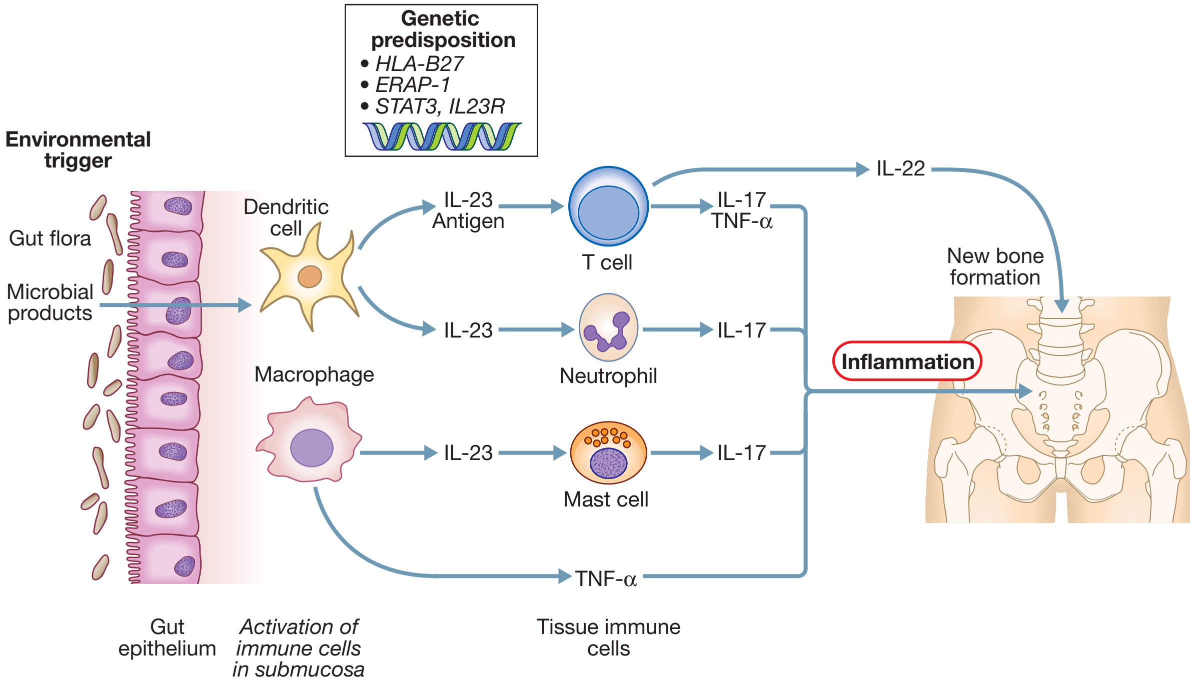

Fig. 24.38 Pathophysiology of axial spondyloarthropathy. In genetically susceptible individuals, it is thought that bacterial components penetrate the mucosal barrier to activate macrophages and dendritic cells in the intestinal submucosa. These cells produce increased amounts of interleukin 23 (IL-23), which acts on T cells, neutrophils and mast cells to make IL-17; IL-17 in turn has a pivotal role in driving inflammation, causing sacroiliitis and enthesitis. Presentation of antigen by dendritic cells also plays a pathogenic part in activating T cells, and tumour necrosis factor (TNF), produced by macrophages and activated T cells, contributes to the pathogenesis of inflammation. Production of IL-22 by T cells is thought to be involved in causing the new bone formation that is typical of axial spondyloarthropathy.

class I molecule HLA-B27. This is particularly striking in patients defined as having AS, more than 95% of whom are positive for HLA-B27. Other susceptibility genes also implicated in susceptibility to AS include *ERAP-1* (an endoplasmic reticulum protein with a role facilitating intracellular antigen processing and binding with its presenting MHC molecule HLA-B27), the IL-23 receptor and downstream signalling molecules involved in directing Th17 cell responses, such as *STAT3* (see Fig. 4.3, p. 65). The HLA-B27 molecule itself is implicated through its antigen-presenting function or because of its propensity to form homodimers that activate leucocytes. HLA-B27 molecules may also misfold, causing increased endoplasmic reticulum stress. This could lead to inflammatory cytokine release by macrophages and dendritic cells, thus triggering inflammatory disease.

Axial spondyloarthritis

Clinical features

The cardinal feature of axSpA is inflammatory back pain and early morning stiffness, with low back pain radiating to the buttocks or posterior thighs if the sacroiliac joints are involved. Symptoms are exacerbated by inactivity and relieved by movement. Musculoskeletal symptoms may be prominent at entheses, may be episodic and, if persistent, can present as widespread pain and be mistaken for fibromyalgia. Fatigue is common. A history of psoriasis (current, previous or in a first-degree relative) and inflammatory bowel symptoms (current or previous) are important clues. Physical signs include a reduced range of lumbar spine movements in all directions, pain on sacroiliac stressing and a high enthesitis index. Entheses that are typically affected include Achilles' insertion, plantar fascia origin, patellar ligament entheses, gluteus medius insertion at the greater trochanter and tendon attachments at humeral epicondyles. A number of validated clinical questionnaires, such as the Bath Ankylosing Spondylitis Disease Activity Index (BASDAI), Bath Ankylosing Spondylitis Functional Index (BASFI) and Ankylosing Spondylitis Disease Activity Score (ASDAS-CRP), can be used to assess disease activity and functional status in AS, though newer assessment tools are being developed that are more specific to a diagnosis of axSpA, such as the Assessment of Spondyloarthritis International Society Health Index (ASAS-H).

Investigations

The diagnosis is aided by ultrasound or MRI of entheses, or by MRI of the sacroiliac joints and spine (Fig. 24.39). Other findings

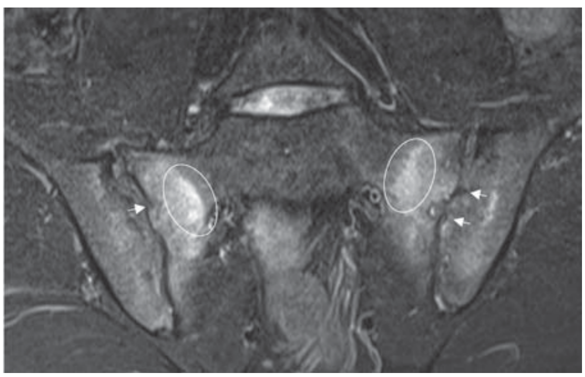

Fig. 24.39 Magnetic resonance imaging appearances in sacroiliitis. Coronal MRI short T1 inversion recovery (STIR) sequence showing bilateral sacroiliitis in axial spondyloarthritis. Bone marrow oedema (circles) is present around both sacroiliac joints, which show irregularities due to erosions (arrows).

may include raised ESR and CRP (although these can be normal), anaemia and positive HLA-B27. Faecal calprotectin is a useful screening test for associated inflammatory bowel disease.

Management

Patient education, NSAID use (optimally, once daily or slow release taken at bedtime) and physical therapy are key interventions at the outset. For severe and/or persistent peripheral musculoskeletal features of SpA, both sulfasalazine and methotrexate are reasonable therapy choices. These medications have no impact on spinal symptoms or disease progression. In patients who fail to respond adequately or who cannot tolerate NSAIDs, progression to biologic therapy with either TNF inhibitors or the IL-7A inhibitor secukinumab should be considered (see Box 24.35, p. 1007). Anti-TNF therapy is effective for both the axial and peripheral lesions of axSpA, but it is as yet unclear whether anti-TNF therapy modifies the natural history of the disease.

Prognosis

With such a recent definition of disease, the markers of prognosis in patients diagnosed with axSpA are not fully understood. It is clear that axSpA can remain mild and/or episodic in many patients for many years. HLA-B27 positivity, high persistent CRP and high functional incapacity are likely to be markers of poor prognosis, if not markers of extension ultimately to AS.

Ankylosing spondylitis

Ankylosing spondylitis (AS) is defined by the presence of sacroiliitis on X-ray and other structural changes on spine X-rays, which may eventually progress to bony fusion of the spine. There is a male-to-female ratio of about 3 : 1. In Europe, more than 90% of those affected are HLA-B27-positive (Caucasian HLA-B27 population prevalence is 9%). The overall prevalence of AS is below 0.5% in most populations. Over 75% of patients are able to remain in employment and enjoy a good quality of life. Even if severe ankylosis develops, functional limitation may not be marked, as long as the spine is fused in an erect posture.

Clinical features

Clinical features are the same as in axSpA. AS typically evolves slowly, with fluctuating symptoms of spinal inflammation; ankylosis develops in many patients over a period of many years. Secondary osteoporosis of the vertebral bodies frequently occurs, leading to an increased risk of vertebral fracture.

In AS, spinal fusion varies in its extent and in most cases does not cause a gross flexion deformity, but a few patients develop marked kyphosis of the dorsal and cervical spine that may interfere with forward vision. This may prove incapacitating, especially when associated with fixed flexion contractures of hips or knees.

Up to 40% of patients also have peripheral musculoskeletal lesions (asymmetrical, affecting entheses of large joints, such as the hips, knees, ankles and shoulders).

Fatigue is a major complaint and is common to all SpAs, but its cause is unknown. Acute anterior uveitis is the most common extra-articular feature, which occasionally precedes joint disease. Other extra-articular features are occasionally observed but are rare (Box 24.61).

Investigations

In AS, X-rays of the sacroiliac joint show irregularity and loss of cortical margins, widening of the joint space and subsequently sclerosis, joint space narrowing and fusion. Lateral thoracolumbar spine X-rays may show anterior 'squaring' of vertebrae due to erosion and sclerosis of the anterior corners and periostitis of the waist. Bridging syndesmophytes may also be seen. These are areas of calcification that follow the outermost fibres of the annulus (Fig. 24.40). In advanced disease, ossification of the anterior longitudinal ligament and facet joint fusion may also be visible. The combination of these features may result in the

i 24.61 Extra-articular features of axial spondyloarthritis and ankylosing spondylitis

- Fatigue, anaemia
- Anterior uveitis (25%)
- Prostatitis (80% of men) and sterile urethritis
- Inflammatory bowel disease (up to 50% have IBD lesions)
- Osteoporosis
- Cardiovascular disease (aortic valve disease 20%)
- Amyloidosis (rare)
- Atypical upper lobe pulmonary fibrosis (very rare)

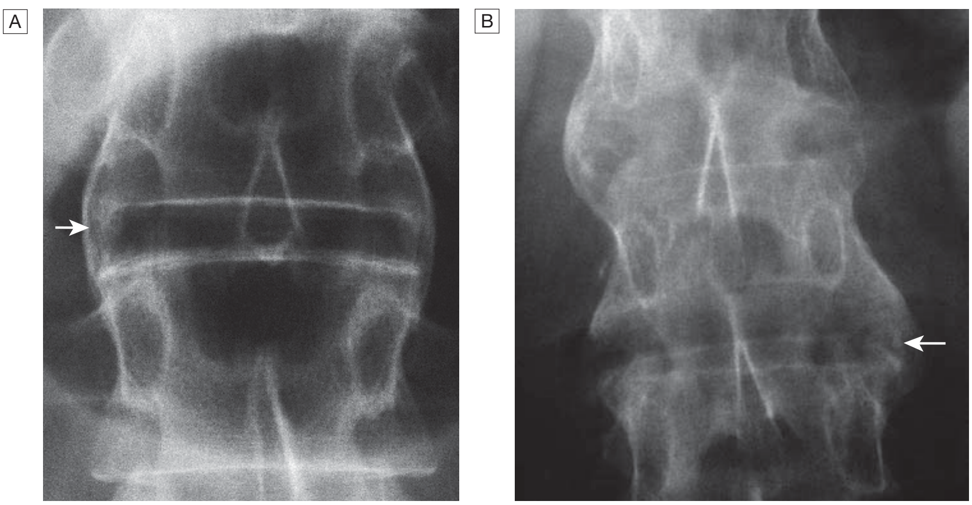

Fig. 24.40 Radiographic changes in spondyloarthritis. **A** Fine symmetrical marginal syndesmophytes typical of ankylosing spondylitis (arrow). **B** Coarse, asymmetrical non-marginal syndesmophytes typical of psoriatic spondylitis (arrow).

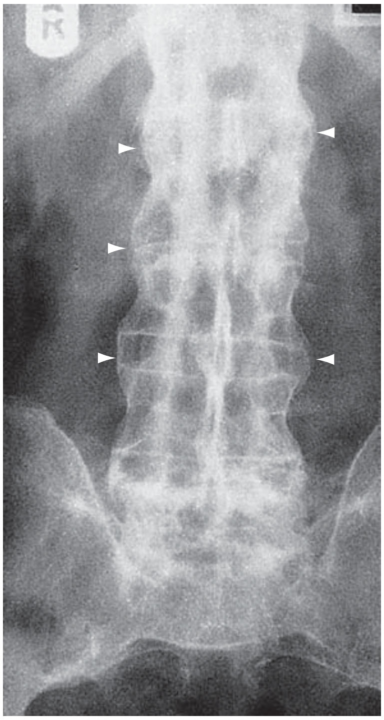

Fig. 24.41 'Bamboo' spine of advanced ankylosing spondylitis. Note the symmetrical marginal syndesmophytes (arrows), sacroiliac joint fusion and generalised osteopenia.

typical 'bamboo' spine (Fig. 24.41). Erosive changes may be seen in the symphysis pubis, ischial tuberosities and peripheral joints. Osteoporosis is common and vertebral fractures may occur. Atlanto-axial dislocation can arise as a late feature. MRI is more sensitive for detection of early sacroiliitis than X-rays (see Fig. 24.39) and can also detect inflammatory changes in the lumbar spine. DXA scanning is important as part of a fragility fracture assessment.

As in axSpA, ESR and CRP are usually raised in active disease but may be normal; anaemia is often present. Autoantibodies, such as RF, ACPA and ANA, are negative.

Management

The aims of management are the same as in axSpA: to relieve pain and stiffness, maintain a maximal range of skeletal mobility and avoid the development of deformities. Mobilising exercises are important and are shown on many online resource sites (e.g. National Ankylosing Spondylitis Society, UK). A long-acting NSAID at night is helpful for alleviation of morning stiffness. Anti-TNF or anti-IL-17A therapy should be considered in patients who are inadequately controlled on standard therapy, as described for axSpA. Biologic therapies are often highly effective at improving symptoms but it is not clear whether they prevent ankylosis or alter the natural history of the disease.

Local glucocorticoid injections can be useful for persistent plantar fasciitis, other enthesopathies and peripheral arthritis. Oral glucocorticoids may be required for acute uveitis but do not help spinal disease. Severe hip, knee or shoulder arthritis with secondary OA may require arthroplasty. Spinal osteotomy, to correct stoop and make eyeline/posture 'more normal', can make a significant difference to patients with severe ankylosed kyphotic spines.

Reactive arthritis

Reactive (spondylo)arthritis (ReA) is a 'reaction' to a number of bacterial triggers with clinical features in keeping with all SpA conditions. The known triggers are *Chlamydia*, *Campylobacter*, *Salmonella*, *Shigella* and *Yersinia*. Notably, non-SpA-related reactive arthritis can occur following infection with many viruses, *Mycoplasma*, *Borrelia*, streptococci and mycobacteria, including *M. leprae*, which causes leprosy (Hansen's disease); however, the 'reaction' in these instances consists typically of myoarthralgias, is not associated with HLA-B27 and is generally not chronic. The arthritis associated with rheumatic fever (p. 515) is also an example of a reactive arthritis that is not associated with HLA-B27.

Sexually acquired reactive arthritis (SARA) is predominantly a disease of young men, with a male preponderance of 15 : 1. This may reflect a difficulty in diagnosing the condition in young women, in whom *Chlamydia* infection is often asymptomatic and is hard to detect in practical terms. Between 1% and 2% of patients with non-specific urethritis seen at genitourinary medicine clinics have SARA (p. 1031). The syndrome of chlamydial urethritis, conjunctivitis and reactive arthritis was formerly known as Reiter's disease.

With enteric triggering infections (enteropathic ReA), HLA-B27 may predict the reactive arthritis and its severity, though the condition occurs in HLA-B27-negative people. The incidence of specific triggering infections causing reactive arthritis around the world varies, depending on the epidemiology of the infection and prevalence of HLA-B27 in the local population.

Clinical features

The onset is typically acute, with an inflammatory enthesitis, oligoarthritis and/or spinal inflammation. Lower limb joints and entheses are predominantly affected. In all types of ReA, there may be considerable systemic disturbance, with fever and weight loss. Achilles insertional enthesitis/tendonitis or plantar fasciitis may also be present. The first attack of arthritis is usually self-limiting, but recurrent or chronic arthritis can develop and about 10% still have active disease 20 years after the initial presentation. Low back pain and stiffness due to enthesitis and osteitis are common and 15–20% of patients develop sacroiliitis. Many extra-articular features in ReA involve the skin, especially in SARA:

- *circinate balanitis*, which starts as vesicles on the coronal margin of the prepuce and glans penis, later rupturing to form superficial erosions with minimal surrounding erythema, some coalescing to give a circular pattern
- *keratoderma blennorrhagica*, which begins as discrete waxy, yellow–brown vesico-papules with desquamating margins, occasionally coalescing to form large crusty plaques on the palms and soles of the feet
- *pustular psoriasis*
- *nail dystrophy* with subungual hyperkeratosis
- *mouth ulcers*
- *conjunctivitis*
- *uveitis*, which is rare with the first attack but arises in 30% of patients with recurring or chronic arthritis.

Other complications in ReA are very rare but include aortic incompetence, conduction defects, pleuro-pericarditis, peripheral neuropathy, seizures and meningoencephalitis.

Investigations

The diagnosis is usually made clinically but joint aspiration may be required to exclude crystal arthritis and articular infection.

24

ESR and CRP are raised, urethritis may be confirmed in the 'two-glass test' by demonstration of mucoid threads in the first-void specimen that clear in the second. High vaginal swabs may reveal *Chlamydia* on culture. Except for post-*Salmonella* arthritis, stool cultures are usually negative by the time the arthritis presents but serology may help confirm previous dysentery. RF, ACPA and ANA are negative.

In chronic or recurrent disease, X-rays show periarticular osteoporosis; proliferative erosions, notably at entheses; periostitis, especially of metatarsals, phalanges and pelvis; and large, 'fluffy' calcaneal spurs. In contrast to AS, radiographic sacroiliitis is often asymmetrical and sometimes unilateral, and syndesmophytes are predominantly coarse and asymmetrical, often extending beyond the contours of the annulus ('non-marginal') (see Fig. 24.40B). Radiographic changes in the peripheral joints and spine are identical to those seen in psoriasis.

Management

Acute ReA should be treated with rest, NSAIDs and analgesics. Intra-articular or systemic glucocorticoids may be required in patients with severe monarticular synovitis or polyarticular disease, respectively. There is no convincing evidence for the use of antibiotics unless a triggering infection is identified. If chlamydial urethritis is diagnosed, it should be treated empirically with a short course of doxycycline or a single dose of azithromycin. Treatment with DMARDs (usually sulfasalazine or methotrexate) should be considered for patients with persistent marked symptoms, recurrent arthritis or severe keratoderma blennorrhagica. Anterior uveitis is a medical emergency requiring topical, subconjunctival or systemic glucocorticoids. For DMARD-recalcitrant cases, anti-TNF therapy should be considered.

Psoriatic arthritis

In the UK and Denmark the estimated population prevalence of psoriatic arthritis (PsA) from registry and coding data is approximately 0.2%. It is likely the true prevalence is considerably higher but this has not been extensively studied. The prevalence of PsA in psoriasis patients, based on clinical assessment, is variable but may be up to 40%. Early PsA may present as axSpA. The onset is usually between 25 and 40 years of age but juvenile forms exist. Occasionally, the arthritis and psoriasis develop synchronously but the onset of musculoskeletal and skin disease is frequently separated by many years. Classification of PsA requires key assessments of family history and screening for enthesitis (Box 24.62).

24.62 The CASPAR criteria for psoriatic arthritis

Inflammatory articular disease (joint, spine or enthesis) with ≥3 points from the following (1 point each unless stated):

- Current psoriasis (scores 2 points)
- History of psoriasis in first- or second-degree relative
- Psoriatic nail dystrophy
- Negative IgM rheumatoid factor[1]
- Current dactylitis
- History of dactylitis
- Juxta-articular new bone[2]

[1]Established by any method except latex. [2]Ill-defined ossification near joint margins (excluding osteophytes) on X-rays of hands or feet.
(CASPAR = **C**l**AS**sification for **P**soriatic **AR**thritis)

Pathophysiology

Genetic factors have an important role in PsA and family studies have suggested that heritability may exceed 80%. Variants in the *HLA-B* and *HLA-C* genes are the strongest genetic risk factors but more than 30 other variants also play a part. Many of these variants overlap with those implicated in psoriasis (p. 1247), where there are more than 40 susceptibility loci. These lie within or close to genes in the IL-12, IL-23 and nuclear factor kappa B (NFκB) signalling pathways. It is thought that an environmental trigger, probably infectious in nature, triggers the disease in genetically susceptible individuals, leading to immune activation involving dendritic cells and T cells. $CD8^+$ T cells (which recognise antigen presented in the context of HLA class I) are more abundant than $CD4^+$ T cells within the joint, which is in keeping with the genetic association between PsA and HLA-C and B variants. There is increasing evidence that the IL-23/IL-17 pathway plays a pivotal role in PsA. It is thought that the triggering stimulus causes over-production of IL-23 by dendritic cells, which in turn promotes differentiation and activation of Th17 cells, which produce the pro-inflammatory cytokine IL-17A. This, along with Th1 cytokines like IFN-γ and TNF-α, acts on macrophages and tissue-resident stromal cells at entheses, in bone and within the joint to produce additional pro-inflammatory cytokines and other mediators, which contribute to inflammation and tissue damage, as shown in Figure 24.42.

Clinical features

The presentation is with pain and stiffness affecting joints, tendons, spine and entheses. Joints are typically not swollen; however, several patterns of joint involvement are recognised (see below), including an oligoarticular form. These patterns are not mutually exclusive. Marked variation in disease patterns exists, including a disease course of intermittent exacerbation and remission. Destructive arthritis and disability are uncommon, except in the case of arthritis mutilans.

Asymmetrical inflammatory mono-/oligoarthritis

This often presents abruptly with a combination of synovitis and adjacent periarticular inflammation. It occurs most characteristically in the hands and feet, when synovitis of a finger or toe is coupled with tenosynovitis, enthesitis and inflammation of intervening tissue to give a 'sausage digit' or dactylitis (Fig. 24.43A). Large joints, such as the knee and ankle, may also be involved, sometimes with very large effusions.

Symmetrical polyarthritis

This accounts for about 25% of cases. It predominates in women and may resemble RA, with symmetrical involvement of small and large joints in both upper and lower limbs. Nodules and other extra-articular features of RA are absent and arthritis is generally less extensive and more benign.

Distal interphalangeal joint arthritis

This is quite a common pattern and can be difficult to distinguish from inflammatory generalised OA. PsA DIP joint disease is associated with psoriatic nail disease (Fig. 24.43B).

Psoriatic spondylitis

This type presents with inflammatory back or neck pain and prominent stiffness symptoms. Any structure in the spine can be involved, including intervertebral disc entheses and facet joints. It may occur alone or with any of the other clinical patterns described above and is typically unilateral or asymmetric in severity.

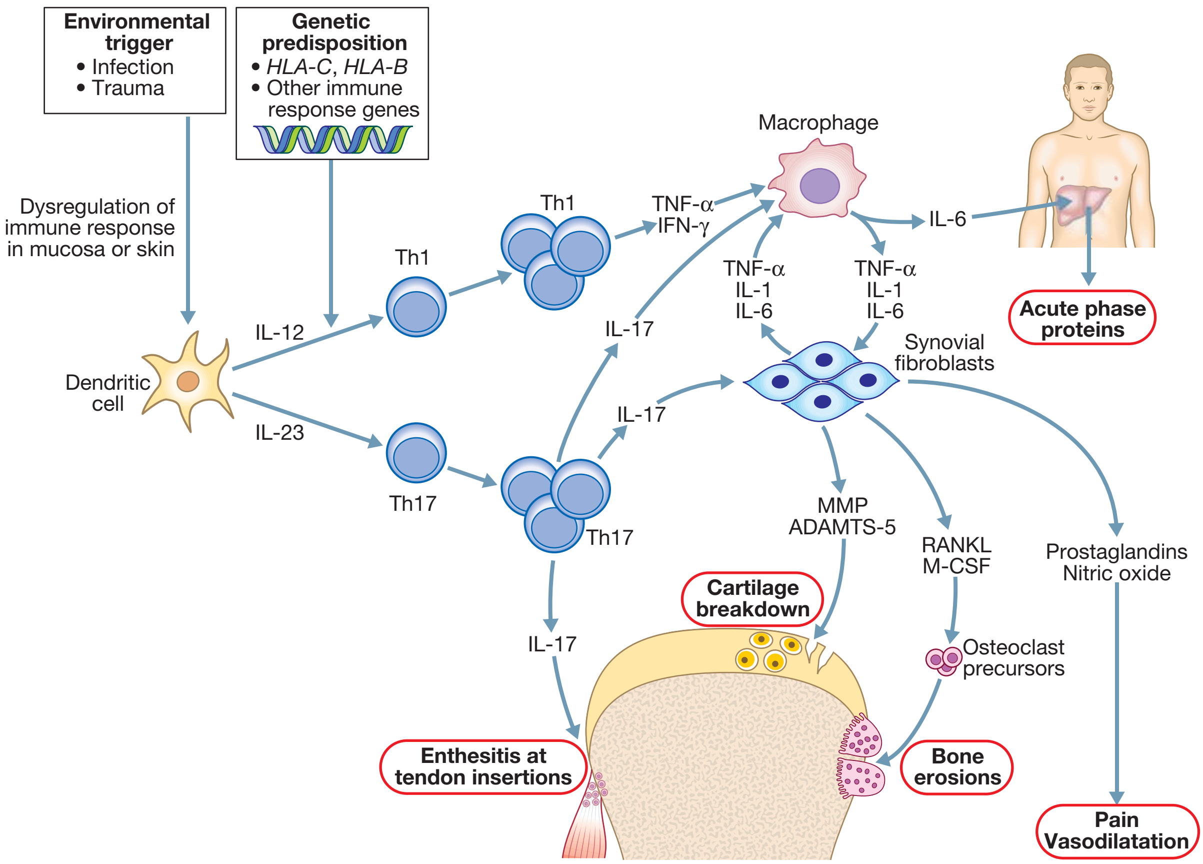

Fig. 24.42 Pathogenesis of psoriatic arthritis. Some of the cytokines and cellular interactions believed to be important in psoriatic arthritis are shown. (ADAMTS-5 = aggrecanase; IL = interleukin; M-CSF = macrophage colony-stimulating factor; MMP = matrix metalloproteinase; TNF = tumour necrosis factor; RANKL = RANK ligand)

Arthritis mutilans

This is a deforming erosive arthritis targeting the fingers and toes; it occurs in 5% of cases of PsA. Prominent cartilage and bone destruction results in marked instability. The encasing skin appears invaginated and 'telescoped' ('main en lorgnette') and the finger can be pulled back to its original length.

Enthesitis-predominant

This form of disease presents with pain and stiffness at the insertion sites of tendons and ligaments into bone (enthesitis). Symptoms can be extensive or localised. Typically affected entheses include Achilles tendon insertions, plantar fascia origins, patellar ligament attachments, hip abductor complex insertion at lateral femoral condyle, gluteus medius insertion at greater trochanter, humeral epicondyle tendon attachments, deltoid origin at acromial edge, intercostal muscle attachments at ribs, and pelvic ligament attachments.

Nail changes include pitting, onycholysis, subungual hyperkeratosis and horizontal ridging, which are found in 85% of patients with PsA and can occur in the absence of skin disease. The characteristic rash of psoriasis (p. 1247) may be widespread, or confined to the scalp, natal cleft, umbilicus and genitals, where it is easily overlooked. Obtaining a history of psoriasis in a first-degree relative can be tricky but is important, given that a positive response contributes to making a diagnosis.

Investigations

The diagnosis is made on clinical grounds. Autoantibodies are generally negative and acute phase reactants, such as ESR and CRP, are raised in only a proportion of patients with active disease. X-rays may be normal or show erosive change with joint space narrowing. Features that favour PsA over RA include the characteristic distribution (see Fig. 24.10, p. 994) of proliferative erosions with marked new bone formation, absence of periarticular osteoporosis and osteosclerosis. Imaging of the axial skeleton often reveals features similar to those in chronic ReA, with coarse, asymmetrical, non-marginal syndesmophytes and asymmetrical sacroiliitis. MRI and ultrasound with power Doppler are increasingly employed to detect synovial inflammation and inflammation at the entheses.

Management

Therapy with NSAIDs and analgesics may be sufficient to manage symptoms in mild disease. Intra-articular glucocorticoid injections can control isolated synovitis or enthesitis. Splints and prolonged rest should be avoided because of the tendency to fibrous and bony ankylosis. Patients with spondylitis should be prescribed the same exercise and posture regime as in axSpA/AS. Therapy with DMARDs should be considered for persistent synovitis unresponsive to conservative treatment. Methotrexate is the drug of first choice and is also effective

Fig. 24.43 Psoriatic arthropathy. A Dactylitis. B Distal interphalangeal joint pattern with accompanying nail dystrophy (pitting and onycholysis).

for skin disease (see EULAR guidelines, 'Further information', p. 1060). Other DMARDs may also be helpful, including sulfasalazine, ciclosporin and leflunomide. Particular attention should be paid to monitoring liver function in patients treated with DMARDs, since abnormalities are common in PsA. Hydroxychloroquine is generally avoided, as it can cause exfoliative skin reactions; it may, however, be tried in the small subset of patients who have mild PsA but no psoriasis and are ANA-positive. Anti-TNF treatment should be considered for individuals with active synovitis who respond inadequately to standard DMARDs, and treatment is effective for both PsA and psoriasis. Ustekinumab, a monoclonal antibody that binds to and neutralises the p40 subunit of IL-12 and IL-23, improves joint, dactylitis and enthesitis lesions in PsA. Secukinumab, a monoclonal antibody that targets IL-17A, has similar efficacy to TNF inhibitors in PsA. Apremilast is an oral small-molecule inhibitor of phosphodiesterase 4 (PDE4), which is effective in PsA when DMARD therapy fails, although it appears to be less efficacious than biologic treatment. Adverse effects include weight loss, depression and suicidal ideation.

Enteropathic (spondylo)arthritis

The overall prevalence of inflammatory musculoskeletal disease in inflammatory bowel diseases (IBDs: Crohn's disease and ulcerative colitis) is not well known, as studies have not adequately assessed enthesitis and osteitis lesions, but the musculoskeletal manifestations are in keeping with an SpA phenotype. Involvement of the peripheral joints is seen in about 20% of IBD patients. Oligoarticular disease predominantly affects the large lower limb joints (knees, ankles and hips). Radiographic evidence of sacroiliitis is present in about 20–25% of IBD patients. In Crohn's disease, more than in colitis, the arthritis usually coincides with exacerbations of the underlying bowel disease and the arthritis improves with effective treatment of the bowel disease. There is some suggestion that the severity and onset of inflammatory musculoskeletal symptoms can vary in association with changes in the integrity of the ileocaecal valve, raising the possibility that changes in gut flora may act as triggers for the associated SpA.

NSAIDs are best avoided, since they can exacerbate IBD. Instead, judicious use of glucocorticoids, sulfasalazine and methotrexate may be considered. Liaison is necessary between gastroenterologist and rheumatologist with regard to choice of therapy. Anti-TNF therapy is effective in enteropathic arthritis but etanercept should be avoided, as it has no efficacy in IBD. When musculoskeletal symptoms worsen despite anti-TNF therapy, it is wise to exclude bacterial overgrowth as a triggering cause (blind-loop syndrome).

Autoimmune connective tissue diseases

Autoimmune connective tissue diseases (AICTDs) share many clinical features and are characterised by dysregulation of immune responses, autoantibody production that is often directed at components of the cell nucleus, and tissue damage.

Systemic lupus erythematosus

Systemic lupus erythematosus (SLE, 'lupus') is a rare disease with a prevalence that ranges from about 0.03% in Caucasians to 0.2% in Afro-Caribbeans. Some 90% of affected patients are female and the peak age at onset is between 20 and 30 years. SLE is associated with considerable morbidity and a fivefold increase in mortality compared to age- and gender-matched controls, mainly because of an increased risk of premature cardiovascular disease.

Pathophysiology

The cause of SLE is incompletely understood but genetic factors play an important role. There is a higher concordance in monozygotic twins and the disease is strongly associated with polymorphic variants at the HLA locus. In a few instances, SLE is associated with inherited mutations in complement components C1q, C2 and C4, in the immunoglobulin receptor FcγRIIIb or in the DNA exonuclease *TREX1*. Genome-wide association studies have identified common polymorphisms near several other genes that predispose to SLE, most of which are involved in regulating immune cell function. From an immunological standpoint, the characteristic feature of SLE is autoantibody production. These autoantibodies have specificity for a wide range of targets but many are directed against antigens present within the cell or within the nucleus. This has led to the hypothesis that SLE may occur because of defects in apoptosis or in the clearance of apoptotic cells, which causes inappropriate exposure of intracellular antigens on the cell surface, leading to polyclonal B- and T-cell activation and autoantibody production. This is supported by the fact that environmental factors that cause flares of lupus, such as ultraviolet light and infections, increase oxidative stress and cause cell damage. Whatever the underlying cause, autoantibody production and immune complex formation are thought to be important mechanisms of tissue damage in active SLE, leading to vasculitis and organ damage.

Clinical features

Symptoms such as fever, weight loss and mild lymphadenopathy may occur during flares of disease activity, whereas others such as fatigue and low-grade joint pains can be constant and not particularly associated with active inflammatory disease.

Arthritis

Arthralgia is a common symptom, occurring in 90% of patients, and is often associated with early morning stiffness. Tenosynovitis may also occur but clinically apparent synovitis with joint swelling is rare. Joint deformities may arise (Jaccoud's arthropathy) as the result of tendon damage but joint erosions are not a feature.

Raynaud's phenomenon

Raynaud's phenomenon (p. 504) is common and may antedate other symptoms by months or years. SLE can present with Raynaud's phenomenon, along with arthralgia or arthritis. Secondary Raynaud's phenomenon associated with SLE and other AICTDs needs to be differentiated from primary Raynaud's phenomenon, which is common in the general population (up to 5%). Features in favour of secondary Raynaud's phenomenon include age at onset of over 25 years, absence of a family history of Raynaud's phenomenon, and occurrence in a male. Examination of capillary nail-fold loops using an ophthalmoscope (and oil placed on the skin) can show loss of the normal loop pattern, with capillary 'fallout' and dilatation and branching of loops; these features support either a diagnosis of systemic sclerosis or severe primary Raynaud's phenomenon. If Raynaud's phenomenon is severe, digital ulceration can occur (Fig. 24.44).

Fig. 24.44 Severe secondary Raynaud's phenomenon leading to digital ulceration.

Skin

The skin is commonly involved in SLE, and many SLE skin eruptions are precipitated by exposure to ultraviolet light. The main types of skin involvement are:

- The classic facial rash (up to 20% of patients). This is erythematous, raised and painful or itchy, and occurs over the cheeks with sparing of the nasolabial folds (Fig. 24.45). Rosacea is a mimic of this rash.
- A discoid rash characterised by hyperkeratosis and follicular plugging, with scarring alopecia if it occurs on the scalp.
- Diffuse, usually non-scarring alopecia, which may also occur with active disease.
- Urticarial eruptions.
- Livedo reticularis (Fig. 24.46), which is also a feature of antiphospholipid syndrome (p. 977) and can become frankly vasculitic, if severe.

Fig. 24.45 Malar rash of systemic lupus erythematosus, sparing the nasolabial folds. The rash is notably similar to rosacea, which may itself be associated with inflammatory joint diseases such as psoriatic arthritis.

Kidney

Renal involvement is one of the main determinants of prognosis and regular monitoring of urinalysis and blood pressure is essential. The typical renal lesion is a proliferative glomerulonephritis (p. 397), characterised by heavy haematuria, proteinuria and casts on urine microscopy.

Cardiovascular

The most common manifestation is pericarditis. Myocarditis and Libman–Sacks endocarditis can also occur. The endocarditis is due to accumulation on the heart valves of sterile fibrin-containing vegetations, which is thought to be a manifestation of hypercoagulability associated with antiphospholipid antibodies. The risk of atherosclerosis is greatly increased, as is the risk of stroke and myocardial infarction. This is thought to be multifactorial due to the adverse effects of inflammation on the endothelium, chronic glucocorticoid therapy and the procoagulant effects of antiphospholipid antibodies.

Lung

Lung involvement is common and most frequently manifests as pleuritic pain (serositis) or pleural effusion. Other features include pneumonitis, atelectasis, reduced lung volume and pulmonary fibrosis that leads to breathlessness. The risk of thromboembolism is increased, especially in patients with antiphospholipid antibodies.

Neurological

Fatigue, headache and poor concentration are common and often occur in the absence of laboratory evidence of active disease. More specific features of cerebral lupus include visual hallucinations, chorea, organic psychosis, transverse myelitis and lymphocytic meningitis.

Haematological

Neutropenia, lymphopenia, thrombocytopenia and haemolytic anaemia may occur, due to antibody-mediated destruction of

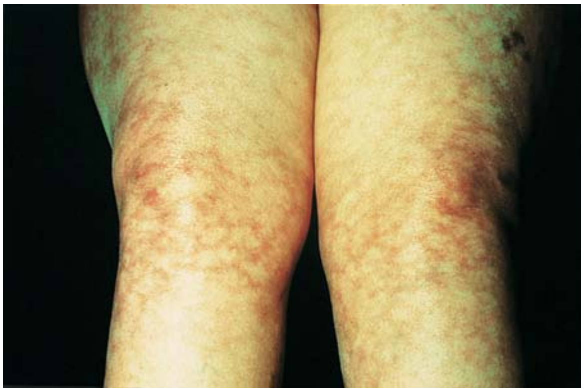

Fig. 24.46 Livedo reticularis (systemic lupus erythematosus and anti-phospholipid syndrome).

peripheral blood cells. The degree of lymphopenia is a good guide to disease activity.

Gastrointestinal

Mouth ulcers may occur and may or may not be painful. Peritoneal serositis can cause acute pain. Mesenteric vasculitis is a serious complication, which can present with abdominal pain, bowel infarction or perforation. Hepatitis is a recognised, though rare, feature.

Paediatric disease

Renal disease and cutaneous manifestations are more frequent in juvenile-onset SLE compared to disease in adults. Similarly, there is subsequently a higher incidence of renal disease, malar rash, Raynaud's phenomenon, cutaneous vasculitis and neuropsychiatric manifestations than in adults.

Investigations

The diagnosis is based on a combination of clinical features and laboratory abnormalities. To fulfil the classification criteria for SLE, at least 4 of the 11 factors shown in Box 24.63 must be present or have occurred in the past. Checking of ANAs, antibodies to ENAs and complement, routine haematology, biochemistry and urinalysis are mandatory. Patients with active SLE test positive for ANA. Some authorities believe that ANA-negative SLE occurs (e.g. in the presence of antibodies to Ro) but others regard SLE as necessarily ANA-positive; the issue may be more to do with sensitivity of the ANA assay at any given time in a disease course. Anti-dsDNA antibodies are positive in many, but not all, patients and are tested at the time of diagnosis by most laboratories using ELISA. ELISAs have low specificity, whereas testing for anti-dsDNA antibodies using *Crithidia luciliae* is highly specific. Patients with active disease tend to have low levels of C3 due to complement consumption, but in some people low C3 and C4 may be the result of inherited complement deficiency in C1, C2 or C4 that predisposes to SLE (p. 66). Studies of other family members can help to differentiate inherited deficiency from complement consumption. A raised ESR, leucopenia and lymphopenia are typical of active SLE, along with anaemia, haemolytic anaemia and thrombocytopenia. CRP is often normal in active SLE, except in the presence of serositis; thus an elevated CRP suggests infection.

Management

The therapeutic goals are to educate the patient about the nature of the illness, to control symptoms and to prevent organ damage and maintain normal function. Patients should be advised to avoid sun and ultraviolet light exposure and to employ sun blocks (sun protection factor 25–50).

Mild to moderate disease

Patients with mild disease restricted to skin and joints can sometimes be managed with analgesics, NSAIDs and hydroxychloroquine. Frequently, however, glucocorticoids are also necessary (prednisolone 5–20 mg/day), often in combination with immunosuppressants such as methotrexate, azathioprine or mycophenolate mofetil (MMF). Increased doses of glucocorticoids may be required for flares in activity or complications such as pleurisy or pericarditis. The monoclonal antibody belimumab, which targets the β-cell growth factor BLyS, has recently been shown to be effective in patients with active SLE who have responded inadequately to standard therapy.

Severe and life-threatening disease

High-dose glucocorticoids and immunosuppressants are required for the treatment of renal, CNS and cardiac involvement. A commonly used regimen is pulsed methylprednisolone (10 mg/kg IV) plus cyclophosphamide (15 mg/kg IV), repeated at 2–3-weekly intervals for six cycles. Cyclophosphamide may cause haemorrhagic cystitis but the risk can be minimised by good hydration and co-prescription of mesna (2-mercaptoethane sulfonate), which binds its urotoxic metabolites. Because of the risk of azoospermia and premature menopause, sperm or oöcyte collection and storage need to be considered prior to treatment with cyclophosphamide.

i 24.63 Criteria for the classification of systemic lupus erythematosus

Features	Characteristics
Malar rash	Fixed erythema, flat or raised, sparing the nasolabial folds
Discoid rash	Erythematous raised patches with adherent keratotic scarring and follicular plugging
Photosensitivity	Rash due to unusual reaction to sunlight
Oral ulcers	Oral or nasopharyngeal ulceration, which may be painless
Arthritis	Non-erosive, involving two or more peripheral joints
Serositis	Pleuritis (history of pleuritic pain or rub, or pleural effusion) *or* pericarditis (rub, electrocardiogram evidence or effusion)
Renal disorder	Persistent proteinuria >0.5 g/24 hrs *or* cellular casts (red cell, granular or tubular)
Neurological disorder	Seizures or psychosis, in the absence of provoking drugs or metabolic derangement
Haematological disorder	Haemolytic anaemia *or* leucopenia* ($<4\times10^9$/L) *or* lymphopenia* ($<1\times10^9$/L) *or* thrombocytopenia* ($<100\times10^9$/L) in the absence of offending drugs
Immunological	Anti-DNA antibodies in abnormal titre *or* presence of antibody to Sm antigen *or* positive antiphospholipid antibodies
Antinuclear antibody (ANA)	Abnormal titre of ANA by immunofluorescence
An adult has SLE if any 4 of 11 features are present serially or simultaneously	

*On two separate occasions.

MMF has been used successfully with high-dose glucocorticoids for renal involvement with results similar to those of pulsed cyclophosphamide but fewer adverse effects. Belimumab in combination with standard therapy significantly decreases disease activity in SLE patients and is safe and well tolerated. Its role in patients with renal and neurological disease is still under investigation.

Rituximab has been reported as being effective in selected cases, though randomised controlled trials have not shown significant overall efficacy.

Maintenance therapy

Following control of acute disease, a typical maintenance regimen is oral prednisolone in a dose of 40–60 mg daily, gradually reducing to 10–15 mg/day or less by 3 months. Azathioprine (2–2.5 mg/kg/day), methotrexate (10–25 mg/week) or MMF (2–3 g/day) should also be prescribed. The long-term aim is to continue the lowest dose of glucocorticoid and immunosuppressant to maintain remission. Cardiovascular risk factors, such as hypertension and hyperlipidaemia, should be controlled and patients should be advised to stop smoking.

Patients with SLE and the antiphospholipid antibody syndrome, who have had previous thrombosis, require life-long warfarin therapy. SLE patients are at risk of osteoporosis and hypovitaminosis D, and should be screened with biochemistry and DXA scanning accordingly.

Systemic sclerosis

Systemic sclerosis (SScl) is an autoimmune disorder of connective tissue, which results in fibrosis affecting the skin, internal organs and vasculature. It is characterised typically by Raynaud's phenomenon, digital ischaemia (Fig. 24.47), sclerodactyly, and cardiac, lung, gut and renal disease. The peak age of onset is in the fourth and fifth decades and overall prevalence is 10–20 per 100 000, with a 4 : 1 female-to-male. It is subdivided into diffuse cutaneous systemic sclerosis (dcSScl: 30% of cases) and limited cutaneous systemic sclerosis (lcSScl: 70% of cases). Some patients with lcSScl have calcinosis and telangiectasia. The prognosis in dcSScl is poor (5-year survival about 70%). Features that associate with a poor prognosis include older age, diffuse skin disease, proteinuria, high ESR, a low gas transfer factor for carbon monoxide (TLCO) and pulmonary hypertension.

Pathophysiology

The cause of SScl is not completely understood. There is evidence for a genetic component and associations with alleles at the HLA locus have been found. The disease occurs in all ethnic groups and race may influence severity. Isolated cases have been reported in which an SScl-like disease has been triggered by exposure to silica dust, vinyl chloride, epoxy resins and trichloroethylene. There is clear evidence of immunological dysfunction: T lymphocytes, especially those of the Th17 subtype, infiltrate the skin and there is abnormal fibroblast activation, leading to increased production of extracellular matrix in the dermis, primarily type I collagen. This results in symmetrical thickening, tightening and induration of the skin (scleroderma). Arterial and arteriolar narrowing occurs due to intimal proliferation and vessel wall inflammation. Endothelial injury causes release of vasoconstrictors and platelet activation, resulting in further ischaemia, which is thought to exacerbate the fibrotic process.

Clinical features

Skin

Initially, there is non-pitting oedema of fingers and flexor tendon sheaths. Subsequently, the skin becomes shiny and taut, and distal skin creases disappear. There can be capillary loss. The face and neck are often involved, with thinning of the lips and radial furrowing. In some patients, skin thickening stops at this stage. Skin involvement restricted to sites distal to the elbow or knee (apart from the face) is thus classified as lcSScl (Fig. 24.48). Involvement proximal to the knee and elbow and on the trunk is classified as 'diffuse disease' (dcSScl).

Raynaud's phenomenon

This is a universal feature and can precede other features by many years. Involvement of small blood vessels in the extremities may cause critical tissue ischaemia, leading to localised distal skin infarction and necrosis.

Musculoskeletal features

Arthralgia and flexor tenosynovitis are common. Restricted hand function is due to skin rather than joint disease and erosive arthropathy is uncommon. Muscle weakness and wasting can result from myositis.

Gastrointestinal involvement

Smooth muscle atrophy and fibrosis in the lower two-thirds of the oesophagus lead to reflux with erosive oesophagitis.

24

Fig. 24.47 Systemic sclerosis. Hands showing tight, shiny skin, sclerodactyly, flexion contractures of the fingers and thickening of the left middle finger extensor tendon sheath.

Fig. 24.48 Typical facial appearance showing telangiectasias in localised cutaneous systemic sclerosis.

Dysphagia and odynophagia may also occur. Involvement of the stomach causes early satiety and occasionally outlet obstruction. Recurrent occult upper gastrointestinal bleeding may indicate a 'watermelon' stomach (antral vascular ectasia; up to 20% of patients). Small intestine involvement may lead to malabsorption due to bacterial overgrowth and intermittent bloating, pain or constipation. Dilatation of bowel due to autonomic neuropathy may cause pseudo-obstruction with nausea, vomiting, abdominal discomfort and distension, often worse after food (symptoms can mimic those of an acute abdomen and can lead to erroneous laparotomy).

Pulmonary involvement

Pulmonary hypertension complicates long-standing disease and is six times more prevalent in lcSScl than in dcSScl. It usually presents with insidiously evolving exertional dyspnoea and signs of right heart failure. Interstitial lung disease is common in patients with dcSScl who have topoisomerase 1 antibodies (Scl70). Dyspnoea can evolve slowly over time or rapidly in occasional cases.

Renal involvement

One of the main causes of death is hypertensive renal crisis, characterised by rapidly developing accelerated phase hypertension (p. 514) and renal failure. Hypertensive renal crisis is much more likely to occur in dcSScl than in lcSScl, and in patients with topoisomerase 1 and RNP antibodies.

Investigations

As SScl can affect multiple organs, routine haematology, renal, liver and bone function tests and urinalysis are essential. ANA is positive in about 70%. About 30% of patients with dcSScl have antibodies to topoisomerase 1 (Scl70). About 60% of patients with lcSScl syndrome have anticentromere antibodies (p. 991). Chest X-ray, transthoracic echocardiography and lung function tests are recommended to assess for interstitial lung disease and pulmonary hypertension (low corrected transfer factor may indicate early pulmonary hypertension). High-resolution lung CT is recommended if interstitial lung disease suspected. If pulmonary hypertension is suspected, right heart catheter measurements should be arranged at a specialist cardiac centre. A barium swallow can assess oesophageal involvement. A hydrogen breath test can indicate bacterial overgrowth (p. 808).

Management

No treatments are available that halt or reverse the fibrotic changes that underlie the disease. The focus of management, therefore, is to slow the effects of the disease on target organs.

- *Raynaud's phenomenon and digital ulcers*. Avoidance of cold exposure, use of thermal insulating gloves/socks and maintenance of a high core temperature all help. If symptoms are persistent, calcium channel blockers, losartan, fluoxetine and sildenafil have efficacy. Courses of intravenous prostacyclin are used for severe disease and critical ischemia (e.g. 6–8 hours daily for 5 days). The endothelin-1 antagonist bosentan is licensed for treating ischaemic digital ulcers, and digital tip tissue health can be maintained with regular use of fucidin–hydrocortisone cream.
- *Gastrointestinal complications*. Oesophageal reflux should be treated with proton pump inhibitors and anti-reflux agents. Rotating courses of antibiotics may be required for bacterial overgrowth (e.g. rifaximin, a tetracycline and metronidazole), while metoclopramide or domperidone may help patients with symptoms of dysmotility/pseudo-obstruction.
- *Hypertension*. Aggressive treatment with ACE inhibitors is needed, even if renal impairment is present.
- *Joint involvement*. This may be treated with analgesics and/or NSAIDs. If synovitis is present and both RA (i.e. an 'overlap' condition, which needs treatment on its own merit) and OA have been ruled out, low-dose methotrexate can be of value.
- *Progressive pulmonary hypertension*. Early treatment with bosentan is required. In severe or progressive disease, heart–lung transplant may be considered.
- *Interstitial lung disease*. Glucocorticoids and (pulse intravenous) cyclophosphamide are the mainstays of treatment in patients who have progressive interstitial lung disease.

Mixed connective tissue disease

Mixed connective tissue disease (MCTD) is a condition in which some clinical features of SScl, myositis and SLE all occur in the same patient. It commonly presents with indolent puffiness of the fingers (the appearance is between that of SpA-type dactylitis and sclerodactyly) with Raynaud's phenomenon and myalgias. Most patients have anti-RNP antibodies. Management focuses on treating the components of the disease (see other sections).

Primary Sjögren's syndrome

Primary Sjögren's syndrome (PSS) is characterised by lymphocytic infiltration of salivary and lacrimal glands, leading to glandular fibrosis and exocrine failure. The typical age of onset is between 40 and 50, with a 9 : 1 female-to-male ratio. The disease may occur with other autoimmune diseases (secondary Sjögren's syndrome).

Clinical features

The eye symptoms, termed keratoconjunctivitis sicca, are due to a lack of lubricating tears, which reflects inflammatory infiltration of the lacrimal glands. Conjunctivitis and blepharitis are frequent, and may lead to filamentary keratitis due to binding of tenacious mucous filaments to the cornea and conjunctiva. Oral involvement manifests as a dry mouth (xerostomia). There is a high incidence of dental caries and high risk of dental failure. Other sites of extraglandular involvement are listed in Box 24.64. Often the most disabling symptom is fatigue. There may be an association with inflammatory small-joint OA (clinical suspicion, though formal studies have not been done). Sialadenitis, osteoarthritis and xerostomia (SOX) syndrome has been described; this may occur independently of PSS or, more likely, constitute a mild form. Both interstitial lung disease and interstitial nephritis (sometimes complicated by renal tubular acidosis) require proactive screening. PSS is associated with a 40-fold increased lifetime risk of lymphoma, though the complication is still very rare.

Investigations

The diagnosis can be established by the Schirmer tear test, which measures tear flow over 5 minutes using absorbent paper strips placed on the lower eyelid; a normal result is more than 6 mm of wetting. Staining with rose bengal may show punctate epithelial abnormalities over the area not covered by the open eyelid. If the diagnosis remains in doubt, it can be confirmed by demonstrating focal lymphocytic infiltrate in a minor salivary gland biopsy. Most patients have an elevated ESR and

i 24.64 Features of primary Sjögren's syndrome

Risk factors	
• Age of onset 40–60 • Female > male	• HLA-B8/DR3
Common clinical features	
• Keratoconjunctivitis sicca • Xerostomia • Salivary gland enlargement • Rashes/skin irritation	• Non-erosive arthralgia • Generalised osteoarthritis • Raynaud's phenomenon • Fatigue
Less common features	
• Low-grade fever • Interstitial lung disease • Anaemia, leucopenia • Thrombocytopenia • Cryoglobulinaemia • Vasculitis	• Peripheral neuropathy • Lymphadenopathy • Lymphoreticular lymphoma • Glomerulonephritis • Interstitial nephritis • Renal tubular acidosis
Autoantibodies frequently detected	
• Rheumatoid factor • Antinuclear antibody • SS-A (anti-Ro)	• SS-B (anti-La) • Gastric parietal cell • Thyroid
Associated autoimmune disorders	
• Systemic lupus erythematosus • Systemic sclerosis • Coeliac disease	• Primary biliary cholangitis • Chronic active hepatitis • Myasthenia gravis

(HLA = human leucocyte antigen)

hypergammaglobulinaemia, and one or more autoantibodies, including ANA and RF. ANA-negative disease exists. Anti-Ro and anti-La antibodies are commonly present (see Box 24.10, p. 992). Patients with joint pain, fatigue and RF (with or without ANA) need careful assessment because a number of possibilities exist: PSS and inflammatory OA; RA with incidental ANA; RA/SLE overlap; or RA/PSS overlap. Knowing ACPA status can help (it is positive in RA). Interstitial lung disease complicates PSS in a sizable minority of patients (persistent dry cough, dyspnoea, coarse 'Velcro' crackles on lung auscultation). A chest X-ray and lung function tests should be performed.

Management

No treatments that have disease-modifying effects have yet been identified and management is symptomatic. Lacrimal substitutes, such as hypromellose, should be used during the day in combination with more viscous lubricating application at night. Soft contact lenses can be useful for corneal protection in patients with filamentary keratitis, and occlusion of the lacrimal ducts is occasionally needed. Artificial saliva sprays, saliva-stimulating tablets, and pastilles and oral gels can be tried for xerostomia but often chewing gum is most effective. Adequate postprandial oral hygiene and prompt treatment of oral candidiasis are essential. Vaginal dryness is treated with lubricants. A trial of systemic pilocarpine (5–30 mg daily in divided doses) is worthwhile in early disease to amplify glandular function. Hydroxychloroquine (200 mg twice daily) is often used to address skin and musculoskeletal features and may help fatigue. Immunosuppression does not improve sicca symptoms but is essential for progressive interstitial lung disease (e.g. glucocorticoids and cyclophosphamide) and for interstitial nephritis (if hydroxychloroquine is ineffective alone). If non-resolving lymphadenopathy or salivary gland enlargement develops, biopsy should be undertaken to exclude malignancy.

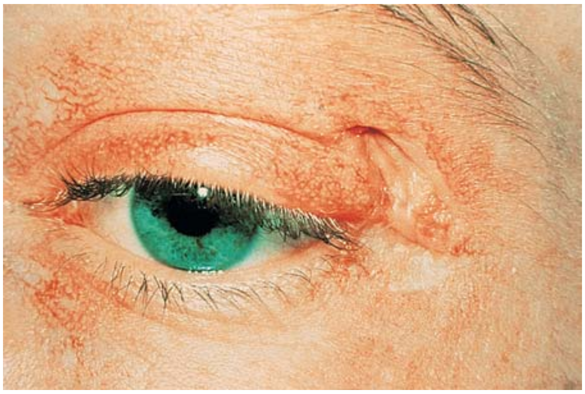

Fig. 24.49 Typical eyelid appearance in dermatomyositis. Note the oedema and telangiectasia.

Polymyositis and dermatomyositis

Polymyositis (PM) and dermatomyositis (DM) are characterised by proximal skeletal and (cardiac and gut) smooth muscle inflammation. In DM, characteristic skin changes also occur. Both diseases are rare, with an incidence of 2–10 cases per million/year. They can occur in isolation or in association with other autoimmune diseases, and both are notably connected with (either previously diagnosed or undisclosed) malignancy.

Clinical features

The typical presentation of PM and DM is with symmetrical proximal muscle weakness over a few weeks, usually affecting the lower limbs more than the upper, in adults between 40 and 60 years of age. Patients report difficulty rising from a chair, climbing stairs and lifting, often (though not always) with muscle pain. Systemic features of fever, weight loss and fatigue are common. Respiratory or pharyngeal muscle involvement can lead to ventilatory failure or aspiration that requires urgent treatment. Interstitial lung disease occurs in up to 30% of patients and is strongly associated with the presence of antisynthetase (Jo-1) antibodies.

In DM, the skin lesions include Gottron's papules, which are scaly, erythematous or violaceous, psoriasiform plaques occurring over the extensor surfaces of PIP and DIP joints, and a heliotrope rash that is a violaceous discoloration of the eyelid in combination with periorbital oedema (Fig. 24.49). Similar rashes occur on the upper back, chest and shoulders ('shawl' distribution). Periungual nail-fold capillaries are often enlarged and tortuous.

Investigations

Muscle biopsy is the pivotal investigation and shows the typical features of fibre necrosis, regeneration and inflammatory cell infiltrate (Fig. 24.50). Occasionally, however, a biopsy may be normal, particularly if myositis is patchy so, invariably, MRI should be used to identify areas of abnormal muscle for biopsy. Serum levels of creatine kinase are typically raised and are a useful measure of disease activity, although a normal creatine kinase does not exclude the diagnosis, particularly in juvenile myositis. Electromyography is very useful for highlighting non-autoimmune/non-inflammatory myopathies. Screening for underlying malignancy should be undertaken routinely (full examination, chest X-ray, serum urine and protein electrophoresis, CT of chest/abdomen/pelvis; prostate-specific antigen should be included in men, and mammography in women).

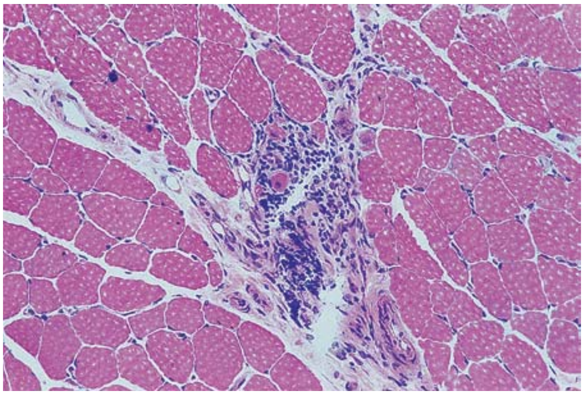

Fig. 24.50 Muscle biopsy from a patient with polymyositis. The sample shows an intense inflammatory cell infiltrate in an area of degenerating and regenerating muscle fibres.

Management

Oral glucocorticoids (prednisolone 1 mg/kg daily) are the mainstay of initial treatment of PM and DM but high-dose intravenous methylprednisolone (1 g/day for 3 days) may be required in patients with respiratory or pharyngeal weakness. If there is a good response, glucocorticoids should be reduced by approximately 25% per month to a maintenance dose of 5–7.5 mg. Although most patients respond well to glucocorticoids, many need additional immunosuppressive therapy. Methotrexate and MMF are the first choices of many but azathioprine and ciclosporin are also used as alternatives. Rituximab appears to show efficacy in a majority of patients, although the only controlled study (which was criticised for its suboptimal design) was negative. In clinical practice, rituximab is an option for use with glucocorticoids, to maintain an early glucocorticoid-induced remission. Intravenous immunoglobulin (IVIg) may be effective in refractory cases. Mepacrine or hydroxychloroquine has been used for skin-predominant disease to some good effect in certain cases. One risk of treatment is glucocorticoid-induced myopathy. If the initial response to treatment is poor, further biopsy then shows type II fibre atrophy in glucocorticoid myopathy (compared with fibre necrosis and regeneration in active myositis).

Juvenile dermatomyositis

Juvenile dermatomyositis (JDM) is by far the most common inflammatory myopathy in children and adolescents, and typically does not require a search for malignancy. The incidence is 2–4 per million (USA and UK) with a median age of onset of 7 years (25% are below 4 years at diagnosis). Many clinical features are similar to those in the adult disease. JDM can be monocyclic, lasting up to 3 years (25–40%), or polycyclic, with periods of remission and relapse (60–75%). In some cases, polycyclic JDM can be chronic and life-long. It is ulcerative in 10–20%. As in adults, calcinosis occurs in about 30%.

Intravenous methylprednisolone, then oral glucocorticoids and methotrexate produce a rapid response in many cases. Cyclophosphamide is used for lesional ulceration. IVIg is given in resistant cases.

Undifferentiated autoimmune connective tissue disease

In some patients, clinical features of AICTD occur, either simultaneously or sequentially, but at any one time the features and results of investigations do not allow a clear diagnosis to be made on the basis of conventional criteria. However, recognising that autoimmunity is present ('autoimmune diathesis') without making a specific diagnosis can help patients move forwards with chronic symptomology. Some of these individuals will progress to having a recognisable AICTD with time; others will continue to have an undifferentiated disease that remains the same for many years, and in others the symptoms will recede. Clinical monitoring and periodic autoimmune serological testing of all patients is sensible.

Adult-onset Still's disease

Adult-onset Still's disease is a rare systemic inflammatory disorder of unknown cause, possibly triggered by infection; it is similar to sJIA. It presents with intermittent fever, rash and arthralgia, and has been associated with pregnancy and the postpartum period and with high levels of IL-18. Splenomegaly, hepatomegaly and lymphadenopathy may be present. Investigations typically provide evidence of an acute phase response, with a markedly elevated serum ferritin. Tests for RF and ANA are negative and so adult-onset Still's disease may be better classified as an autoinflammatory rather than an autoimmune disease. Most patients respond to glucocorticoids but immunosuppressants, such as azathioprine or MMF, can be added when response is inadequate. Canakinumab or anakinra can be used for patients with resistant disease.

Vasculitis

Vasculitis is characterised by inflammation and necrosis of blood-vessel walls, with associated damage to skin, kidney, lung, heart, brain and gastrointestinal tract. There is a wide spectrum of involvement and severity, ranging from mild and transient disease affecting only the skin, to life-threatening fulminant disease with multiple organ failure. Principal sites of involvement for the main types of vasculitis are summarised in Figure 24.51. The clinical features result from a combination of local tissue ischaemia (due to vessel inflammation and narrowing) and the systemic effects of widespread inflammation. Systemic vasculitis should be considered in any patient with fever, weight loss, fatigue,

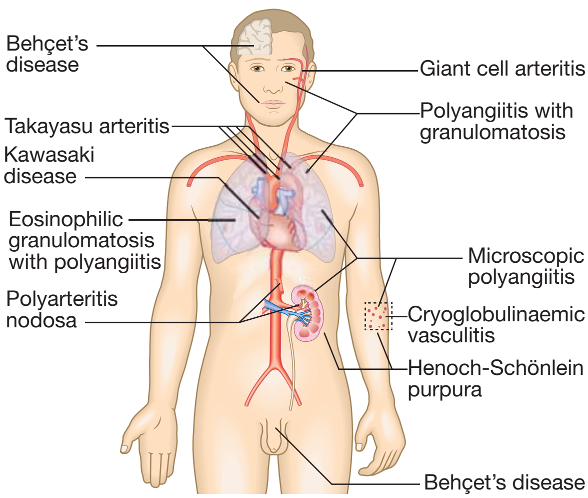

Fig. 24.51 Types of vasculitis. The anatomical targets of different forms of vasculitis are shown.

i 24.65 Clinical features of systemic vasculitis

Systemic	
• Malaise • Fever • Night sweats	• Weight loss with arthralgia and myalgia

• Sensory or motor neuropathy	

evidence of multisystem involvement, rashes, raised inflammatory markers and abnormal urinalysis (Box 24.65).

Antineutrophil cytoplasmic antibody-associated vasculitis

Antineutrophil cytoplasmic antibody-associated vasculitis (AAV) is a life-threatening disorder characterised by inflammatory infiltration of small blood vessels, fibrinoid necrosis and the presence of circulating antibodies to antineutrophil cytoplasmic antibody (ANCA). The combined incidence is about 10–15/1 000 000. Two main subtypes are recognised. Microscopic polyangiitis is a necrotising small-vessel vasculitis found with rapidly progressive glomerulonephritis, often in association with alveolar haemorrhage. Cutaneous and gastrointestinal involvement is common and other features include neuropathy (15%) and pleural effusions (15%). Patients are usually myeloperoxidase (MPO) antibody-positive. Secondly, granulomatosis with polyangiitis (formerly known as Wegener's granulomatosis) is characterised by granuloma formation, mainly affecting the nasal passages, airways and kidney. A minority of patients present with glomerulonephritis. The most common presentation of granulomatosis with polyangiitis is with epistaxis, nasal crusting and sinusitis, but haemoptysis and mucosal ulceration may also occur. Deafness may be a feature due to inner ear involvement, and proptosis may occur because of inflammation of the retro-orbital tissue (Fig. 24.52). This causes diplopia due to entrapment of the extra-ocular muscles, or loss of vision due to optic nerve compression. Disturbance of colour vision is an early feature of optic nerve compression. Untreated nasal disease ultimately leads to destruction of bone and cartilage. Migratory pulmonary infiltrates and nodules occur in 50% of patients (as seen on high-resolution CT of lungs). Patients with granulomatosis with polyangiitis are usually proteinase-3 (PR3) antibody-positive (ELISA).

Patients with active disease usually have a leucocytosis with elevated CRP, ESR and PR3. Complement levels are usually normal or slightly elevated. Imaging of the upper airways or chest

Fig. 24.52 **Eye involvement in antineutrophil cytoplasmic antibody-associated vasculitis.**

with MRI can be useful in localising abnormalities but, where possible, the diagnosis should be confirmed by biopsy of the kidney or lesions in the sinuses and upper airways.

Management for organ-threatening or acute–severe disease is with high-dose glucocorticoids (e.g. daily pulse intravenous methylprednisolone 0.5–1 g for 3 days, then oral prednisolone 0.5 mg/kg) and intravenous cyclophosphamide (e.g. 0.5–1 g every 2 weeks for 3 months), followed by maintenance therapy with lower-dose glucocorticoids and azathioprine, methotrexate or MMF. Plasmapheresis should be considered for fulminant lung disease. Rituximab in combination with high-dose glucocorticoids is equally effective as *oral* cyclophosphamide at inducing remission in AAV. Glucocorticoids and methotrexate are an effective combination for treating limited AAV where there is indolent sinus, lung or skin disease. AAV has a tendency to relapse and patients must be followed on a regular and long-term basis, monitoring urinalysis for blood and protein, plasma creatinine, ESR, CRP, lung function and PR3 or MPO antibody titres.

Takayasu arteritis

Takayasu arteritis affects the aorta, its major branches and occasionally the pulmonary arteries. The typical age at onset is 25–30 years, with an 8:1 female-to-male ratio. It has a worldwide distribution but is most common in Asia. Takayasu arteritis is characterised by granulomatous inflammation of the vessel wall, leading to occlusion or weakening of the vessel wall. It presents with claudication, fever, arthralgia and weight loss. Clinical examination may reveal loss of pulses, bruits, hypertension and aortic incompetence. Investigation will identify an acute phase response and normocytic, normochromic anaemia but the diagnosis is based on angiography, which reveals coarctation, occlusion and aneurysmal dilatation. Treatment is with high-dose glucocorticoids and immunosuppressants, as described for ANCA-associated vasculitis. With successful treatment, the 5-year survival is 83%.

Kawasaki disease

Kawasaki disease is a vasculitis that mostly involves the coronary vessels. It presents as an acute systemic disorder, usually affecting children under 5 years. It occurs mainly in Japan and other Asian countries, such as China and Korea, but other ethnic groups may also be affected. Presentation is with fever, generalised rash, including palms and soles, inflamed oral mucosa and conjunctival injection resembling a viral exanthem. The cause is unknown but

Fig. 24.53 Rash of systemic vasculitis (palpable purpura).

is thought to be an abnormal immune response to an infectious trigger. Cardiovascular complications include coronary arteritis, leading to myocardial infarction, transient coronary dilatation, myocarditis, pericarditis, peripheral vascular insufficiency and gangrene. Treatment is with aspirin (5 mg/kg daily for 14 days) and IVIg (400 mg/kg daily for 4 days).

Polyarteritis nodosa

Polyarteritis nodosa has a peak incidence between the ages of 40 and 50, with a male-to-female ratio of 2 : 1. The annual incidence is about 2/1 000 000. Hepatitis B is an important risk factor and the incidence is 10 times higher in the Inuit of Alaska, in whom hepatitis B infection is endemic. Presentation is with fever, myalgia, arthralgia and weight loss, in combination with manifestations of multisystem disease. The most common skin lesions are palpable purpura (Fig. 24.53), ulceration, infarction and livedo reticularis (see Fig. 24.46). Pathological changes comprise necrotising inflammation and vessel occlusion, and in 70% of patients arteritis of the vasa nervorum leads to neuropathy, which is typically symmetrical and affects both sensory and motor function. Severe hypertension and/or renal impairment may occur due to multiple renal infarctions but glomerulonephritis is rare (in contrast to microscopic polyangiitis). The diagnosis is confirmed by conventional or magnetic resonance angiography, which shows multiple aneurysms and smooth narrowing of mesenteric, hepatic or renal systems, or by muscle or sural nerve biopsy, which reveals the histological changes described above. Treatment is with high-dose glucocorticoids and immunosuppressants, as described for ANCA-associated vasculitis.

Giant cell arteritis and polymyalgia rheumatica

Giant cell arteritis (GCA) is a granulomatous arteritis that affects any large (including aorta) and medium-sized arteries. It is commonly associated with polymyalgia rheumatica (PMR), which presents with symmetrical, immobility-associated neck and shoulder girdle pain and stiffness. Since many patients with GCA have symptoms of PMR, and many patients with PMR go on to develop GCA if untreated, many rheumatologists consider them to be different manifestations of the same underlying disorder. Both diseases are rare under the age of 60 years. The average age at onset is 70, with a female-to-male ratio of about 3 : 1. The overall prevalence is about 20 per 100 000 in those over the age of 50 years.

24.66 Conditions that can mimic polymyalgia rheumatica

- Calcium pyrophosphate disease
- Spondyloarthritis
- Hyper-/hypothyroidism
- Psoriatic arthritis (enthesopathic)
- Systemic vasculitis
- Myeloma
- Inflammatory myopathy (particularly inclusion body myositis, p. 1059)
- Lambert–Eaton syndrome (p. 1143)
- Multiple separate lesions (cervical spondylosis, cervical radiculopathy, bilateral subacromial impingement, facet joint arthritis, osteoarthritis of the acromioclavicular joint)

Clinical features

The cardinal symptom of GCA is headache, which is often localised to the temporal or occipital region and may be accompanied by scalp tenderness. Jaw pain develops in some patients, brought on by chewing or talking. Visual disturbance can occur (most specifically amaurosis) and a catastrophic presentation is with blindness in one eye due to occlusion of the posterior ciliary artery. On fundoscopy, the optic disc may appear pale and swollen with haemorrhages, but these changes may take 24–36 hours to develop and the fundi may initially appear normal. Rarely, neurological involvement may occur, with transient ischaemic attacks, brainstem infarcts and hemiparesis.

In GCA, constitutional symptoms, such as weight loss, fatigue, malaise and night sweats, are common. With PMR, there may be stiffness and painful restriction of active shoulder movements on waking. Muscles are not otherwise tender, and weakness and muscle-wasting are absent. Other conditions that cause PMR-like symptoms are shown in Box 24.66.

Investigations

The typical laboratory abnormality is an elevated ESR, often with a normochromic, normocytic anaemia. CRP may also be elevated and abnormal liver function can occur. Rarely, PMR and GCA can present with a normal ESR. More objective evidence for GCA should be obtained whenever possible. There are three investigations to consider: temporal artery biopsy, ultrasound of the temporal arteries and ^{19}fluorodeoxyglucose positron emission tomography (^{19}FDG PET scan). Characteristic biopsy findings are fragmentation of the internal elastic lamina with necrosis of the media in combination with a mixed inflammatory cell infiltrate. Diagnostic yield is highest with multiple biopsies and multiple section analysis (to detect ‘skip’ lesions). A negative biopsy does not exclude the diagnosis. On ultrasound examination, affected temporal arteries show a ‘halo’ sign. A strongly positive ^{19}FDG PET scan is highly specific but sensitivity is low. Caution is needed in interpreting weakly positive images. Low-grade vascular uptake may occur in atheromatous arterial disease.

Management

Prednisolone should be commenced urgently in suspected GCA because of the risk of visual loss (Box 24.67). Response

24.67 Emergency management of giant cell arteritis

- Take blood for CRP, ESR, FBC, bone/liver/renal function, serum protein electrophoresis, CPK, RF, ACPA, ANA, ANCA, complement C3 and C4, immunoglobulins, PTH, TSH, vitamin D and urine electrophoresis
- Commence prednisolone (40–60 mg daily), and simultaneously, a weekly oral bisphosphonate and calcium with vitamin D supplements
- Consider urgent ophthalmology examination and temporal artery biopsy in patients with visual symptoms
- Consider obtaining temporal artery ultrasound or ^{19}FDG-PET scan
- Review within 1 week and adjust glucocorticoid doses according to clinical response and results of investigations

(ACPA = anti-citrullinated peptide antibody; ANA = antinuclear antibody; ANCA = antineutrophil cytoplasmic antibody; CPK = creatine phosphokinase; CRP = C-reactive protein; ESR = erythrocyte sedimentation rate; FBC = full blood count; ^{19}FDG-PET = ^{19}fluorodeoxyglucose positron emission tomography; PTH = parathyroid hormone; RF = rheumatoid factor; TSH = thyroid-stimulating hormone)

is dramatic, such that symptoms will completely resolve within 48–72 hours of starting therapy in virtually all patients. It is customary to use higher doses in GCA (60–80 mg prednisolone) than in PMR (15–20 mg), although the evidence base for this is weak. In both conditions, the glucocorticoid dose should be progressively reduced, guided by symptoms and ESR, with the aim of reaching a dose of 10–15 mg by about 8 weeks. The rate of reduction should then be slowed by 1 mg per month. If symptoms recur, the dose should be increased to that which previously controlled the symptoms, and reduction attempted again in another few weeks. Most patients need glucocorticoids for an average of 12–24 months. For advice on prophylaxis against giant cell-induced osteoporosis, see page 1047.

Eosinophilic granulomatosis with polyangiitis (Churg–Strauss syndrome)

Eosinophilic granulomatosis with polyangiitis (formerly known as Churg–Strauss syndrome) is a small-vessel vasculitis with an incidence of about 1–3 per 1 000 000. It is associated with eosinophilia. Some patients have a prodromal period for many years, characterised by allergic rhinitis, nasal polyposis and late-onset asthma that is often difficult to control. The typical acute presentation is with a triad of skin lesions (purpura or nodules), asymmetric mononeuritis multiplex and eosinophilia. Pulmonary infiltrates and pleural or pericardial effusions due to serositis may be present. Up to 50% of patients have abdominal symptoms provoked by mesenteric vasculitis. Patients with active disease have raised levels of ESR and CRP and an eosinophilia. Although antibodies to MPO or PR3 can be detected in up to 60% of cases, eosinophilic granulomatosis with polyangiitis is considered to be a distinct disorder from the other ANCA-associated vasculitides. Biopsy of an affected site reveals a small-vessel vasculitis with eosinophilic infiltration of the vessel wall. Management is with high-dose glucocorticoids and cyclophosphamide, followed by maintenance therapy with low-dose glucocorticoids and azathioprine, methotrexate or MMF.

Henoch–Schönlein purpura

Henoch–Schönlein purpura is a small-vessel vasculitis caused by immune complex deposition following an infectious trigger. It is predominantly a disease of children and young adults. The usual presentation is with purpura over the buttocks and lower legs, accompanied by abdominal pain, gastrointestinal bleeding and arthralgia. Nephritis can also occur and may present up to 4 weeks after the onset of other symptoms. Biopsy of affected tissue shows a vasculitis with IgA deposits in the vessel wall. Henoch–Schönlein purpura is usually a self-limiting disorder that settles spontaneously without specific treatment. Glucocorticoids and immunosuppressive therapy may be required in patients with more severe disease, particularly in the presence of nephritis.

Cryoglobulinaemic vasculitis

This is a small-vessel vasculitis that occurs when immunoglobulins precipitate out in the cold. Cryoglobulins are classified into three types (see Box 4.21, p. 84). Types II and III are associated with vasculitis. The typical presentation is with a vasculitic rash over the lower limbs, arthralgia, Raynaud's phenomenon and neuropathy. Some cases are secondary to hepatitis C infection and others are associated with other autoimmune diseases. Affected patients should be screened for evidence of hepatitis B and C infection, and if the results are positive, these should be treated appropriately (pp. 875 and 878). There is no consensus as to how best to treat cryoglobulinaemic vasculitis in the absence of an obvious trigger. Glucocorticoids and immunosuppressive therapy are often used empirically but their efficacy is uncertain. In severe cases, plasmapheresis can be considered.

Behçet's disease

This is a vasculitis of unknown aetiology that characteristically targets small arteries and venules. It is rare in Western Europe but more common in 'Silk Route' countries, around the Mediterranean and in Japan, where there is a strong association with HLA-B51.

Oral ulcers are universal (Fig. 24.54). Unlike aphthous ulcers, they are usually deep and multiple, and last for 10–30 days. Genital ulcers are also a common problem, occurring in 60–80% of cases. The usual skin lesions are erythema nodosum or acneiform lesions but migratory thrombophlebitis and vasculitis also occur. Ocular involvement is common and may include anterior or posterior uveitis or retinal vasculitis. Neurological involvement occurs in 5% and mainly involves the brainstem,

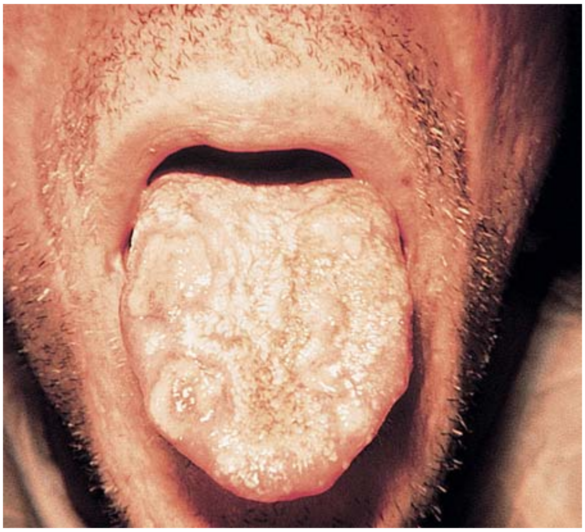

Fig. 24.54 Oral ulceration in Behçet's disease.

24

i 24.68 Criteria for the diagnosis of Behçet's disease

Recurrent oral ulceration: minor aphthous, major aphthous or herpetiform ulceration at least three times in 12 months *plus* two of the following:

- Recurrent genital ulceration
- Eye lesions: anterior uveitis, posterior uveitis, cells in vitreous on slit-lamp examination, retinal vasculitis
- Skin lesions: erythema nodosum, pseudofolliculitis, papulopustular lesions, acneiform nodules
- Positive pathergy test

although the meninges, hemispheres and cord can also be affected, causing pyramidal signs, cranial nerve lesions, brainstem symptoms or hemiparesis. Recurrent thromboses also occur. Renal involvement is extremely rare.

The diagnosis is primarily made on clinical grounds (Box 24.68) but one characteristic feature that can be of diagnostic value is the pathergy test, which involves pricking the skin with a needle and looking for evidence of pustule development within 48 hours.

Oral ulceration can be managed with topical glucocorticoid preparations (soluble prednisolone mouthwashes, glucocorticoid pastes). Colchicine can be effective for erythema nodosum and arthralgia. Thalidomide (100–300 mg per day for 28 days initially) is very effective for resistant oral and genital ulceration but is teratogenic and neurotoxic. Glucocorticoids and immunosuppressants are indicated for uveitis and neurological disease.

Relapsing polychondritis

Relapsing polychondritis is a rare inflammatory disease of cartilage that classically presents with acute pain and swelling of one or both ear pinnae, sparing the lower non-cartilaginous portion. Around 30% of patients have coexisting autoimmune or connective tissue disease. Involvement of tracheobronchial cartilage leads to a hoarse voice, cough, stridor or expiratory wheeze. Other manifestations include collapse of the bridge of the nose, scleritis, hearing loss and cardiac valve dysfunction. Cartilage biopsy shows an inflammatory infiltrate in the perichondrium. Both ESR and CRP are raised in active disease. Pulmonary function tests, including flow–volume loops, should be performed to assess the degree of laryngotracheal disease, since this is an important cause of mortality. Mild disease usually responds to low-dose glucocorticoids or NSAIDs, whereas major tracheobronchial involvement requires high-dose glucocorticoids and immunosuppressants, as described for SLE.

Diseases of bone

Osteoporosis

Osteoporosis is the most common bone disease. It has been estimated that more than 8.9 million fractures occur annually worldwide and most of these occur in patients with osteopenia or osteoporosis. About one-third of all women and one-fifth of men aged 50 and above suffer fractures at some point in life. The burden of osteoporosis-related fractures is predicted to increase by two- to threefold by 2050 on a worldwide basis, due to ageing of the population. Osteoporosis is under-diagnosed and under-treated in Asia and the Indian subcontinent, particularly in rural areas, due to low provision of technologies like DXA, which are required to make the diagnosis. Fractures in patients with osteoporosis can affect any bone but common sites are the forearm (Colles' fracture), spine (vertebral fractures), humerus and hip. All of these fractures become more common with increasing age (Fig. 24.55). Since only about one-third of vertebral fractures come to medical attention (clinical vertebral fractures), the true number of patients with vertebral fracture is much greater than that shown in Figure 24.55. Of these, hip fractures are the most serious and have an immediate mortality of about 12% and a continued increase in mortality of about 20% when compared with age-matched controls. Treatment of hip fracture accounts for the majority of the health-care costs associated with osteoporosis.

Pathophysiology

The defining feature of osteoporosis is reduced bone density, which causes micro-architectural deterioration of bone tissue and leads to an increased risk of fracture, in response to minor trauma. The risk of fracture increases markedly with age in both genders (Fig. 24.55). This is mostly attributable to an increased risk of falling with age (p. 1308) but is also due in part to an age-related decline in bone mass, especially in women (Fig. 24.56). Bone mass increases during growth to reach a peak between the ages of 20 and about 45 years, but falls thereafter in both genders with an accelerated phase of bone loss after the menopause in women due to oestrogen deficiency. The loss of bone with ageing is caused by an imbalance in the bone remodelling cycle, whereby the amount of new bone formed by osteoblasts cannot keep pace with the amount that is removed by osteoclasts (see Fig. 24.2, p. 985). The reduction in bone formation is thought to be partly due to differentiation of bone marrow stem cells to adipocytes, as opposed to osteoblasts. Osteoporosis sometimes occurs because of failure to attain adequate levels of peak bone mass but is more commonly due to age-related bone loss.

Osteoporosis is a complex disease that can occur in association with a wide variety of risk factors, as summarised in Box 24.69. Genetic factors account for up to 80% of variation in bone density, and genome-wide association studies have shown that susceptibility is determined in part by a large number of common variants, some of which are involved in the RANK and Wnt signalling pathways (see Fig. 24.3, p. 986). Rarely, osteoporosis may be caused by mutations in single genes. Environmental factors, such as exercise and calcium intake during growth and adolescence, are important in maximising peak bone mass and in regulating rates of post-menopausal bone loss. Smoking has a detrimental effect on BMD and is associated with an increased fracture risk, partly because female smokers have an earlier menopause than non-smokers. Heavy alcohol intake is a recognised cause of osteoporosis and fractures but moderate intake does not substantially alter risk.

Idiopathic osteoporosis

The term idiopathic osteoporosis is frequently used to describe the occurrence of osteoporosis in patients with no specific underlying cause. It is slightly misleading, since most, if not all, patients in this category have age-related osteoporosis or osteoporosis associated with inheritance of genetic variants that regulate bone density.

Secondary osteoporosis

Osteoporosis can occur in association with a variety of diseases and drug treatments, and in many cases more than one disease

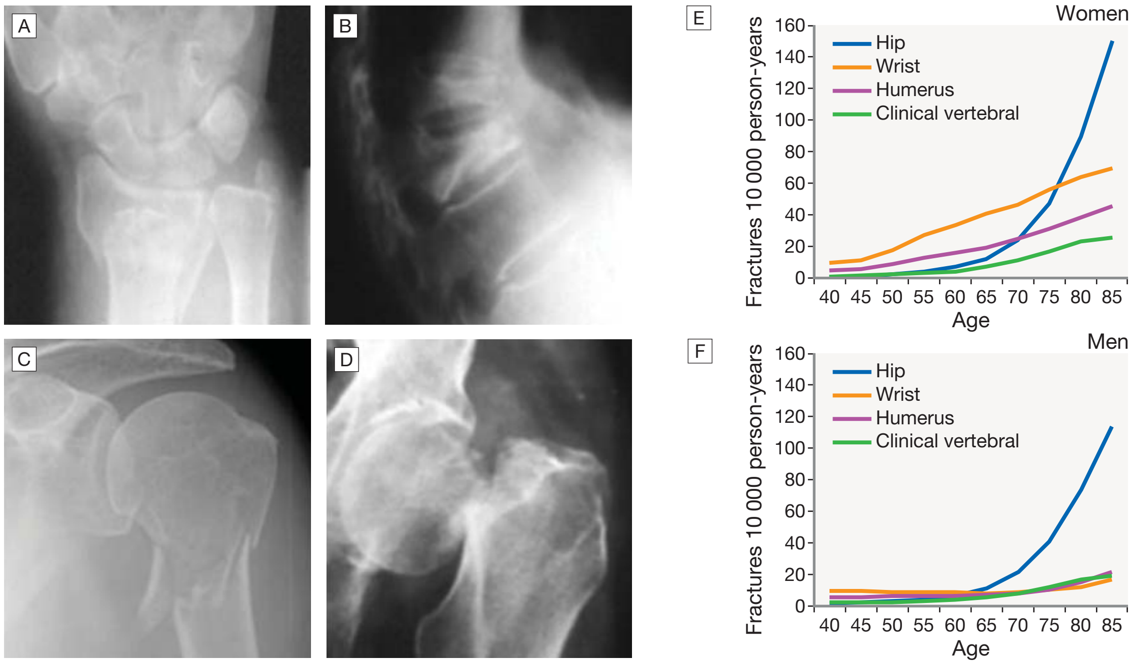

Fig. 24.55 Fractures associated with osteoporosis. A X-ray of wrist. B Vertebrae. C Humerus. D Hip. E and F The changing incidence of each of these fractures with age in women and men, respectively. *From Curtis EM, van der Velde R, Moon RJ, et al. Epidemiology of fractures in the United Kingdom 1988–2012: variation with age, sex, geography, ethnicity and socioeconomic status. Bone 2016; 87:19–26.*

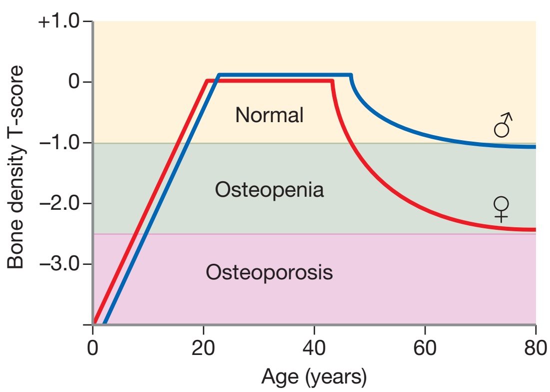

Fig. 24.56 Changes in bone mass and microstructure with age. Changes in men (blue line) and women (red line).

or risk factor is operative. The most important causes are summarised in Box 24.69. Secondary causes of osteoporosis are particularly common in men, occurring in up to 50% of patients. Hypogonadism, glucocorticoid use (see below) and alcohol excess are the most important predisposing factors.

Glucocorticoid-induced osteoporosis

Glucocorticoid-induced osteoporosis is a common problem in patients with systemic inflammatory and chronic pulmonary diseases. The risk of osteoporosis is related to dose and duration of glucocorticoid therapy and increases substantially in patients who have taken more than 7.5 mg of prednisolone daily for more than 3 months (or an equivalent dose of another glucocorticoid). Inhaled glucocorticoids can reduce bone density but the risk of osteoporosis is much lower than with systemic therapy. Glucocorticoids mainly cause osteoporosis by inhibiting bone formation and causing apoptosis of osteoblasts and osteocytes. Other contributory mechanisms include inhibition of intestinal calcium absorption, increased renal excretion of calcium and secondary hyperparathyroidism, which stimulates osteoclastic bone resorption.

Pregnancy-associated osteoporosis

This is a rare form of osteoporosis that typically presents with back pain and multiple vertebral fractures during the second or third trimester. The cause is unknown but may relate to an exaggeration of the bone loss that normally occurs during pregnancy in patients with pre-existing low bone mass.

Clinical features

Osteoporosis does not cause symptoms until a fracture occurs. Non-vertebral fractures are almost always caused by a traumatic event, most usually a simple fall. The term 'fragility fracture' is used to describe a fracture that occurs as the result of a fall from standing height or less. These are typical of osteoporosis. It is important to remember that the majority of people who suffer a fragility fracture do not have osteoporosis; some have normal bone density but most have osteopenia (Fig. 24.57 and p. 988). The clinical signs of fracture are pain, local tenderness and deformity. In hip fracture, the patient is (with rare exceptions) unable to weight-bear and has a shortened and externally rotated limb on the affected side. The presentation of vertebral fractures is variable. Some patients present with acute severe back pain. This may radiate to the anterior chest or abdominal wall and be mistaken for a myocardial infarction, aortic dissection or intra-abdominal pathology (p. 176). In others the presentation is with height loss and kyphosis in the absence of pain or with chronic back pain. Sometimes the presentation of osteoporosis is with radiological osteopenia or as a vertebral deformity on an X-ray that has been performed for other reasons.

24.69 Risk factors for osteoporosis

Genetics

- Single-gene disorders:
  - *LRP5* mutations
  - Oestrogen receptor mutations
- Polygenic inheritance:
  - Common variants in many pathways

Endocrine disease

- Hypogonadism
- Hyperthyroidism
- Hyperparathyroidism
- Cushing's syndrome

Inflammatory disease

- Inflammatory bowel disease
- Ankylosing spondylitis
- Rheumatoid arthritis

Drugs

- Glucocorticoids
- Gonadotrophin-releasing hormone (GnRH) agonists
- Levothyroxine over-replacement
- Aromatase inhibitors
- Thiazolidinediones
- Anticonvulsants
- Alcohol intake > 3 U/day
- Heparin

Gastrointestinal disease

- Malabsorption
- Chronic liver disease

Lung disease

- Chronic obstructive pulmonary disease
- Cystic fibrosis

Miscellaneous

- Myeloma
- Homocystinuria
- Anorexia nervosa*
- Highly trained athletes*
- HIV infection
- Gaucher's disease
- Systemic mastocytosis
- Immobilisation
- Body mass index < 18
- Heavy smoking
- Autoantibodies to osteoprotegerin (OPG)

*Hypogonadism also plays a role in osteoporosis associated with these conditions.

Investigations

The most important investigation is DXA at the lumbar spine and hip (see Fig. 24.9, p. 990). This should be considered in patients age over 50 who have already suffered a fragility fracture, and in those with clinical risk factors (Box 24.70) when a fracture risk assessment tool (p. 1060) has returned an elevated value. The risk at which DXA should be performed remains a subject of debate but a 10-year risk of over 10% has been suggested, since there is evidence of benefit from treatment at this level. Other indications for DXA are in patients under 50 years who have very strong risk factors, such as premature menopause or high-dose glucocorticoids. Figure 24.58 provides a suggested algorithm for the investigation of patients with suspected osteoporosis.

A history should be taken to identify any predisposing causes, such as early menopause, excessive alcohol intake, smoking and glucocorticoid therapy. Signs of endocrine disease, neoplasia and inflammatory disease should be sought on clinical examination. A falls history should be taken and a 'get up and go' test performed, especially in older patients (p. 1303). Screening for secondary causes of osteoporosis should be performed, as summarised in Box 24.71.

Management

The aim of treatment is to reduce the risk of fracture and this can be achieved by a combination of approaches.

24.70 Indications for dual X-ray absorptiometry (DXA)

- Low-trauma fracture, age > 50 years
- Clinical risk factors and 10-year fracture risk > 10%
- Glucocorticoid therapy (> 7.5 mg prednisolone daily for > 3 months)
- Assessment of response of osteoporosis to treatment
- Assessment of progression of osteopenia to osteoporosis
- Age < 50 years and very strong risk factors for osteoporosis

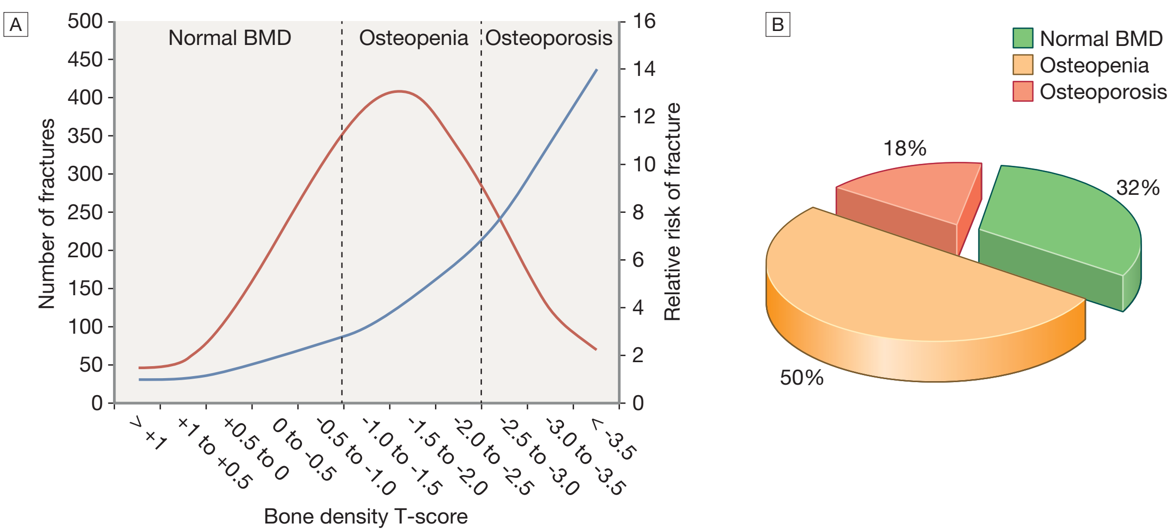

Fig. 24.57 Relation between bone mineral density (BMD) and fractures. A The relative risk of fracture increases exponentially as BMD falls (blue line), and is 14-fold higher in people with a T-score of <–3.5 compared with those with normal BMD. In absolute terms, however, more fractures occur in people with normal BMD or osteopenia (red line). B The proportions of fractures that occur in people with normal BMD, osteopenia and osteoporosis.

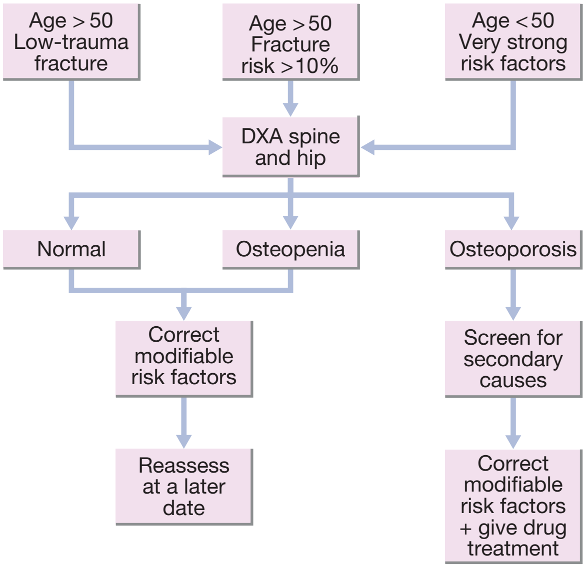

Fig. 24.58 Algorithm for the investigation of patients with suspected osteoporosis. Fracture risk is assessed using FRAX or QFracture (see 'Further information', p. 1060).

i 24.71 Investigations in osteoporosis

Investigation	Secondary cause of osteoporosis
Urea, creatinine and electrolytes	Chronic kidney disease
Liver function tests and albumin	Chronic liver disease
Full blood count, erythrocyte sedimentation rate	Inflammatory disease Myeloma
Tissue transglutaminase antibodies	Coeliac disease
Serum calcium and phosphate	Primary hyperparathyroidism
Serum 25(OH)D and alkaline phosphatase	Vitamin D deficiency Osteomalacia
Serum parathyroid hormone	Primary hyperparathyroidism
Thyroid function tests	Hyperthyroidism
Serum protein electrophoresis	Myeloma Monoclonal gammopathy of uncertain significance
Urinary Bence Jones protein	Myeloma
Testosterone and gonadotrophins	Male hypogonadism
Oestrogen and gonadotrophins	Female hypogonadism[1]
Bone biopsy	Unexplained early-onset osteoporosis[2] Renal disease Multiple possible causes of low bone mass

[1]Only required for unexplained osteoporosis in young women who are amenorrhoeic. [2]Seldom required.

Non-pharmacological interventions

Advice on smoking cessation, moderation of alcohol intake, adequate dietary calcium intake and exercise should be given. Those with recurrent falls or unsteadiness on a 'get up and go' test should be referred to a multidisciplinary falls prevention team

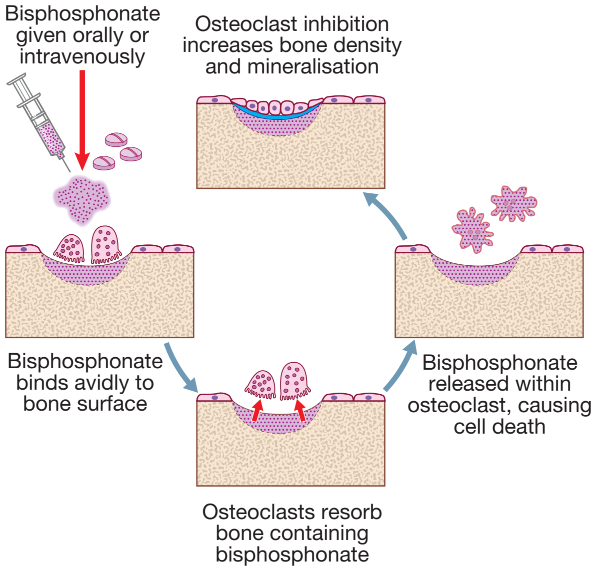

Fig. 24.59 Mechanism of action of bisphosphonates.

(p. 1308). Hip protectors can reduce the risk of hip fracture in selected patients but adherence is often poor.

Pharmacological interventions

Several drug treatments are now available to reduce the risk of fracture in osteoporosis. The dosages, mode of administration and indications are summarised in Box 24.72. More detail on the individual drugs is provided below.

Bisphosphonates Bisphosphonates are the first-line treatment for osteoporosis. These are a class of drugs with a central core of P-C-P atoms, to which various side-chains are attached. Following administration, they target bone surfaces and are ingested by osteoclasts during the process of bone resorption. The bisphosphonate is released within the osteoclasts and impairs bone resorption. This in turn causes an increase in bone density but this is principally due to increased mineralisation of bone, rather than an increase in bone mass (Fig. 24.59). Bisphosphonates reduce the risk of fracture in patients with osteoporosis but do not completely prevent fractures occurring.

Oral bisphosphonates are typically given for a period of 5 years, at which point the need for continued therapy should be evaluated, with a repeat DXA if possible. If patients have remained free of fractures after 5 years and if BMD levels have increased and no longer remain in the osteoporotic range, it is usual to instigate a 5-year spell off therapy. Treatment may be continued for up to 10 years in patients whose BMD levels remain in the osteoporotic range after 5 years. A change in treatment should be considered in patients who have lost BMD despite oral bisphosphonates (more than 4%). Most commonly, this will be a switch to parenteral zoledronic acid but teriparatide (TPTD) can also be considered in those with severe spinal osteoporosis. With intravenous zoledronic acid, 3 years of therapy is equivalent to 6 years in terms of fracture risk reduction and many experts recommend periods of 3 years on and 3 years off treatment to reduce the risk of over-suppression of bone turnover.

Oral bisphosphonates are poorly absorbed from the gastrointestinal tract and should be taken on an empty stomach

24.72 Drug treatments for osteoporosis

Drug	Regimen	Postmenopausal osteoporosis	Glucocorticoid osteoporosis	Male osteoporosis
Alendronic acid	70 mg/week orally	✓	✓	✓
Risedronate	35 mg/week orally	✓	✓	✓
Ibandronate	150 mg/monthly orally 3 mg/3-monthly IV	✓	✓	✓
Zoledronic acid	5 mg annually IV	✓	✓	✓
Denosumab	60 mg 6-monthly SC	✓	–	✓
Calcium/vitamin D	Calcium 500–1000 mg daily Vitamin D 400–800 IU orally	✓	✓	✓
Teriparatide	20 μg/day SC	✓	✓	✓
Abaloparatide	80 μg/day SC	✓	–	–
Hormone replacement therapy	Various preparations	✓	–	–
Raloxifene	60 mg/day orally	✓	–	–
Tibolone	1.25 mg/day orally	✓	–	–

(IV = intravenous; SC = subcutaneous)

24.73 Adverse effects of bisphosphonates

Common

- Upper gastrointestinal intolerance (oral)
- Acute phase response (intravenous)

Less common

- Atrial fibrillation (intravenous zoledronic acid)
- Hypocalcaemia (intravenous bisphosphonates)
- Atypical subtrochanteric fractures

Rare

- Uveitis
- Osteonecrosis of the jaw
- Oesophageal ulceration

with plain water; no food should be eaten for 30–45 minutes after administration. They are contraindicated in patients with oesophageal stricture or achalasia, since tablets may stick in the oesophagus, causing ulceration and perforation. Upper gastrointestinal upset occurs in about 5% of cases. Oral bisphosphonates can be used in patients with gastro-oesophageal reflux disease but may cause worsening of symptoms. The most common adverse effect with intravenous bisphosphonates is a transient influenza-like illness typified by fever, malaise, anorexia and generalised aches, which occurs 24–48 hours after administration. This is self-limiting but can be treated with paracetamol or NSAIDs if necessary. It predominantly occurs after the first exposure and tolerance develops thereafter. Other adverse effects are shown in Box 24.73. Osteonecrosis of the jaw is characterised by the presence of necrotic bone in the mandible or maxilla, typically occurring after tooth extraction when the socket fails to heal. This complication is very rare in osteoporosis but patients receiving bisphosphonates should be advised to pay attention to good oral hygiene. There is no evidence that temporarily stopping bisphosphonates for tooth extraction alters the risk of osteonecrosis of the jaw. Atypical subtrochanteric fractures have been described in patients who have received long-term bisphosphonates and appear to be the result of over-suppression of normal bone remodelling. In the vast majority, the benefits of bisphosphonate therapy far outweigh the risks but it is important for treatment to be targeted to patients with low BMD who are most likely to benefit.

Denosumab Denosumab is a monoclonal antibody that inhibits bone resorption by neutralising the effects of RANKL (see Fig. 24.2, p. 985). It is administered by subcutaneous injection of 60 mg every 6 months in the treatment of osteoporosis and has similar efficacy to zoledronic acid. One potential adverse effect is hypocalcaemia but this can be mitigated by calcium and vitamin D supplements. Denosumab may rarely cause osteonecrosis of the jaw and atypical subtrochanteric fractures. If it is stopped, there is a rebound increase in bone turnover that can be associated with a greater risk of fracture and even hypercalcaemia. Because of this, many experts advise giving a bisphosphonate following cessation of denosumab.

Calcium and vitamin D Combined calcium and vitamin D supplements have limited efficacy in the prevention of osteoporotic fractures when given alone but are widely used as an adjunct to other treatments. A typical daily dosage is 1000 mg calcium and 800 IU vitamin D. Calcium and vitamin D supplements have efficacy in preventing fragility fractures in elderly or institutionalised patients who are at high risk of deficiency (Box 24.74). Vitamin D supplements alone do not prevent fractures in osteoporosis but there is evidence that the response to bisphosphonates is blunted in patients with vitamin D deficiency. If the patient's dietary calcium is sufficient, stand-alone vitamin D supplements (800 IU daily) can be prescribed as an adjunct to anti-osteoporosis therapies.

Teriparatide Teriparatide (TPTD) is the 1-34 fragment of human PTH. It is an effective treatment for osteoporosis, which works by stimulating new bone formation. Although TPTD also stimulates bone resorption, the increase in bone formation is greater, resulting in increased bone density, particularly at sites rich in trabecular bone such as the spine. It is given by a self-administered subcutaneous injection in a dose of 20 μg daily for 2 years. At the end of this period, bisphosphonate therapy or another

24.74 Osteoporosis in old age

- **Bone loss**: due to increased bone turnover, with an age-related defect switch in differentiation of bone marrow stromal cells to form adipocytes as opposed to osteoblasts.
- **Fractures due to osteoporosis**: common cause of morbidity and mortality, although fracture healing is not delayed by age.
- **Recurrent fractures**: those who suffer a fragility fracture are at increased risk of further fracture, so should be investigated for osteoporosis and treated if this is confirmed.
- **Falls**: risk factors for falls (such as visual and neuromuscular impairments) are independent risk factors for hip fracture in elderly individuals, so intervention to prevent falls is as important as treatment of osteoporosis (p. 1308).
- **Intravenous zoledronic acid**: reduces mortality and subsequent fracture in selected elderly patients with hip fractures.
- **Calcium and vitamin D**: reduce the risk of fractures in those who are housebound or living in care homes.

inhibitor of bone resorption should be administered to maintain the increase in BMD. TPTD and oral bisphosphonates should not be given in combination, however, since the bisphosphonate blunts the anabolic effect. The efficacy of TPTD for prevention of non-vertebral fractures is similar to that of bisphosphonates but it is superior to oral bisphosphonates in preventing vertebral fractures. The most common adverse effects are headache, muscle cramps and dizziness. Mild hypercalcaemia may occur but it is usually asymptomatic and does not require discontinuation of treatment. Monitoring of serum calcium is not required during TPTD treatment.

Abaloparatide Abaloparatide is the 1-34 fragment of PTH-related protein. It works in a similar way to TPTD to stimulate bone formation. It is given as a self-administered injection of 80 μg daily for 18 months. At the end of this period an inhibitor of bone resorption should be given to maintain the increase in bone mass. Efficacy has been demonstrated for the prevention of vertebral fractures with effects similar to those of TPTD. Adverse effects are similar to those of TPTD.

Hormone replacement therapy Cyclical HRT with oestrogen and progestogen prevents post-menopausal bone loss and reduces the risk of vertebral and non-vertebral fractures in post-menopausal women. It is primarily indicated for the prevention of osteoporosis in women with an early menopause (p. 655) and for treatment of women with osteoporosis in their early fifties who have troublesome menopausal symptoms. It is not recommended above the age of 60 because the risk of an increased risk of breast cancer, cardiovascular disease and venous thromboembolic disease.

Raloxifene Raloxifene is a selective oestrogen receptor modulator (SERM) that acts as a partial agonist at oestrogen receptors in bone and liver, but as an antagonist in breast and endometrium. It is effective in reducing the risk of vertebral fractures but does not influence the risk of non-vertebral fracture and is seldom used. Adverse effects include muscle cramps, worsening of hot flushes and an increased risk of venous thromboembolic disease. Bazedoxifene is a related SERM that has similar effects to raloxifene.

Tibolone Tibolone has partial agonist activity at oestrogen, progestogen and androgen receptors. It has been shown to prevent vertebral and non-vertebral fractures in post-menopausal osteoporosis. Treatment is associated with a slightly increased risk of stroke but a reduced risk of breast cancer.

Other drugs Romosozumab is antibody directed against sclerostin, which is under development for the treatment of osteoporosis. It increases bone formation, inhibits bone resorption and increases BMD. When given subcutaneously in a dose of 210 mg monthly, it reduces the risk of vertebral fractures in patients with postmenopausal osteoporosis. Calcitriol (1,25$(OH)_2D_3$), the active metabolite of vitamin D, is licensed for treatment of osteoporosis but it is seldom used because the data on fracture prevention are less robust than for other agents.

Surgery

Orthopaedic surgery with internal fixation is frequently required to reduce and stabilise osteoporotic fractures. Patients with intracapsular fracture of the femoral neck generally need hemi-arthroplasty or total hip replacement in view of the high risk of avascular necrosis.

Vertebroplasty is sometimes used in the treatment of painful vertebral compression fractures. It involves injecting methyl methacrylate (MMA) into the affected vertebral body under sedation and local anaesthesia. While randomised trials have shown that vertebroplasty provides no better pain relief than a sham procedure, it is still widely used, particularly in North America. Kyphoplasty is used under similar circumstances, but in this case a needle is introduced into the affected vertebral body and a balloon is inflated, which is then filled with MMA. It has similar efficacy to vertebroplasty but adverse effects are more common. Adverse effects with both procedures include spinal cord compression due to leakage of MMA and fat embolism.

Osteomalacia, rickets and vitamin D deficiency

Osteomalacia and rickets are characterised by defective mineralisation of bone. The most common cause is vitamin D deficiency, but both conditions can also occur as the result of inherited defects in renal phosphate excretion, and inherited defects in the vitamin D receptor and in the pathways responsible for vitamin D activation. Other causes are summarised in Box 24.75 and are discussed in more detail below. The term osteomalacia refers to the syndrome when it occurs in adults and rickets is the equivalent syndrome in children. The disease remains prevalent in frail older people who have a poor diet and limited sunlight exposure, and in some Muslim women.

Vitamin D deficiency

Vitamin D deficiency is defined to exist when serum 25(OH)D concentrations are below 25 nmol/L (10 ng/mL). People with vitamin D levels in the range 25–50 nmol/L (10–20 ng/mL) are classified as having vitamin D insufficiency, whereas those with 25(OH)D levels above 50 nmol/L (20 ng/mL) are classified as having normal vitamin D status. In the elderly, a more appropriate normal threshold may be 75 nmol/L (30 ng/mL) or more, though there is some debate on the issue and evidence is not conclusive. The likelihood of developing vitamin D deficiency is strongly related to sunlight exposure. It is common in northern latitudes (or southern latitudes in the southern hemisphere) and shows seasonal variation. Vitamin D deficiency is also common in women who, for cultural reasons, cover their skin and face. Vitamin D

i 24.75 Causes of osteomalacia and rickets

Cause	Predisposing factor	Mechanism
Vitamin D deficiency		
Classical	Lack of sunlight exposure and poor diet	Reduced cholecalciferol synthesis in the skin/low levels of vitamin D in the diet
Gastrointestinal disease	Malabsorption	Malabsorption of dietary vitamin D and calcium
Failure of 1,25 vitamin D synthesis		
Chronic renal failure	Hyperphosphataemia and kidney damage	Impaired conversion of $25(OH)D_3$ to $1,25(OH)_2D_3$
Vitamin D-resistant rickets type I (autosomal recessive)	Loss-of-function mutations in renal 25(OH)D 1α-hydroxylase enzyme	Impaired conversion of $25(OH)D_3$ to $1,25(OH)_2D_3$
Vitamin D receptor defects		
Vitamin D-resistant rickets type II (autosomal recessive)	Loss-of-function mutations in vitamin D receptor	Impaired response to $1,25(OH)_2D_3$
Defects in phosphate and pyrophosphate metabolism		
Hypophosphataemic rickets (X-linked dominant)	Mutations in *PHEX*	Increased FGF23 production (mechanism unclear)
Autosomal dominant hypophosphataemic rickets	Mutation in *FGF23*	Mutant FGF23 is resistant to degradation
Autosomal recessive hypophosphataemic rickets	Mutations in *DMP1*	Increased production of FGF23 Local deficiency of DMP1 inhibits mineralisation
Tumour-induced hypophosphataemic osteomalacia	Ectopic production of FGF23 by tumour	Over-production of FGF23
Hypophosphatasia	Mutations in *ALPL*, which encodes alkaline phosphatase	Inhibition of bone mineralisation due to accumulation of pyrophosphate in bone
Iatrogenic and other causes		
Bisphosphonate therapy	High-dose etidronate/pamidronate	Drug-induced impairment of mineralisation
Aluminium	Use of aluminium-containing phosphate binders or aluminium in dialysis fluid	Aluminium-induced impairment of mineralisation
Fluoride	High fluoride in water	Inhibition of mineralisation by fluoride

(FGF23 = fibroblast growth factor 23)

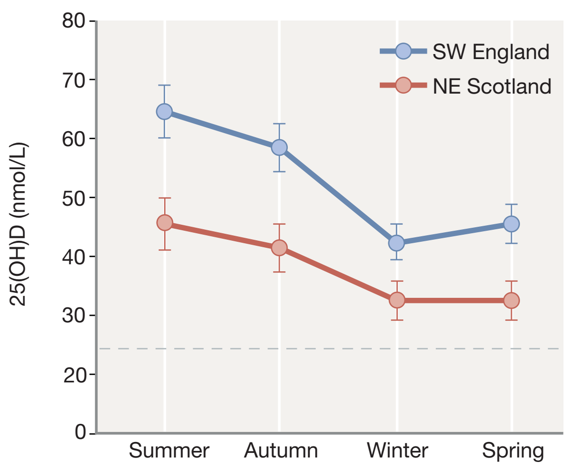

Fig. 24.60 Seasonal changes in vitamin D concentrations. To convert nmol/L to ng/mL, multiply by 2.5. *Adapted from McDonald HM, Mavroeidi A, Fraser WD, et al. Sunlight and dietary contributions to the seasonal vitamin D status of cohorts of healthy postmenopausal women living at northerly latitudes: a major cause for concern? Osteoporosis Int 2011; 22:2461–2472.*

deficiency is more common in the winter and spring, and less common in summer and autumn (Fig. 24.60).

Pathogenesis

The source of vitamin D and pathways involved in regulating its metabolism are shown in Figure 24.61. In normal individuals, vitamin D (also known as cholecalciferol) comes from two sources: about 70% is made in the skin, where 7-dehydrocholesterol is converted to cholecalciferol under the influence of ultraviolet light, whereas the remaining 30% is derived from the diet. The main dietary sources are oily fish and meat, although bread and dairy products are fortified with vitamin D in some countries. On entering the circulation, vitamin D is hydroxylated in the liver to form 25(OH) vitamin D and this is further hydroxylated in the kidney to form $1,25(OH)_2D$, the biologically active metabolite. The $1,25(OH)_2D$ primarily acts on the gut to increase intestinal calcium absorption but also acts on the skeleton to stimulate bone remodelling. Synthesis of $1,25(OH)_2D$ is regulated by a negative feedback loop orchestrated by the parathyroid glands. When vitamin D levels fall – as the result of lower sunlight exposure or dietary lack – production of $1,25(OH)_2D$ is reduced, causing a reduction in calcium absorption from the gut. This causes a transient fall in serum calcium, which is detected by calcium-sensing receptors on the parathyroid chief cells; this increases PTH secretion, which restores calcium levels to normal. Vitamin D deficiency is, therefore, usually characterised by a low level of 25(OH)D and a raised level of PTH. Sometimes, low 25(OH)D levels may be observed in the presence of a normal PTH concentration. This is of uncertain clinical significance but might be due to variations in levels of vitamin D-binding protein. Serum concentrations of vitamin D are under genetic control and are associated with variants close to the *GC* gene, which encodes vitamin D-binding protein; the *DHCR7* gene, which encodes 7-dehydrocholesterol reductase, responsible for catalysing conversion of 7-DHC to 25(OH)D; the *CYP2R1* gene, which encodes vitamin D-25-hydroxylase, responsible for hydroxylation of vitamin D in the liver; and the *CYP24A1* gene, which encodes vitamin D-24-hydroxylase, responsible for converting 25(OH)D to the inactive metabolite $24,25(OH)_2D$.

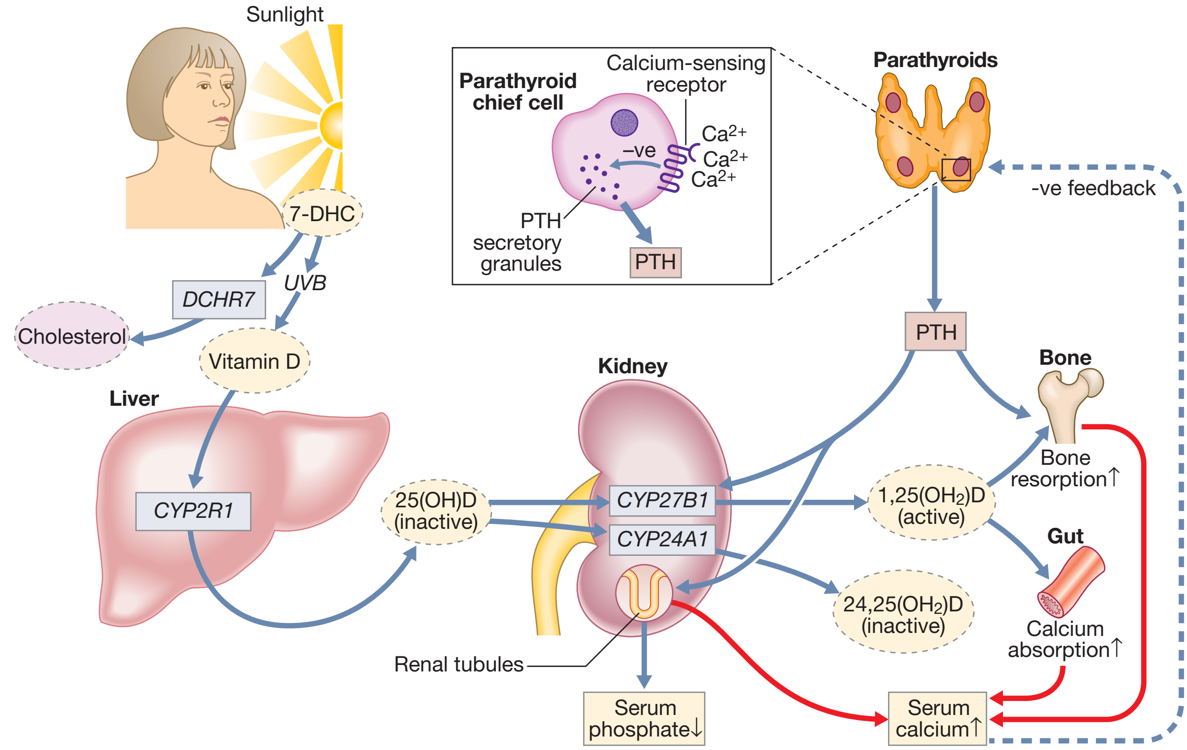

Fig. 24.61 Vitamin D metabolism. Vitamin D is produced in the skin from 7-dehydrocholesterol (7-DHC) by ultraviolet B (UVB) light. The 7-dehydrocholesterol reductase enzyme, which is encoded by the *DHCR7* gene, opposes the effect of UVB by converting 7-DHC to cholesterol. The vitamin D then undergoes hydroxylation steps in the liver and kidney to form the active metabolite 1,25$(OH)_2$D, which regulates calcium homeostasis by stimulating calcium absorption from the diet and bone resorption. See text for details.

Clinical features

Vitamin D deficiency does not cause symptoms and the diagnosis is made as the result of biochemical testing. Low circulating concentrations of vitamin D have been associated with a wide range of diseases, including most types of cancer, diabetes, multiple sclerosis and chronic inflammatory diseases. These associations are unlikely to be causal but most probably arise as the result of reduced sunlight exposure and poor diet in people who are ill. If vitamin D deficiency is prolonged and severe, then osteomalacia and rickets may occur, as discussed below. The consequences of biochemical vitamin D deficiency and insufficiency on bone health and general health are unclear.

Investigations

The diagnosis can be made by measurement of serum 25(OH)D. In patients with low 25(OH)D, measurements of PTH, serum calcium, phosphate and ALP should also be considered. Low levels of 25(OH)D in the absence of other abnormalities is unlikely to be of any clinical significance and may be due to low levels of vitamin D-binding protein. If low 25(OH)D levels are combined with raised levels of PTH, this is of more significance since it indicates secondary hyperparathyroidism. Serum ALP, calcium and phosphate levels are normal in uncomplicated vitamin D deficiency.

Management

The clinical benefit of treating biochemical vitamin D deficiency is uncertain. Vitamin D supplements should be considered in patients who have low 25(OH)D levels and raised levels of PTH. In most patients, cholecalciferol in a dose of 800 IU daily should be sufficient to correct the deficiency. The benefit of treating seasonal vitamin D deficiency or vitamin D insufficiency is uncertain. There is some evidence that response to bisphosphonate treatment of osteoporosis is impaired in patients with vitamin D deficiency and this is another indication for supplements. In patients who are receiving intravenous bisphosphonates and denosumab for osteoporosis, vitamin D deficiency should be corrected by supplementation to reduce the risk of hypocalcaemia. In this case, it is customary to give higher doses of vitamin D, such as 20 000–25 000 IU once a week for 4 weeks or to give lower doses over a more prolonged period.

Osteomalacia and rickets

Severe and prolonged vitamin D deficiency can result in the occurrence of osteomalacia in adults and rickets in children. Improvements in nutrition mean that these are now relatively uncommon conditions in developed countries but they remain prevalent in elderly housebound individuals, some Muslim women who wear a veil (hijab) that covers a large amount of exposed skin, and people with malabsorption.

Pathogenesis

Osteomalacia and rickets occur as the result of chronic secondary hyperparathyroidism, which invariably accompanies severe and long-standing vitamin D deficiency. The sustained elevation in PTH levels maintains normal levels of serum calcium by increasing bone resorption, which eventually causes progressive demineralisation of the skeleton. Phosphate that is released during the process of bone resorption is lost through increased renal excretion, resulting in hypophosphataemia. The raised levels of PTH stimulate osteoblast activity and cause new bone formation

but the matrix is not mineralised properly because of deficiency of calcium and phosphate. The under-mineralised bone is soft, mechanically weak and subject to fractures, particularly stress fractures. Normal levels of serum calcium tend to be maintained until a very advanced stage, when hypocalcaemia may occur.

Clinical features

Vitamin D deficiency in children causes delayed development, muscle hypotonia, craniotabes (small unossified areas in membranous bones of the skull that yield to finger pressure with a cracking feeling), bossing of the frontal and parietal bones and delayed anterior fontanelle closure, enlargement of epiphyses at the lower end of the radius, and swelling of the rib costochondral junctions ('rickety rosary'). Osteomalacia in adults can present with fractures and low BMD, mimicking osteoporosis. Other symptoms include bone pain and general malaise. Proximal muscle weakness is prominent and the patient may walk with a waddling gait and struggle to climb stairs or stand up from a chair. There may be bone and muscle tenderness on pressure, and focal bone pain can be due to fissure fractures of the ribs and pelvis.

Investigations

The diagnosis can usually be made by measurement of serum 25(OH)D, PTH, calcium, phosphate and ALP. Typically, serum ALP levels are raised, 25(OH)D levels are undetectable and PTH is markedly elevated. Serum phosphate levels tend to be low but serum calcium is usually normal, unless the disease is advanced. X-rays often show osteopenia or vertebral crush fractures and, with more advanced disease, focal radiolucent areas (pseudofractures or Looser's zones) may be seen in ribs, pelvis and long bones (Fig. 24.62A). In children, there is thickening and widening of the epiphyseal plate. A radionuclide bone scan may show multiple hot spots in the ribs and pelvis at the site of fractures and the appearance may be mistaken for metastases. Where there is doubt, the diagnosis can be confirmed by bone biopsy, which shows the pathognomonic features of increased thickness and extent of osteoid seams (Fig. 24.62B).

Healing pseudofractures with callus formation are also visible at the inferior and superior pubic rami on the right side (arrows). B Photomicrograph of bone biopsy from an osteomalacic patient showing thick osteoid seams (stained light blue, arrows) that cover almost all of the bone surface. Calcified bone is stained dark blue.

Management

Osteomalacia and rickets respond promptly to treatment with vitamin D. A wide variety of doses can be used. Treatment with between 10 000 and 25 000 IU daily for 2–4 weeks is associated with rapid clinical improvement, an elevation in serum 25(OH)D and a reduction in PTH. Serum ALP levels sometimes rise initially as mineralisation of bone increases but eventually fall to within the reference range as the bone disease heals. Subsequently, the dose of vitamin D can usually be reduced to a maintenance level of 800–1600 IU daily (10–20 μg), except in patients with malabsorption, who may require higher doses.

Vitamin D-resistant rickets

This is a genetically determined condition that presents in childhood with rickets that is resistant to therapy with vitamin D in standard dosages.

Pathogenesis

Type I vitamin D-resistant rickets (VDRR) is caused by inactivating mutations in the 25-hydroxyvitamin D 1α-hydroxylase (*CYP27B1*) enzyme, which converts 25(OH)D to the active metabolite $1,25(OH)_2D_3$. Type II VDRR is caused by inactivating mutations in the vitamin D receptor, which impair its ability to activate gene transcription. Both are recessive disorders and consanguinity is common.

Clinical features

These are as described above for infantile rickets. The diagnosis is usually first suspected when the patient fails to respond to vitamin D supplementation.

Investigations

The biochemical features of type I VDRR are similar to those of ordinary vitamin D deficiency, except that levels of 25(OH)D are normal but $1,25(OH)_2D$ is low. In type II VDRR, 25(OH)D is normal but PTH and $1,25(OH)_2D_3$ values are raised.

Management

Type I VDRR responds fully to treatment with the active vitamin D metabolites 1α-hydroxyvitamin D (1–2 μg daily, orally) or 1,25-dihydroxyvitamin D (0.25–1.5 μg daily, orally). Calcium supplements are not necessary unless there is dietary deficiency. Type II VDRR sometimes responds partially to very high doses of active vitamin D metabolites, which can activate the mutant receptor, although additional calcium and phosphate supplements are also necessary.

Hereditary hypophosphataemic rickets

This group of disorders are caused by inherited defects in renal tubular phosphate reabsorption. The most common is X-linked hypophosphataemic rickets (XLH), but autosomal dominant and autosomal recessive forms also occur (Box 24.75).

Pathophysiology

All forms of hereditary hypophosphataemic rickets are associated with raised circulating concentrations of the phosphate-regulating hormone fibroblast growth factor 23 (FGF23). This hormone is produced by osteocytes (see Fig 24.3, p. 986) and enters the circulation, where it is normally inactivated by proteolytic cleavage. Production of FGF23 by osteocytes is under tonic inhibition by DMP1 and PHEX. In XLH, the inhibitory effect on FGF23 production is lost due to mutations in *PHEX* and a similar situation occurs in autosomal recessive hypophosphataemic rickets (ARHR1) due to loss-of-function mutations in *DMP1*. Mutations in the *ENPP1* gene, which encodes a phosphatase responsible for degradation of pyrophosphate, can also cause a recessive form of hypophosphataemic rickets (ARHR2). In autosomal dominant hypophosphataemic rickets (ADHR), the FGF23 protein carries mutations that prevent FGF23 being degraded, thereby causing accumulation of intact FGF23 hormone in the circulation. In all three diseases, the elevation in FGF23 results in osteomalacia and rickets by causing phosphaturia by up-regulation of sodium-dependent phosphate transporters in the renal tubules, and also by inhibiting conversion of 25(OH)D to 1,25$(OH)_2$D by the kidney, which in turn causes reduced calcium and phosphate absorption from the gut.

Clinical features

The presentation is with symptoms and signs of rickets during childhood that do not respond to vitamin D supplementation. In adults, hypophosphataemic rickets may be accompanied by dental abscesses, and by bone and joint pain due to the development of an enthesopathy.

Investigations

The diagnosis can be confirmed by the finding of low serum phosphate levels and a reduction in tubular reabsorption of phosphate. Serum levels of vitamin D are normal and PTH is normal or slightly elevated. Serum concentrations of FGF23 are markedly elevated. The causal mutation can be defined by genetic testing.

Management

The aim of treatment is to ameliorate symptoms, restore normal growth and maintain serum phosphate levels within the reference range. Traditionally, treatment has been with phosphate supplements (1–4 g daily) and 1-α-hydroxyvitamin D (1–2 μg daily) or 1,25-dihydroxyvitamin D (0.5–1.5 μg daily) with the aim of promoting intestinal calcium and phosphate absorption. Levels of calcium and phosphate, as well as renal function, should be monitored regularly and the doses of phosphate and vitamin D metabolites carefully titrated to maintain serum phosphate within the normal range but avoid hypercalcaemia. Recently, a neutralising antibody to FGF23 has been developed that can reverse the biochemical abnormalities in hereditary hypophosphataemic rickets and it is likely that this will be a future treatment option.

Tumour-induced osteomalacia

This is a rare syndrome caused by over-production of FGF23 by mesenchymal tumours. The presentation is with severe osteomalacia and hypophosphataemia in an adult patient with no obvious predisposing risk factor for vitamin D deficiency. Biochemical findings are as described for hereditary hypophosphataemic rickets. The underlying tumour can sometimes be identified by whole-body MRI or CT. Medical management is with phosphate supplements and active vitamin D metabolites but the treatment of choice is surgical resection of the primary tumour, which is curative.

Hypophosphatasia

Hypophosphatasia is an autosomal recessive disorder caused by loss-of-function mutations in the *TNALP* gene, which result in accumulation of pyrophosphate and inhibition of bone mineralisation. Chondrocalcinosis may also occur. The typical presentation is with severe intractable rickets during infancy, sometimes in association with seizures. Investigations show low or undetectable levels of serum ALP but normal levels of calcium, phosphate, PTH and vitamin D metabolites. Urinary excretion of pyridoxal 5′ phosphate and phosphoethanolamine (substrates for ALP) is increased. Until recently, this condition was fatal during childhood but remarkable therapeutic responses have been obtained with recombinant ALP therapy (asfotase alfa), which is curative. Heterozygous carriers of mutation in *TNALP* may present in adulthood with osteoporosis, fractures and low ALP values. The best mode of treatment for these patients remains to be determined, except that bisphosphonates should be avoided since they may exacerbate the mineralisation defect.

Other causes of osteomalacia

These are summarised in Box 24.75. Osteomalacia may occur as a component of renal osteodystrophy in patients with chronic kidney disease. The mechanism is reduced conversion of 25(OH)D into the active metabolite 1,25$(OH)_2$D by the failing kidney (p. 418). Aluminium intoxication is now rare due to reduced use of aluminium-containing phosphate binders and removal of aluminium from the water supplies used in dialysis. If aluminium intoxication is suspected, the diagnosis can be confirmed by demonstration of aluminium at the calcification front in a bone biopsy. Osteomalacia due to bisphosphonates has mostly been described in patients with Paget's disease who are receiving etidronate and high-dose pamidronate. It is usually asymptomatic and healing occurs when treatment is stopped. Excessive fluoride intake causes osteomalacia due to direct inhibition of mineralisation and is common in parts of the world where there is a high fluoride content in drinking water. The condition reverses when fluoride intake is reduced.

Paget's disease of bone

Paget's disease of bone (PDB) is characterised by focal areas of increased and disorganised bone remodelling involving one or more skeletal sites. The disease is common in the UK, affecting about 1% of those aged above 55, and in other countries in Europe. It is rare in Scandinavia, the Indian subcontinent and the rest of Asia. The prevalence doubles each decade from the age of 50 onwards and affects up to 8% of the UK population by the age of 85.

Pathophysiology

The primary abnormality is increased osteoclastic bone resorption, accompanied by marrow fibrosis, increased vascularity of bone and increased, but disorganised, bone formation. Osteoclasts in PDB are greater in number and unusually large, containing characteristic nuclear inclusion bodies. Genetic factors are important and mutations in the *SQSTM1* gene are a common

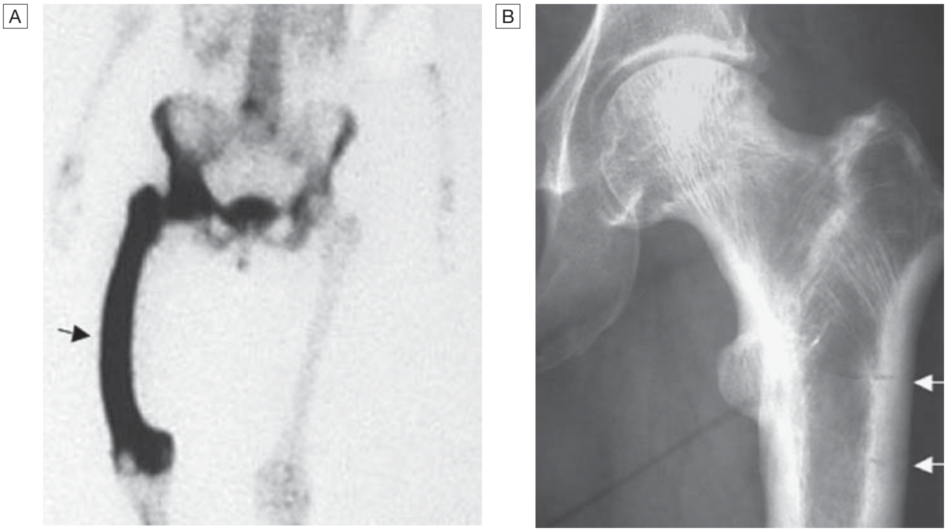

Fig. 24.63 Paget's disease. **A** ^{99m}Tc-labelled bisphosphonate scintigraphy from a patient with Paget's disease, illustrating the intense tracer uptake and deformity of the affected femur. **B** The typical radiographic features with expansion of the femur, alternating areas of osteosclerosis and radiolucency of the trochanter, and pseudofractures breaching the bone cortex (arrows).

cause of classical PDB. The presence of nuclear inclusion bodies in osteoclasts has fuelled speculation that PDB might be caused by a slow virus infection but this is unproven. Biomechanical factors may influence which bones are affected, as PDB often starts at sites of muscle insertions into bone and, in some cases, localises to bones or limbs that have been subjected to repetitive trauma or overuse. Involvement of subchondral bone can compromise the joint and predispose to OA. The prevalence of PDB has fallen in many countries over recent decades, suggesting that environmental factors play a role, but the identity of these triggers remains unclear.

Clinical features

The axial skeleton is predominantly affected and common sites of involvement are the pelvis, femur, tibia, lumbar spine, skull and scapula. The most common presentation is with bone pain localised to an affected site but bone deformity, deafness and pathological fractures may also be presenting features. Many patients are asymptomatic and the diagnosis is frequently made on the basis of an X-ray or blood test performed for another reason. Clinical signs include bone deformity and expansion, and increased warmth over an affected bone. Neurological problems, such as deafness, cranial nerve defects, nerve root pain, spinal cord compression and spinal stenosis, may occur due to enlargement of affected bones and encroachment on the spinal cord and nerve foramina. Surprisingly, deafness seldom results from compression of the auditory nerve but is conductive, due to osteosclerosis of the temporal bone. The increased vascularity of Pagetic bone can rarely precipitate high-output cardiac failure in elderly patients with limited cardiac reserve. Osteosarcoma is an unusual but serious complication that presents with increasing pain and swelling of an affected site.

Investigations

The characteristic features are an isolated elevation in ALP and bone expansion on X-rays, with alternating areas of radiolucency and osteosclerosis (Fig. 24.63B). Levels of ALP can be normal if only a single bone is affected. The best way of identifying affected sites is a radionuclide bone scan, which shows increased uptake in affected bones (Fig. 24.63A). If the bone scan is positive, X-rays should be taken to confirm the diagnosis. Bone biopsy is not usually required but may help to exclude osteosclerotic metastases in cases of diagnostic uncertainty.

i 24.76 Medical management of Paget's disease

Drug	Route of administration	Dose
Etidronate	Oral	400 mg daily for 3–6 months
Tiludronate	Oral	400 mg daily for 3–6 months
Risedronate	Oral	30 mg daily for 2 months
Pamidronate	IV	1–3×60 mg infusions
Zoledronic acid	IV	1×5 mg infusion
Calcitonin	SC	100–200 IU 3 times weekly for 2–3 months

Management

The main indication for treatment with inhibitors of bone resorption is bone pain, which is thought to be due to increased metabolic activity (Box 24.76). Patients should be carefully assessed to determine the cause of the pain since it can be difficult to differentiate the pain caused by increased metabolic activity of PDB from that caused by complications such as bone deformity, nerve compression symptoms and OA. The bisphosphonates pamidronate, risedronate and zoledronic acid are highly effective at suppressing the elevations in bone turnover that are characteristic of PDB and also improve bone pain that is caused by increased metabolic activity. If there is doubt about whether the pain is due to PDB, it can be worthwhile giving a therapeutic trial of bisphosphonate to determine whether the symptoms improve. A positive response indicates that the pain was due to increased metabolic activity. There is no evidence as yet to suggest that bisphosphonates prevent the development of complications in PDB. Repeated courses of bisphosphonates can be given if symptoms recur.

Fig. 24.64 **Complex regional pain syndrome (osteodystrophy).** ^{99m}Tc-labelled bisphosphonate scintigraphy showing increased uptake in femoral condyle.

Other bone diseases

Complex regional pain syndrome type 1

Complex regional pain syndrome (CRPS) type 1 is characterised by gradual onset of pain, swelling and local tenderness, usually affecting a limb extremity. It may be triggered by fracture but can also occur in association with soft tissue injury, pregnancy and intercurrent illness or can develop spontaneously. The cause is unknown but abnormalities of the sympathetic nervous system are thought to play a pathogenic role. The affected limb is swollen and tender, and there may be evidence of regional autonomic dysfunction, with abnormal sweating and changes in skin colour and temperature. The diagnosis is primarily clinical, based on the features shown in Box 34.12 (p. 1349). Support for the diagnosis can be obtained with MRI, which shows bone marrow oedema, or radionuclide bone scan, which shows a local increase in tracer uptake (Fig. 24.64). X-rays show localised osteoporosis. Haematology, biochemistry and immunology are normal.

The aims of treatment are to control pain and encourage mobilisation. Analgesics, NSAIDs, antineuropathic agents, calcitonin, glucocorticoids, β-adrenoceptor antagonists (β-blockers), sympathectomy and bisphosphonates have all been tried but none is particularly effective. Although some cases resolve with time, many individuals have persistent symptoms and fail to regain normal function.

Osteonecrosis

Osteonecrosis describes death of bone due to impairment of its blood supply. The most commonly affected sites are the femoral head, humeral head and femoral condyles. In some cases, the condition occurs as the result of direct trauma that interrupts the blood supply to the affected bone. This is the reason for osteonecrosis of the femoral head in patients with subtrochanteric fractures of the femoral neck, and in patients with thrombophilia and haemoglobinopathies, such as sickle cell disease. Other important predisposing factors include high-dose glucocorticoid treatment, alcohol excess, SLE, HIV and radiotherapy, but in many of these conditions the pathophysiology is poorly understood. The presentation is with pain localised to the affected site, which is exacerbated by weight-bearing. The diagnosis can be confirmed by MRI, which shows evidence of subchondral necrotic bone and bone marrow oedema. X-rays are normal in the early stages but later may show evidence of osteosclerosis and deformity of the affected bone. There is no specific treatment. Management should focus on controlling pain and encouraging mobilisation (p. 1000). Symptoms often improve spontaneously with time but joint replacement may be required in patients who have persisting pain in association with significant structural damage to the affected joint.

Scheuermann's osteochondritis

This disorder predominantly affects adolescent boys, who develop a dorsal kyphosis in association with irregular radiographic ossification of the vertebral end plates. It has a strong genetic component and may be inherited in an autosomal dominant manner. Most patients are asymptomatic but back pain, aggravated by exercise and relieved by rest, may occur. Excessive exercise and heavy manual labour before epiphyseal fusion has occurred may aggravate symptoms. Management consists of advice to avoid excessive activity and provision of protective postural exercises. Rarely, corrective surgery may be required if there is severe deformity. Scheuermann's disease can sometimes present for the first time in adulthood, when it can be confused with osteoporotic vertebral fractures. It can be differentiated from osteoporosis by the characteristic X-ray changes, which show mild wedge deformity of 3–4 adjacent vertebrae, irregularity of the vertebral end plates, and normal BMD on DXA examination.

Polyostotic fibrous dysplasia

This is an acquired systemic disorder that mainly affects the skeleton and is caused by somatic mutations in the *GNAS1* gene. The characteristic presentation is with bone pain and pathological fractures. Associated features include endocrine dysfunction, especially precocious puberty, and café-au-lait skin pigmentation (McCune–Albright syndrome). The diagnosis can usually be made by imaging, which shows focal, predominantly osteolytic lesions with bone expansion on X-rays (Fig. 24.65), and focal increased uptake on bone scan. The condition can resemble Paget's disease of bone but the earlier age of onset and pattern of involvement are usually distinctive. Very rarely, malignant change can occur and should be suspected if there is a sudden increase in pain and swelling. Management is symptomatic. Intravenous bisphosphonates are often used in an attempt to control pain but the evidence base for their use is weak. Orthopaedic surgery may be required for treatment of fracture and deformity. Endocrine manifestations, such as precocious puberty (p. 654), may require specific treatment.

Osteogenesis imperfecta

Osteogenesis imperfecta (OI) is the name given to a group of disorders characterised by severe osteoporosis and multiple fractures in infancy and childhood. Most cases are caused by mutations in the *COL1A1* and *COL1A2* genes, which encode the proteins that make type I collagen. These result in reduced collagen production (in mild OI) or in formation of abnormal collagen chains that are rapidly degraded (in severe OI). Mutations

Fig. 24.65 McCune–Albright syndrome. X-ray of tibia in a patient with McCune–Albright syndrome showing expansile osteolytic lesion.

in several other genes have been described that can cause OI, some of which affect post-translational modification of collagen and others that affect bone formation. Many patients have no family history. Some of these have new mutations whereas others may have recessive forms of the disease. The Sillence classification is commonly used to grade severity. This varies from neonatal lethal OI (type II), through very severe OI with multiple fractures in infancy and childhood (types III and IV), to mild (type I), in which affected patients typically have blue sclerae. The diagnosis of OI is usually obvious clinically, based on the presentation with multiple low-trauma fractures during infancy. The disease can be mistaken for non-accidental injury in childhood and for osteoporosis in adulthood; in such cases, genetic testing can be of diagnostic value. Treatment is multidisciplinary, involving surgical reduction and fixation of fractures and correction of limb deformities, and physiotherapy and occupational therapy for rehabilitation of patients with bone deformity. Bisphosphonates are widely used in the treatment of OI, especially intravenous pamidronate in children, but there is limited evidence for efficacy in fracture prevention.

Osteopetrosis

Osteopetrosis is a rare group of inherited diseases caused by failure of osteoclast function. Presentation is highly variable, ranging from a lethal disorder that presents with bone marrow failure in infancy to a milder and sometimes asymptomatic form that presents in adulthood. Severe osteopetrosis is inherited in an autosomal recessive manner and presents with failure to thrive, delayed dentition, cranial nerve palsies (due to absent cranial foramina), blindness, anaemia and recurrent infections due to bone marrow failure. The adult-onset type (Albers–Schönberg disease) shows autosomal dominant inheritance and presents with bone pain, cranial nerve palsies, osteomyelitis, OA or fracture, or is sometimes detected as an incidental radiographic finding. The responsible mutations affect either the genes that regulate osteoclast differentiation (*RANK*, *RANKL*), causing ‘osteoclast-poor’ osteopetrosis, or the genes involved in bone resorption, causing ‘osteoclast-rich’ osteopetrosis. These include mutations in the *TCIRG1* gene, which encodes a component of the osteoclast proton pump, and mutations in the *CLCN7* gene, which encodes the osteoclast chloride pump. Management is difficult. IFN-γ treatment can improve blood counts and reduce frequency of infections, but in severe cases haematopoietic stem cell transplantation is required to provide a source of osteoclasts that resorb bone normally.

Sclerosing bone dysplasias

These are rare diseases characterised by osteosclerosis and increased bone formation. Van Buchem’s disease and sclerosteosis are recessive disorders caused by loss-of-function mutations in the *SOST* gene, which normally suppresses bone formation (see Fig. 24.3, p. 986). The resulting lack of sclerostin causes increased bone formation and bone overgrowth, leading to enlargement of the cranium and jaw, tall stature and cranial nerve palsies. There is no effective treatment. High bone mass syndrome is a benign disorder caused by mutations in the *LRP4* or *LRP5* gene, which is characterised by unusually high bone density. The mutations render the LRP receptors resistant to the inhibitory effects of SOST. Most patients are asymptomatic but bone overgrowth in the palate (torus palatinus) and enlargement of the mandible can occur in later life. Treatment is not usually required. Camurati–Engelmann disease is an autosomal dominant condition caused by gain of function in the *TGFB1* gene. It presents with bone pain, muscle weakness and osteosclerosis mainly affecting the diaphysis of long bones. Glucocorticoids can help the bone pain, although usually analgesics are also required.

Bone and joint tumours

Primary tumours of bones and joints are rare, have a peak incidence in childhood and adolescence, and can be benign or malignant (Box 24.77). Paget’s disease of bone (p. 1053) accounts for most cases of osteosarcoma occurring above the age of 40.

Osteosarcoma

This is a rare tumour with an incidence of 0.6–0.85 per 100 000 population. It is the most common primary bone tumour. Most

24.77 Primary tumours of the musculoskeletal system

Cell type	Benign	Malignant
Osteoblast	Osteoid osteoma	Osteosarcoma
Chondrocyte	Chondroma Osteochondroma	Chondrosarcoma
Fibroblast	Fibroma	Fibrosarcoma
Bone marrow cell	Eosinophilic granuloma	Ewing’s sarcoma
Endothelial cell	Haemangioma	Angiosarcoma
Osteoclast precursor	Giant cell tumour	Malignant giant cell tumour

patients present under the age of 30 but osteosarcoma also occurs in the elderly in association with Paget's disease. The presentation is with local pain and swelling. X-rays show expansion of the bone with a surrounding soft tissue mass, often containing islands of calcification. If the diagnosis is being considered, MRI or CT should be performed to determine the extent of tumour. Patients suspected of having osteosarcoma should be referred to a specialist team for biopsy. Treatment depends on histological type but generally involves surgical removal of the tumour, followed by chemotherapy and radiotherapy. The prognosis is normally good in cases that present in childhood and adolescence, but poor in elderly patients with osteosarcoma related to Paget's disease of bone.

Chondrosarcoma

This is the second most common primary bone tumour. Presentation is as described for osteosarcoma. The treatment of choice is surgical resection since chondrosarcomas are relatively resistant to chemotherapy and radiotherapy. The prognosis is good for low-grade tumours but poor for anaplastic tumours.

Ewing's sarcoma

This is the third most common sarcoma, which presents almost exclusively under the age of 40. Presentation is as described for osteosarcoma. Treatment is by local excision and surgical resection. The prognosis is excellent for patients who present before metastasis has occurred.

Metastatic bone disease

Metastatic bone disease may present in a variety of ways: with localised or generalised progressive bone pain, generalised regional pain, symptoms of spinal cord compression, or acute pain due to pathological fracture. Systemic features, such as weight loss and anorexia, and symptoms referable to the primary tumour are often present. The tumours that most commonly metastasise to bone are myeloma and those of bronchus, breast, prostate, kidney and thyroid. Management is discussed in Chapter 33.

Rheumatological involvement in other diseases

Many systemic diseases can affect the locomotor system, and many drugs may cause adverse locomotor effects (Box 24.78). The most common examples are described here. Bone disease in sarcoidosis is described on page 608, haemophilia on page 972 and sickle-cell anaemia on page 952.

Malignant disease

Malignant disease can cause a variety of non-metastatic musculoskeletal problems (Box 24.79). One of the most striking is hypertrophic pulmonary osteoarthropathy (HPOA), characterised by clubbing and painful swelling of the limbs, periosteal new bone formation and arthralgia/arthritis. The most common causes are bronchial carcinoma and mesothelioma (pp. 598 and 618). Bone scans show increased periosteal uptake before new bone is apparent on X-ray. The course follows that of the underlying malignancy and HPOA resolves if this is cured.

24.78 Drug-induced effects on the musculoskeletal system

Musculoskeletal problem	Principal drug
Secondary gout	Thiazides, furosemide, alcohol
Osteoporosis	Glucocorticoids, heparin, glitazones, aromatase inhibitors, GnRH agonists
Osteomalacia	Anticonvulsants, etidronate and pamidronate (high-dose)
Osteonecrosis	Glucocorticoids, alcohol
Drug-induced lupus syndrome	Procainamide, hydralazine, isoniazid, chlorpromazine
Arthralgias, arthritis	Glucocorticoid withdrawal, glibenclamide, methyldopa, ciclosporin, isoniazid, barbiturates
Myalgia	Glucocorticoid withdrawal, L-tryptophan, fibrates, statins
Myopathy	Glucocorticoids, chloroquine
Myositis, myasthenia	Penicillamine, statins
Cramps	Glucocorticoids, ACTH, diuretics, carbenoxolone
Vasculitis	Amphetamines, thiazides

(ACTH = adrenocorticotrophic hormone; GnRH = gonadotrophin-releasing hormone)

24.79 Rheumatological manifestations of malignancy

- Polyarthritis
- Dermatomyositis and polymyositis
- Hypophosphataemic osteomalacia
- Hypertrophic osteoarthropathy
- Vasculitis, connective tissue disease
- Raynaud's syndrome
- Polymyalgia rheumatica-like syndrome

Endocrine disease

Hypothyroidism (p. 639) may present with carpal tunnel syndrome or, rarely, with painful, symmetrical proximal myopathy and muscle hypertrophy. Both resolve with levothyroxine replacement. Primary hyperparathyroidism (p. 663) is associated with osteoporosis and also predisposes to calcium pyrophosphate dihydrate deposition disease and to calcific periarthritis, especially in patients with renal disease.

Diabetes mellitus (Ch. 20) commonly causes diabetic cheiroarthropathy, characterised by tightening of skin and periarticular structures, causing flexion deformities of the fingers that may be painful. Diabetic osteopathy presents as forefoot pain with radiographic progression from osteopenia to complete osteolysis of the phalanges and metatarsals. Diabetes also predisposes to osteoporosis, fragility fractures, adhesive capsulitis, Dupuytren's contracture, septic arthritis and Charcot's joints.

Acromegaly (p. 685) can be associated with mechanical back pain, with normal or excessive movement; carpal tunnel syndrome; and Raynaud's syndrome and an arthropathy (50%). The arthropathy mainly affects the large joints and has clinical similarities to OA but with a normal or increased range of movement. X-rays may show widening of joint spaces, squaring of bone ends, generalised osteopenia and tufting of terminal phalanges. It does not improve with treatment of the acromegaly.

Haematological disease

Haemochromatosis (p. 895) is complicated by an arthropathy in about 50% of cases. It typically presents between the ages of 40 and 50, and may predate other features of the disease. The small joints of the hands and wrists are typically affected but the hips, shoulders and knees may also be involved. The X-ray changes resemble OA but cysts are often multiple and prominent, with little osteophyte formation. Involvement of the radiocarpal and MCP joints may occur, which is unusual in primary OA, and about 30% have calcium pyrophosphate dihydrate deposition disease and/or pseudogout. Treatment of the haemochromatosis does not influence the arthropathy, and management is as described for OA. Haemophilia (p. 972) can be complicated by haemarthrosis, which, if recurrent, can result in the development of secondary OA. Sickle-cell disease (p. 952) may be associated with bone pain, osteonecrosis and osteomyelitis. Thalassaemia (p. 953) may be complicated by bone deformity, especially affecting the craniofacial bones, and by osteoporosis.

Neurological disease

Neurological disease may result in rapidly destructive arthritis of joints, first described by Charcot in association with syphilis. The cause is incompletely understood but may involve repetitive trauma as the result of sensory loss and altered blood flow secondary to impaired sympathetic nervous system control. The main predisposing diseases and sites of involvement are:

- diabetic neuropathy (hindfoot)
- syringomyelia (shoulder, elbow, wrist)
- leprosy (hands, feet)
- tabes dorsalis (knees, spine).

The presentation is with subacute or chronic monoarthritis. Pain can occur, especially at the onset, but once the joint is severely deranged, pain is often minimal and signs become disproportionately greater than symptoms. The joint is often grossly swollen, with effusion, crepitus, marked instability and deformity, but usually no increased warmth. X-rays show disorganisation of normal joint architecture and often multiple loose bodies (Fig. 24.66), and either no (atrophic) or gross (hypertrophic) new bone formation. Management principally involves orthoses and occasionally arthrodesis.

Fig. 24.66 Wrist X-ray showing a neuropathic (Charcot) joint in a patient with syringomyelia. Note the disorganised architecture with complete loss of the proximal carpal row, bony fragments and soft tissue swelling.

Miscellaneous conditions

Anterior tibial compartment syndrome

This is characterised by severe pain in the front of the lower leg, aggravated by exercise and relieved by rest. Symptoms result from fascial compression of the muscles in the anterior tibial compartment and may be associated with foot drop. Treatment is by surgical decompression.

Carpal tunnel syndrome

This is a common nerve entrapment syndrome caused by compression of the median nerve at the wrist. It presents with numbness, tingling and pain in a median nerve distribution (p. 1139). The most common causes are hypothyroidism, diabetes mellitus, RA, obesity and pregnancy, especially in the third trimester. In some patients, no underlying cause may be identified. Carpal tunnel syndrome often responds to treatment of the underlying condition but other options include local glucocorticoid injections and surgical decompression.

Diffuse idiopathic skeletal hyperostosis

Diffuse idiopathic skeletal hyperostosis (DISH) is a common disorder, affecting 10% of men and 8% of women over the age of 65, and is associated with obesity, hypertension and type 2 diabetes mellitus. It is characterised by florid new bone formation along the anterolateral aspect of at least four contiguous vertebral bodies (Fig. 24.67). DISH is distinguished from lumbar spondylosis by the absence of disc space narrowing and marginal vertebral body sclerosis, and from ankylosing spondylitis by the absence of sacroiliitis or apophyseal joint fusion. It is usually an

Fig. 24.67 Diffuse idiopathic skeletal hyperostosis (DISH). Anteroposterior X-ray of the thoracic spine showing right-sided, flowing new bone joining more than four contiguous vertebrae. The disc spaces are preserved.

asymptomatic radiographic finding but can cause back pain or pain at peripheral sites, such as the heel, in association with calcaneal spur formation.

Dupuytren's contracture

Dupuytren's contracture results from fibrosis and contracture of the superficial palmar fascia of the hands. The patient is unable to extend the fingers fully and there is puckering of the skin with palpable nodules. The ring and little fingers are usually the first and worst affected. Dupuytren's contracture is usually painless but causes problems due to limitation of hand function and snagging of the curled fingers in pockets. It is age-related, usually bilateral and more common in men. There is a strong genetic component and sometimes may be familial, with dominant inheritance. The condition can be associated with plantar fibromatosis, Peyronie's disease, alcohol misuse and chronic vibration injury. It is very slowly progressive. Often no treatment is required but it can be treated medically by local injections of collagenase or surgically by fasciotomy if symptoms are troublesome.

Hypermobility syndromes

Hypermobility is characterised by increased joint laxity and joint pain. Causes include Marfan's syndrome, resulting from mutations in the *FBN1* gene (p. 508); osteogenesis imperfecta (p. 1055); and Ehlers–Danlos syndrome types I, II and IV, caused by mutations in the *COL3A1*, *COL5A1* and *COL5A2* genes (p. 970).

The term hypermobile Ehlers–Danlos syndrome (hEDS), which is also known as EDS type III, is used to describe a polygenic form of hypermobility. Many patients with this condition have hypermobile joints but do not have symptoms, whereas in others a range of symptoms can occur, including chronic joint and ligamentous pain, fibromyalgia-like symptoms, recurrent dislocations, easy bruising, abdominal symptoms, mitral valve prolapse (p. 520) and postural tachycardia syndrome, in which there is dizziness, hypotension and an increased heart rate on standing. The diagnosis of EDS type III is clinical and can be made when the modified Beighton score is 4 or above in the presence of arthralgia in four or more joints (Box 24.80). There is no specific treatment, apart from the general principles listed on page 1000, but some patients become very disabled as the result of their symptoms and are difficult to manage.

Inclusion body myositis

Inclusion body myositis is the most frequent primary myopathy in middle age and after. It is characterised by slowly progressive muscle weakness and atrophy, with pathological changes of inflammation, degeneration and mitochondrial abnormality in affected muscle fibres. Inclusion body myositis typically presents with distal muscle weakness. In time, muscles atrophy. Investigation is the same as for polymyositis (p. 1039). There is typically a slightly elevated creatine kinase and myopathic changes on EMG. Muscle biopsy shows abnormal fibres containing rimmed vacuoles and filamentous inclusions in the nucleus and cytoplasm. Therapeutic response to glucocorticoids and immunosuppressants is notably poor. There is anecdotal report of efficacy with IVIg but trial evidence is lacking.

i 24.80 Modified Beighton score for joint hypermobility

Clinical test	Score
Extend little finger >90°	1 point each side
Bring thumb back parallel to/touching forearm	1 point each side
Extend elbow >10°	1 point each side
Extend knee >10°	1 point each side
Touch floor with flat of hands, legs straight	1 point
Hypermobile = a score of 6 or more points out of a possible 9 for epidemiological studies, or 4 or more points (with arthralgia in four or more joints) for a clinical diagnosis of the benign joint hypermobility syndrome	

Periodic fever syndromes

These are a group of rare inherited disorders that present with intermittent attacks of fever, rash, arthralgia and myalgia. They are discussed in more detail on page 81.

Pigmented villonodular synovitis

Pigmented villonodular synovitis is an uncommon proliferative disorder of synovium, which typically affects young adults. It is caused by a somatic chromosomal translocation in synovial cells that places the *CSF1* gene downstream of the *COL6A3* gene promoter. The result is local over-production of M-CSF, which causes accumulation of macrophages in the joint. The presentation is with joint swelling, limitation of movement and local discomfort. The diagnosis can be confirmed by MRI or synovial biopsy. Treatment is by surgical or radiation synovectomy.

Scoliosis

Scoliosis is characterised by an abnormal lateral curvature of the spine of greater than 10°. It typically presents during childhood or adolescence but usually persists into adulthood, when it can be associated with back pain, deformity and secondary OA. In about 20% of cases, scoliosis is secondary to a neuromuscular disorder, such as muscular dystrophy, cerebral palsy or neurofibromatosis. It may also occur in association with connective tissue disorders, such as Marfan's syndrome. The term idiopathic scoliosis is used to described the remaining cases where there is no obvious cause. In fact, there is strong evidence from twin studies that idiopathic scoliosis is genetically mediated. The diagnosis can usually be made clinically by physical examination, which shows the characteristic spinal deformity. Spinal X-rays can be used to confirm the diagnosis and assess severity. External bracing and/or surgical intervention are often performed in adolescents with severe deformities to correct deformity or prevent progression but the evidence base is poor. In adulthood, treatment is symptomatic in nature with analgesics, NSAID or antineuropathic medications.

Spondylolysis

Spondylolysis describes a break in the integrity of the neural arch. The principal cause is an acquired defect in the pars interarticularis due to a fracture, mainly seen in gymnasts, dancers and runners, in whom it is an important cause of back pain. Spondylolisthesis describes the condition in which a defect causes slippage of a vertebra on the one below. This may be congenital, post-traumatic or degenerative. Rarely, it can result from metastatic destruction of the posterior elements. Uncomplicated spondylolysis does not cause symptoms but spondylolisthesis can lead to low back pain

aggravated by standing and walking. Occasionally, symptoms of nerve root or spinal compression may occur. The diagnosis can be made on lateral X-rays of the lumbar spine but MRI may be required if there is neurological involvement. Advice on posture and muscle-strengthening exercises is required in mild cases. Surgical fusion is indicated for severe and recurrent low back pain. Surgical decompression is mandatory prior to fusion in patients with significant lumbar stenosis or symptoms of cauda equina compression.

Synovitis–acne–pustulosis–hyperostosis–osteitis syndrome

The synovitis–acne–pustulosis–hyperostosis–osteitis (SAPHO) syndrome is a disorder characterised by bone pain and swelling due to a sterile osteomyelitis and hyperostosis predominantly targeting the clavicles and bones of the anterior chest wall. SAPHO syndrome is thought to be part of a spectrum of autoinflammatory bone diseases that includes chronic recurrent (sterile) multifocal osteomyelitis in children and adolescents. Other features include a pustulotic rash affecting the palms and soles of the feet, sacroiliitis and synovitis of peripheral joints. It most commonly presents in children and young or middle-aged adults. Various treatments have been used, including glucocorticoids, DMARDs, bisphosphonates, anakinra and TNF blockers, with most success arising from biologic use. The cause is unknown but has been suggested to be an autoimmune process triggered by a bacterial or viral pathogen.

Trigger finger

This occurs as the result of stenosing tenosynovitis in the flexor tendon sheath, with intermittent locking of the finger in flexion. It can arise spontaneously or in association with inflammatory diseases such as RA. Symptoms usually respond to local glucocorticoid injections but surgical decompression is occasionally required.

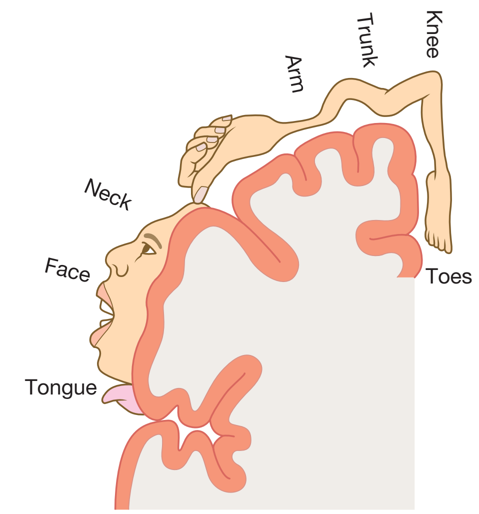
1 Examination of gait and posture

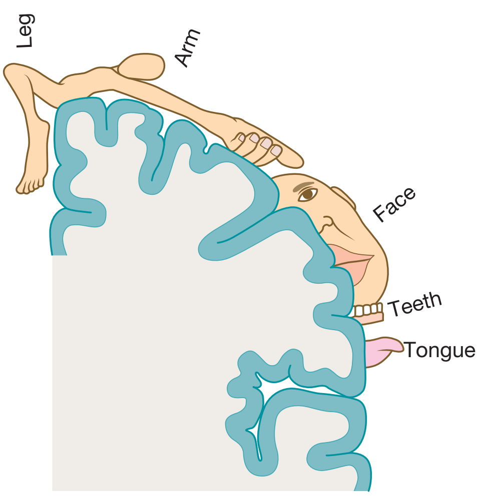
Procedure	Abnormality	Disease
Rising from chair	Difficulty rising	Proximal muscle weakness or joint disorders
Gait initiation	Difficulty starting to walk, frozen	Cerebrovascular disease or parkinsonism
Posture	Stooped	Parkinsonism
Retropulsion/ anteropulsion	Postural instability	Parkinsonism
Arms during walking	Reduced arm swing	Parkinsonism or upper motor neuron lesion
	Enhanced tremor	Parkinsonism
	Dystonic posturing	Dystonia
Gait pattern	Circumduction (stiff leg moves outwards in ‘circular’ manner)	Hemiparesis, typically after stroke
	‘Slapping’, high-stepping due to foot drop	L5 radiculopathy or common peroneal nerve lesion
	Narrow-based, short strides, freezing in doorways	Parkinsonism
	Stiff-legged, scissors gait	Spastic paraparesis (multiple sclerosis, vascular disease, spinal cord lesions)
	Wide-based, unsteady, unable to perform tandem gait	Cerebellar lesion
	Waddling gait	Myopathies with proximal weakness



4 Examination of cranial nerves

Nerve	Name	Tests
I	Olfactory	Ask patient about sense of smell (examine only if change is reported)
II	Optic	Visual acuity and colour vision Visual fields Pupillary responses Ophthalmoscopy
III	Oculomotor	Eyelids (ptosis) Pupil size, symmetry, reactions Eye movements
IV	Trochlear	Eye movements (superior oblique muscle)
V	Trigeminal	Facial sensation Corneal reflex Muscles of mastication
VI	Abducens	Eye movements (lateral rectus muscle)
VII	Facial	Facial symmetry and movements
VIII	Vestibulocochlear	Otoscopy Hearing Tuning fork tests (Rinne and Weber)
IX	Glossopharyngeal	Swallowing
X	Vagus	Palatal elevation (uvula deviates to side opposite lesion) Swallowing Cough (bovine) Speech
XI	Accessory	Look for wasting of trapezius/sternocleidomastoid Elevation of shoulders Turning head to right and left
XII	Hypoglossal	Look for wasting/fasciculation Tongue protrusion (deviates to side of lesion)

6 Root values of tendon reflexes



Reflex	Root value
Arm	
Biceps jerk	C5
Supinator jerk	C6
Triceps jerk	C7
Finger jerk	C8
Leg	
Knee jerk	L3/L4
Ankle jerk	S1

Motor

Motor cortex
(pre-central gyrus)

Sensory

Somatic cortex
(post-central gyrus)

Motor and sensory homunculi. The motor and sensory homunculi illustrate the cortical areas serving each anatomical area within the pre-central (motor) and post-central (sensory) gyri.

The complexity of the brain differentiates us from other species, and its interactions with the spinal cord and peripheral nerves combine to allow us to perceive and react to the external world while maintaining a stable internal environment. The cerebral cortex provides a platform for processing information and forming a response, and in doing so, both forms and is affected by our personality and mental state.

Neurology has for too long been misperceived as a specialty in which intricate clinical examination and numerous investigations are required to diagnose obscure and untreatable conditions. In fact, nervous system disorders are common, accounting for around 10% of the UK's general practice consultations, 20% of acute medical admissions, and most chronic physical disability. The development of specific, effective treatments has made accurate diagnosis essential. Neurological management requires knowledge of a range of common conditions, which can then be applied to individual patients after careful history-taking, with lesser contributions arising from targeted examination and considered investigation.

Pathological and anatomical localisation of symptoms and signs is important, but skill can be required to identify those *not* associated with neurological disease, differentiating patients requiring investigation and treatment from those who need reassurance.

Initially, it is important to exclude conditions that constitute neurological emergencies (Box 25.1). If the presentation is not an emergency, time can be taken to reach a diagnosis. The history should provide a hypothesis for the site and nature of the potential pathology, which a focused examination may refine, and direct appropriate further investigations. An informed discussion with the patient and family regarding diagnosis, management and prognosis may then take place.

As stroke has become a specific subspecialty in many centres, it is described in a separate chapter, although it is clearly a neurological condition. This chapter should be read with it, to help clarify how the presentation, diagnosis and management of stroke present their own challenges.

Functional anatomy and physiology

Cells of the nervous system

The nervous system comprises billions of specialised cells, forming a spectacular network of connections, each human brain having almost as many connections as there are grains of sand in the whole world. In addition to neurons, there are three types of glial cells. Astrocytes form the structural framework for neurons

25.1 Neurological emergencies

- Status epilepticus (p. 1080)
- Stroke (if thrombolysis available) (p. 1158)
- Guillain–Barré syndrome (p. 1140)
- Myasthenia gravis (if bulbar and/or respiratory) (p. 1141)
- Spinal cord compression (p. 1136)

- Neuroleptic malignant syndrome (p. 1197)

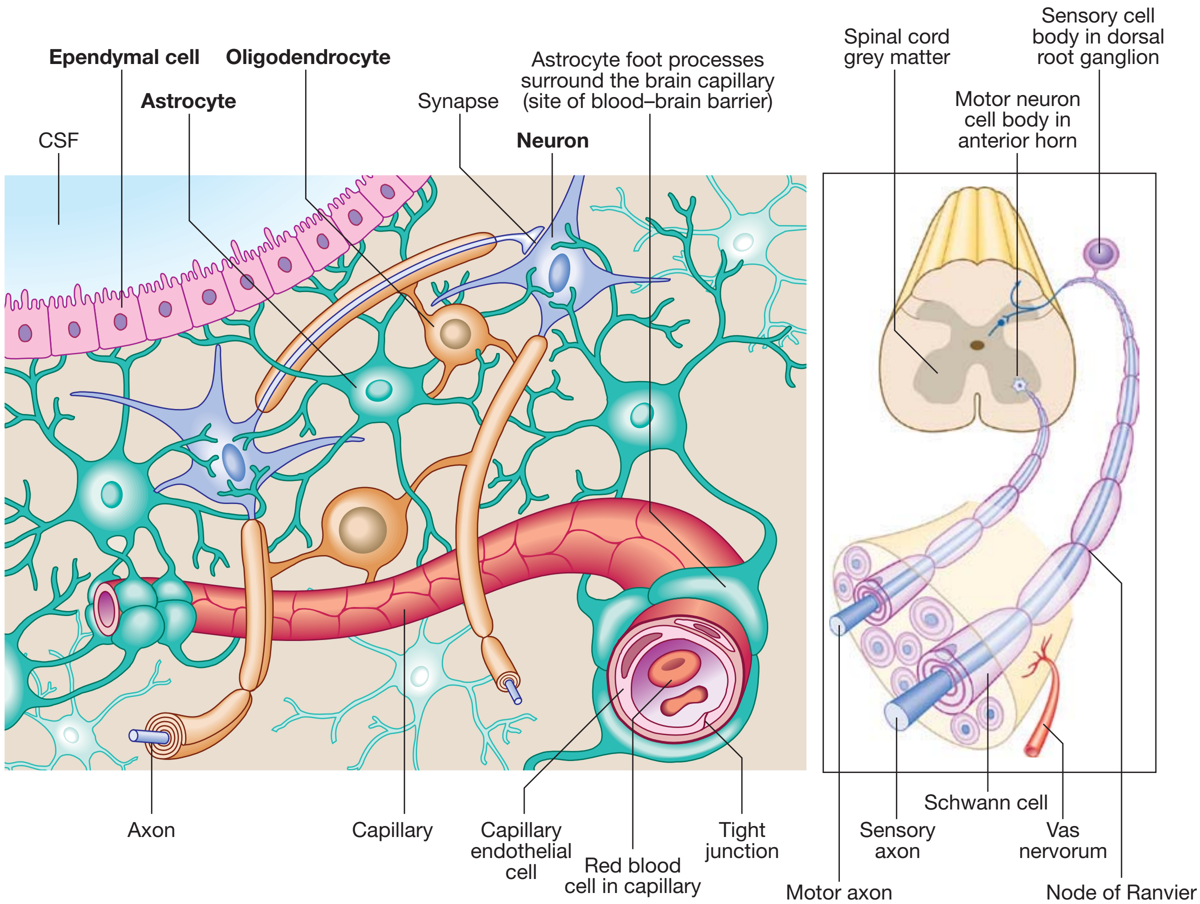

Fig. 25.1 Cells of the nervous system. (CSF = cerebrospinal fluid)

and control their biochemical environment, their foot processes adjoining small blood vessels and forming the blood–brain barrier (Fig. 25.1). Oligodendrocytes are responsible for the formation and maintenance of the myelin sheath, which surrounds axons and is essential for maintaining the speed and consistency of action potential propagation along axons. Peripheral nerves have axons invested in myelin made by oligodendrocytes (Schwann cells). Microglial cells derive from monocytes/macrophages and play a role in fighting infection and removing damaged cells. Ependymal cells line the cerebral ventricles.

Generation and transmission of the nervous impulse

The role of the central nervous system (CNS) is to generate outputs in response to external stimuli and changes in internal conditions. The CNS has to maintain a delicate balance between responsivity to external stimuli and remaining stoic enough to remain stable in a rapidly changing environment. Each neuron receives input by synaptic transmission from dendrites (branched projections of other neurons), which sum to produce output in the form of an action potential that is then conducted along the axon, resulting in synaptic transmission to other neurons or, in the motor system, to muscle cells. Summation of the inputs causes net changes in the target neuron's electrochemical gradient, which, if large enough, will trigger an action potential. Communication between cells is by synaptic transmission that involves the release of neurotransmitters to interact with structures on the target cell's surface, including ion channels and other cell surface receptors (Fig. 25.2). At least 20 different neurotransmitters are known to act at different sites in the nervous system, most of which are potentially amenable to pharmacological manipulation.

Each neuronal cell body may receive synaptic input from thousands of other neurons. The synapsing neuron terminals are also subject to feedback regulation via receptor sites on the pre-synaptic membrane, modifying the release of transmitter across the synaptic cleft. In addition to such acute effects, some neurotransmitters produce long-term modulation of metabolic function or gene expression. This effect probably underlies more complex processes such as long-term memory.

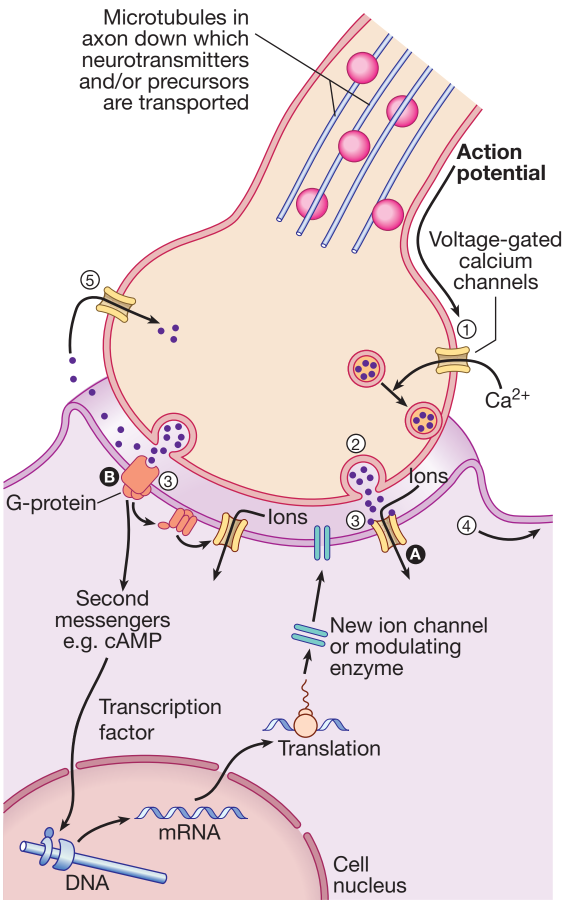

Fig. 25.2 Neurotransmission and neurotransmitters. (1) An action potential arriving at the nerve terminal depolarises the membrane and this opens voltage-gated calcium channels. (2) Entry of calcium causes the fusion of synaptic vesicles containing neurotransmitters with the pre-synaptic membrane and release of the neurotransmitter across the synaptic cleft. (3) The neurotransmitter binds to receptors on the post-synaptic membrane either (A) to open ligand-gated ion channels that, by allowing ion entry, depolarise the membrane and initiate an action potential (4), or (B) to bind to metabotropic receptors that activate an effector enzyme (e.g. adenylyl cyclase) and thus modulate gene transcription via the intracellular second messenger system, leading to changes in synthesis of ion channels or modulating enzymes. (5) Neurotransmitters are taken up at the pre-synaptic membrane and/or metabolised. (cAMP = cyclic adenosine monophosphate; DNA = deoxyribonucleic acid; mRNA = messenger ribonucleic acid)

Functional anatomy of the nervous system

Major components of the nervous system and their inter-relationships are depicted in Figure 25.3.

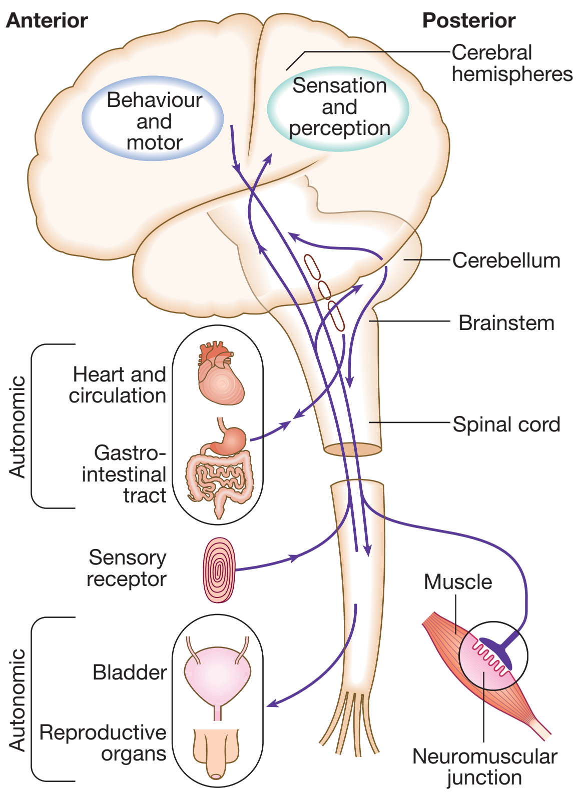

Fig. 25.3 The major anatomical components of the nervous system.

Cerebral hemispheres

The cerebral hemispheres coordinate the highest level of nervous function, the anterior half dealing with executive ('doing') functions and the posterior half constructing a perception of the environment. Each cerebral hemisphere has four functionally specialised lobes (Box 25.2 and Fig. 25.4), with some functions being distributed asymmetrically ('lateralised'), to produce cerebral dominance for functions such as motor control, speech or memory. Cerebral dominance aligns limb dominance with language function: in right-handed individuals the left hemisphere is almost always dominant, while around half of left-handers have a dominant right hemisphere.

Frontal lobes are concerned with executive function, movement, behaviour and planning. As well as the primary and supplementary motor cortex, there are specialised areas for control of eye movements, speech (Broca's area) and micturition.

The parietal lobes integrate sensory perception. The primary sensory cortex lies in the post-central gyrus of the parietal lobe. Much of the remainder is devoted to 'association' cortex, which processes and interprets input from the various sensory modalities. The supramarginal and angular gyri of the dominant parietal lobe form part of the language area (p. 1088). Close to these are regions dealing with numerical function. The non-dominant parietal lobe is concerned with spatial awareness and orientation.

The temporal lobes contain the primary auditory cortex and primary vestibular cortex. On the inner medial sides lie the olfactory and parahippocampal cortices, which are involved in memory function. The temporal lobes also link intimately to the limbic system, including the hippocampus and the amygdala, which are involved in memory and emotional processing. The dominant temporal lobe also participates in language functions, particularly verbal comprehension (Wernicke's area). Musical processing occurs across both temporal lobes, rhythm on the dominant side and melody/pitch on the non-dominant.

The occipital lobes are responsible for visual interpretation. The contralateral visual hemifield is represented in each primary visual cortex, with surrounding areas processing specific visual submodalities such as colour, movement or depth, and the analysis of more complex visual patterns such as faces.

Deep to the grey matter in the cortices, and the white matter (composed of neuronal axons), are collections of cells known as the basal ganglia that are concerned with motor control; the thalamus, which is responsible for the level of attention to sensory perception; the limbic system, concerned with emotion and memory; and the hypothalamus, responsible for homeostasis, such as temperature

25.2 Cortical lobar functions

		Effects of damage		
Lobe	**Function**	**Cognitive/behavioural**	**Associated physical signs**	**Positive phenomena**
Frontal	Personality Emotional control Social behaviour Contralateral motor control Language Micturition	Disinhibition Lack of initiation Antisocial behaviour Impaired memory Expressive dysphasia Incontinence	Impaired smell Contralateral hemiparesis Frontal release signs[1]	Seizures – often nocturnal with motor activity Versive head movements
Parietal: dominant	Language Calculation	Dysphasia Acalculia Dyslexia Apraxia[3] Agnosia[5]	Contralateral hemisensory loss Astereognosis[2] Agraphaesthesia[4] Contralateral homonymous lower quadrantanopia Asymmetry of optokinetic nystagmus (OKN)	Focal sensory seizures
Parietal: non-dominant	Spatial orientation Constructional skills	Neglect of contralateral side Spatial disorientation Constructional apraxia Dressing apraxia	Contralateral hemisensory loss Astereognosis[2] Agraphaesthesia[4] Contralateral homonymous lower quadrantanopia Asymmetry of OKN	Focal sensory seizures
Temporal: dominant	Auditory perception Language Verbal memory Smell Balance	Receptive aphasia Dyslexia Impaired verbal memory	Contralateral homonymous upper quadrantanopia	Complex hallucinations (smell, sound, vision, memory)
Temporal: non-dominant	Auditory perception Melody/pitch perception Non-verbal memory Smell Balance	Impaired non-verbal memory Impaired musical skills (tonal perception)	Contralateral homonymous upper quadrantanopia	Complex hallucinations (smell, sound, vision, memory)
Occipital	Visual processing	Visual inattention Visual loss Visual agnosia	Homonymous hemianopia (macular sparing)	Simple visual hallucinations (e.g. phosphenes, zigzag lines)

[1]Grasp reflex, palmomental response, pout response. [2]Inability to determine three-dimensional shape by touch. [3]Inability to perform complex movements in the presence of normal motor, sensory and cerebellar function. [4]Inability to 'read' numbers or letters drawn on hand, with the eyes shut. [5]Inability to recognise familiar objects, e.g. faces.

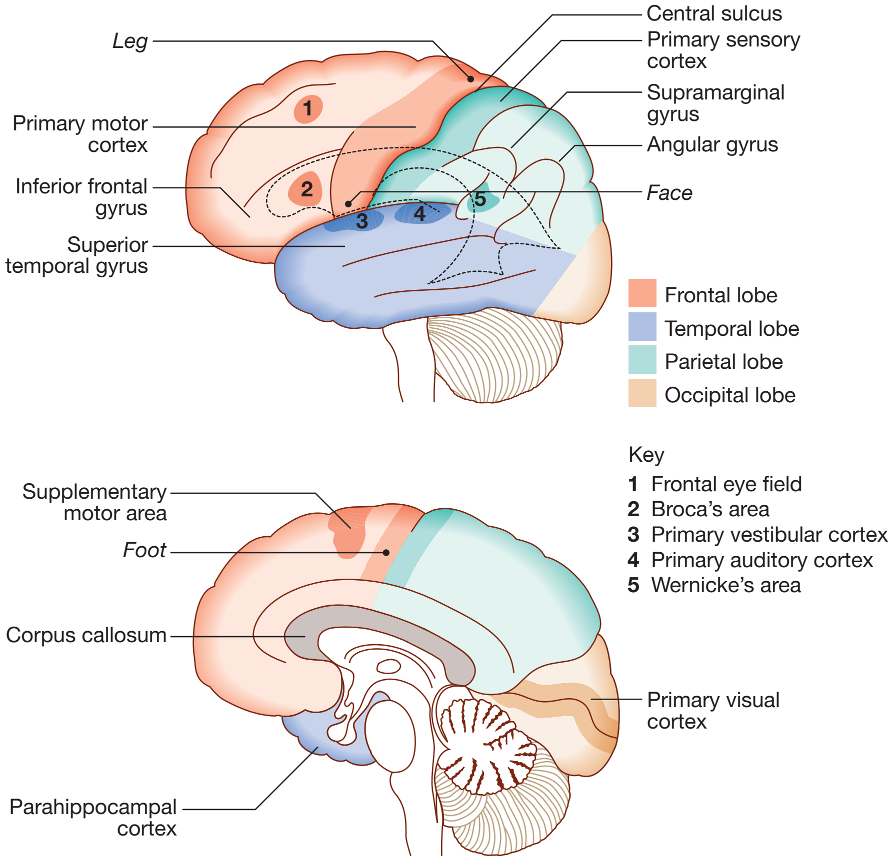

Fig. 25.4 Anatomy of the cerebral cortex.

and appetite control. The cerebral ventricles contain cerebrospinal fluid (CSF), which cushions the brain during cranial movement.

CSF is formed in the lateral ventricles and protects and nourishes the CNS. CSF flows from third to fourth ventricles and through foramina in the brainstem to dissipate over the surface of the CNS, eventually being reabsorbed into the cerebral venous system (see Fig. 25.44, p. 1132).

The brainstem

In addition to containing all the sensory and motor pathways entering and leaving the hemispheres, the brainstem houses the nuclei and projections of most cranial nerves, as well as other important collections of neurons in the reticular formation (Fig. 25.5). Cranial nerve nuclei provide motor control to muscles of the head (including face and eyes) and coordinate sensory input from the special sense organs and the face, nose, mouth, larynx and pharynx. They also relay autonomic messages, including pupillary, salivary and lacrimal functions. The reticular formation is mainly involved in control of conjugate eye movements, the maintenance of balance and arousal, and cardiorespiratory control.

The spinal cord

The spinal cord is the route for virtually all communication between the extracranial structures and the CNS. Afferent and efferent fibres are grouped in discrete bundles but collections of cells in the grey matter are responsible for lower-order motor reflexes and the primary processing of sensory information.

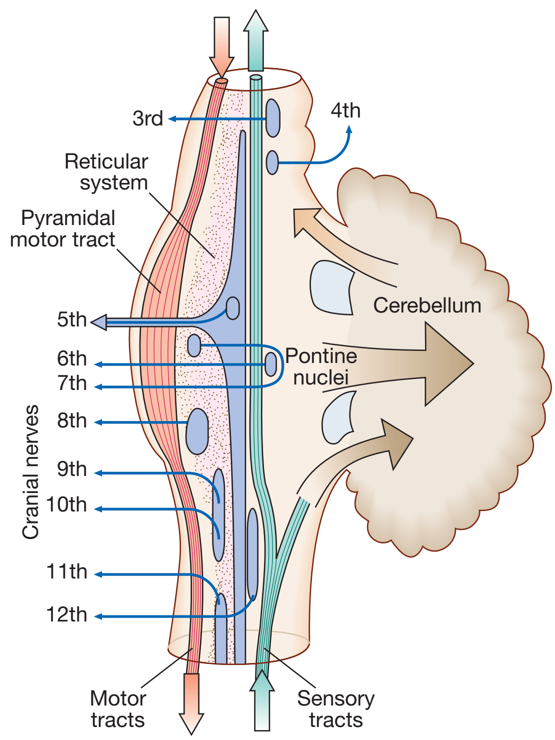

Fig. 25.5 Anatomy of the brainstem.

25

Sensory peripheral nervous system

The sensory cell bodies of peripheral nerves are situated just outside the spinal cord, in the dorsal root ganglia in the spinal exit foramina, while the distal ends of their neurons utilise various specialised endings for the conversion of external stimuli into action potentials. Sensory nerves consist of a combination of large, fast, myelinated axons (which carry information about joint position sense and commands to muscles) and smaller, slower, unmyelinated axons (which carry information about pain and temperature, as well as autonomic function).

Motor peripheral nervous system

The anterior horns of the spinal cord comprise cell bodies of the lower motor neurons. To increase conduction speed, peripheral motor nerve axons are wrapped in myelin produced by Schwann cells. Motor neurons release acetylcholine across the neuromuscular junction, which changes the muscle end-plate potential and initiates muscle contraction.

The autonomic system

The autonomic system regulates the cardiovascular and respiratory systems, the smooth muscle of the gastrointestinal tract, and many exocrine and endocrine glands throughout the body. The autonomic system is controlled centrally by diffuse modulatory systems in the brainstem, limbic system, hypothalamus and frontal lobes, which are concerned with arousal and background behavioural responses to threat. Autonomic output divides functionally and pharmacologically into two divisions: the parasympathetic and sympathetic systems.

The motor system

A programme of movement formulated by the pre-motor cortex is converted into a series of excitatory and inhibitory signals in the motor cortex that are transmitted to the spinal cord in the pyramidal tract (Fig. 25.6). This passes through the internal capsule and the ventral brainstem before crossing (decussating) in the medulla to enter the lateral columns of the spinal cord. The pyramidal tract 'upper motor neurons' synapse with the anterior horn cells of the spinal cord grey matter, which form the lower motor neurons.

Any movement necessitates changes in posture and muscle tone, sometimes in quite separate muscle groups to those involved in the actual movement. The motor system consists of a hierarchy of controls that maintain body posture and muscle tone, on which any movement is superimposed. In the grey matter of the spinal cord, the lowest order of the motor hierarchy controls reflex responses to stretch. Muscle spindles sense lengthening of the muscle; they provide the afferent side of the stretch reflex and initiate a monosynaptic reflex leading to protective or reactive muscle contraction. Inputs from the brainstem are largely inhibitory. Polysynaptic connections in the spinal cord grey matter control more complex reflex actions of flexion and extension of the limbs that form the basic building blocks of coordinated actions, but complete control requires input from the extrapyramidal system and the cerebellum.

Lower motor neurons

Lower motor neurons in the anterior horn of the spinal cord innervate a group of muscle fibres termed a 'motor unit'. Loss of lower motor neurons causes loss of contraction within this unit, resulting in weakness and reduced muscle tone. Subsequently, denervated muscle fibres atrophy, causing muscle wasting, and depolarise spontaneously, causing 'fibrillations'. Except in the tongue, these are usually perceptible only on electromyography (EMG; p. 1076). With the passage of time, neighbouring intact neurons sprout to provide re-innervation, but the neuromuscular junctions of the enlarged motor units are unstable and depolarise spontaneously, causing fasciculations (large enough to be visible). Fasciculations therefore imply chronic denervation with partial re-innervation.

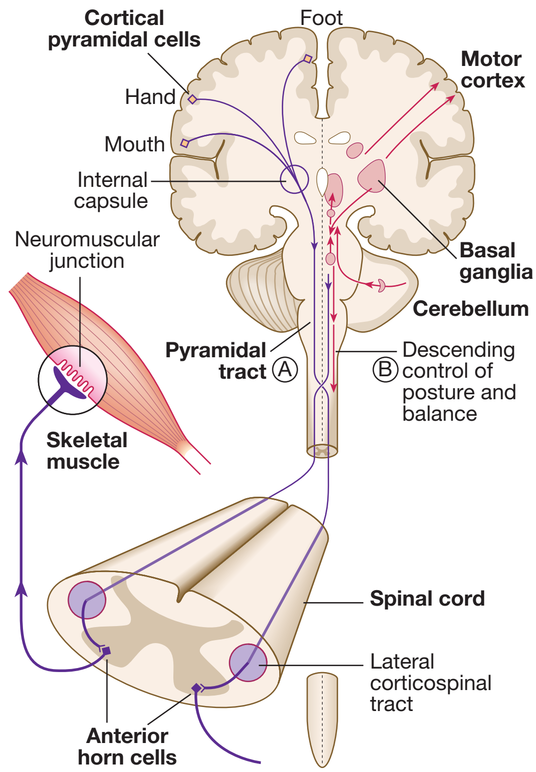

Fig. 25.6 The motor system. Neurons from the motor cortex descend as the pyramidal tract in the internal capsule and cerebral peduncle to the ventral brainstem, where most cross low in the medulla (A). In the spinal cord the upper motor neurons form the corticospinal tract in the lateral column before synapsing with the lower motor neurons in the anterior horns. The activity in the motor cortex is modulated by influences from the basal ganglia and cerebellum. Pathways descending from these structures control posture and balance (B).

Upper motor neurons

Upper motor neurons have both inhibitory and excitatory influence on the function of lower motor neurons in the anterior horn. Lesions affecting the upper motor neuron result in increased tone, most evident in the strongest muscle groups (i.e. the extensors of the lower limbs and the flexors of the upper limbs). The weakness of upper motor neuron lesions is conversely more pronounced in the opposing muscle groups. Loss of inhibition will also lead to brisk reflexes and enhanced reflex patterns of movement, such as flexion withdrawal to noxious stimuli and spasms of extension. The increased tone is more apparent during rapid stretching ('spastic catch') but may quickly give way with sustained tension (the 'clasp-knife' phenomenon). More primitive reflexes are also released, manifest as extensor plantar

responses. Spasticity may not be present until some weeks after the onset of an upper motor neuron lesion.

The extrapyramidal system

Circuits between the basal ganglia and the motor cortex constitute the extrapyramidal system, which controls muscle tone, body posture and the initiation of movement (see Fig. 25.6). Lesions of the extrapyramidal system produce an increase in tone that, unlike spasticity, is continuous throughout the range of movement at any speed of stretch ('lead pipe' rigidity). Involuntary movements are also a feature of extrapyramidal lesions (p. 1084), and tremor in combination with rigidity produces typical 'cogwheel' rigidity. Extrapyramidal lesions also cause slowed and clumsy movements (bradykinesia), which characteristically reduce in size with repetition, as well as postural instability, which can precipitate falls.

The cerebellum

The cerebellum fine-tunes and coordinates movement initiated by the motor cortex, including articulation of speech. It also participates in the planning and learning of skilled movements through reciprocal connections with the thalamus and cortex. A lesion in a cerebellar hemisphere causes lack of coordination on the same side of the body. Cerebellar dysfunction impairs the smoothness of eye movements, causing nystagmus, and renders speech dysarthric. In the limbs, the initial movement is normal, but as the target is approached, the accuracy of the movement deteriorates, producing an 'intention tremor'. The distances of targets are misjudged (dysmetria), resulting in 'past-pointing'. The ability to produce rapid, accurate, regularly alternating movements is also impaired (dysdiadochokinesis). The central vermis of the cerebellum is concerned with the coordination of gait and posture. Disorders of this area therefore produce a characteristic ataxic gait (see below).

Vision

The neurological organisation of visual pathways is shown in Figure 25.7. Fibres from ganglion cells in the retina pass to the optic disc and then backwards through the lamina cribrosa to the optic nerve. Nasal optic nerve fibres (subserving the temporal visual field) cross at the chiasm but temporal fibres do not. Hence, fibres in each optic tract and further posteriorly carry representation of contralateral visual space. From the lateral geniculate nucleus, lower fibres pass through the temporal lobes on their way to the primary visual area in the occipital cortex, while the upper fibres pass through the parietal lobe.

Normally, the eyes move conjugately (in the same direction at the same speed), though horizontal convergence allows fusion of images at different distances. The control of eye movements begins in the cerebral hemispheres, particularly within the frontal eye fields, and the pathway then descends to the brainstem with input from the visual cortex, superior colliculus and cerebellum. Horizontal and vertical gaze centres in the pons and mid-brain, respectively, coordinate output to the ocular motor nerve nuclei (3, 4 and 6), which are connected to each other by the medial longitudinal fasciculus (MLF) (Fig. 25.8). The MLF is particularly important in coordinating horizontal movements of the eyes. The resulting signals to extraocular muscles are supplied by the oculomotor (3rd), trochlear (4th) and abducens (6th) cranial nerves.

The pupillary size is determined by a combination of parasympathetic and sympathetic activity. Parasympathetic fibres originate in the Edinger–Westphal subnucleus of the 3rd nerve, and pass with the 3rd nerve to synapse in the ciliary ganglion before supplying the constrictor pupillae of the iris. Sympathetic fibres originate in the hypothalamus, pass down the brainstem and cervical spinal cord to emerge at T1, return up to the eye in association with the internal carotid artery, and supply the dilator pupillae.

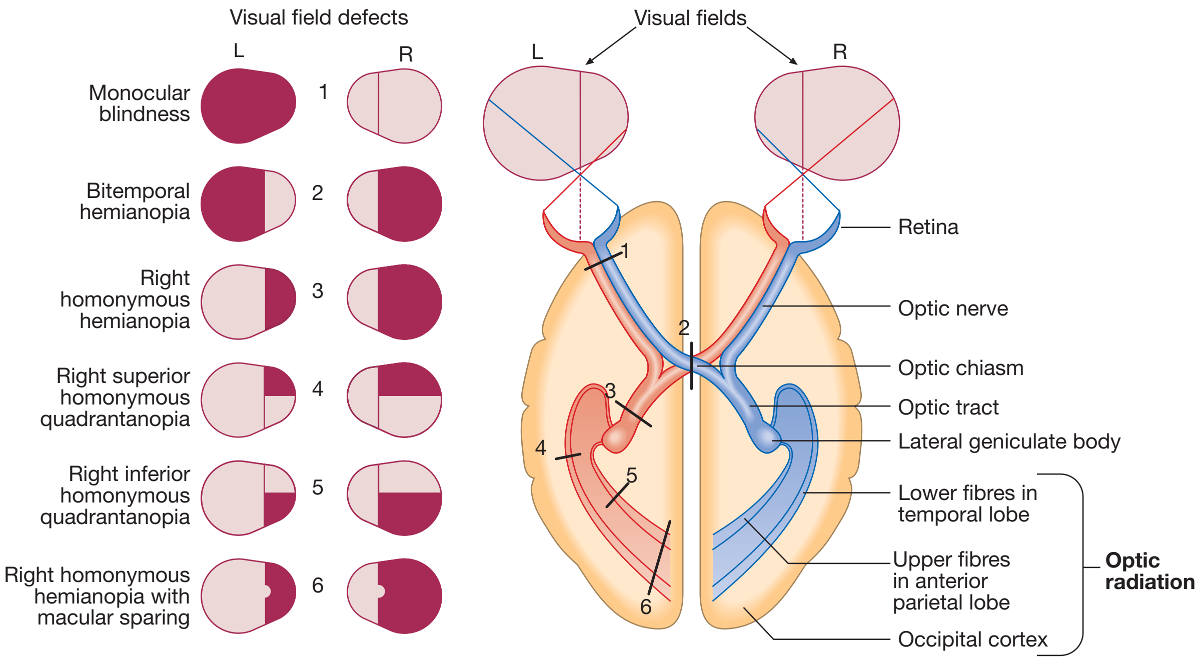

Fig. 25.7 Visual pathways and visual field defects. Schematic representation of eyes and brain in transverse section.

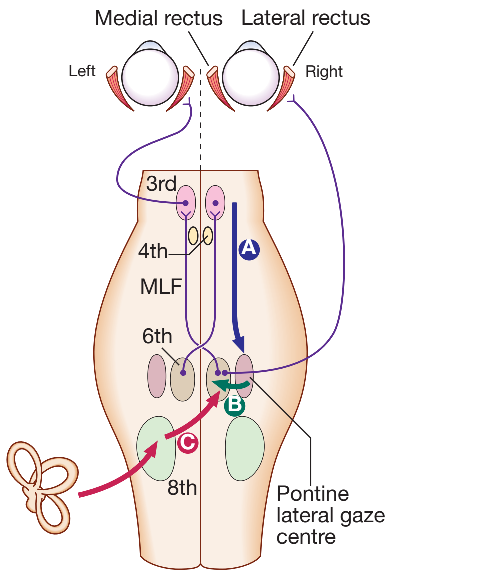

Fig. 25.8 Control of conjugate eye movements. Downward projections pass from the cortex to the pontine lateral gaze centre (A). The pontine gaze centre projects to the 6th cranial nerve nucleus (B), which innervates the ipsilateral lateral rectus and projects to the contralateral 3rd nerve nucleus (and hence medial rectus) via the medial longitudinal fasciculus (MLF). Tonic inputs from the vestibular apparatus (C) project to the contralateral 6th nerve nucleus via the vestibular nuclei.

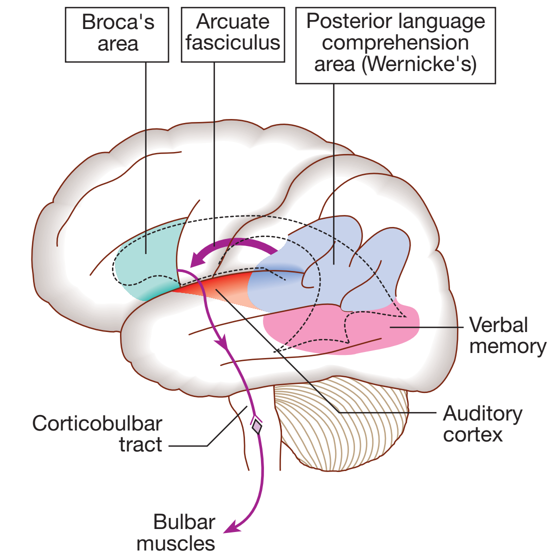

Fig. 25.9 Areas of the cerebral cortex involved in the generation of spoken language.

Speech

Much of the cerebral cortex is involved in the process of forming and interpreting communicating sounds, especially in the dominant hemisphere (see Box 25.2). Decoding of speech sounds (phonemes) is carried out in the upper part of the posterior temporal lobe. The attribution of meaning, as well as the formulation of the language required for the expression of ideas and concepts, occurs predominantly in the lower parts of the anterior parietal lobe (the angular and supramarginal gyri). The temporal speech comprehension region is called Wernicke's area (Fig. 25.9). Other parts of the temporal lobe contribute to verbal memory, where lexicons of meaningful words are 'stored'. Parts of the non-dominant parietal lobe appear to contribute to non-verbal aspects of language in recognising meaningful intonation patterns (prosody).

The frontal language area is in the posterior end of the dominant inferior frontal gyrus known as Broca's area. This receives input from the temporal and parietal lobes via the arcuate fasciculus. The motor commands generated in Broca's area pass to the cranial nerve nuclei in the pons and medulla, as well as to the anterior horn cells in the spinal cord. Nerve impulses to the lips, tongue, palate, pharynx, larynx and respiratory muscles result in the series of ordered sounds comprising speech. The cerebellum also plays an important role in coordinating speech, and lesions of the cerebellum lead to dysarthria, where the problem lies in motor articulation of speech.

The somatosensory system

The body surface can be described by dermatomes, each dermatome being an area of skin in which sensory nerves derive from a single spinal nerve root (Fig. 25.10). Sensory information ascends in two anatomically discrete systems (Fig. 25.11). Fibres from proprioceptive organs and those mediating specific sensation (including vibration) enter the spinal cord at the posterior horn and pass without synapsing into the ipsilateral posterior columns. In contrast, fibres conveying pain and temperature sensory information (nociceptive neurons) synapse with second-order neurons that cross the midline in the spinal cord before ascending in the contralateral anterolateral spinothalamic tract to the brainstem.

The second-order neurons of the dorsal column sensory system cross the midline in the upper medulla to ascend through the brainstem. Here they lie just medial to the (already crossed) spinothalamic pathway. Brainstem lesions can therefore cause sensory loss affecting all modalities on the contralateral side of the body. Distribution of facial sensory loss due to brainstem lesions arises from the anatomy of the trigeminal fibres within the brainstem. Fibres from the back of the face (near the ears) descend within the brainstem to the upper part of the spinal cord before synapsing, the second-order neurons crossing the midline and then ascending with the spinothalamic fibres. Fibres conveying sensation from more anterior areas of the face descend a shorter distance in the brainstem. Thus, sensory loss in the face from low brainstem lesions is in a 'balaclava helmet' distribution, as the longer descending trigeminal fibres are affected. Both dorsal column and spinothalamic tracts end in the thalamus, relaying from there to the parietal cortex.

Pain

Pain is a complex perception that is only partly related to activity in nociceptor neurons (p. 1338 and Fig. 34.2). Higher up, chronic and severe pain interacts extensively with mood and can exacerbate or be exacerbated by mood disorder, including depression and anxiety. Modification of psychological and psychiatric sequelae is a vital part of pain management (p. 1343).

Sphincter control

The sympathetic supply to the bladder arises from roots T11–L2 to synapse in the inferior hypogastric plexus, while the parasympathetic supply leaves from S2–4. In addition, a somatic supply to the external (voluntary) sphincter arises from S2–4, travelling via the pudendal nerves.

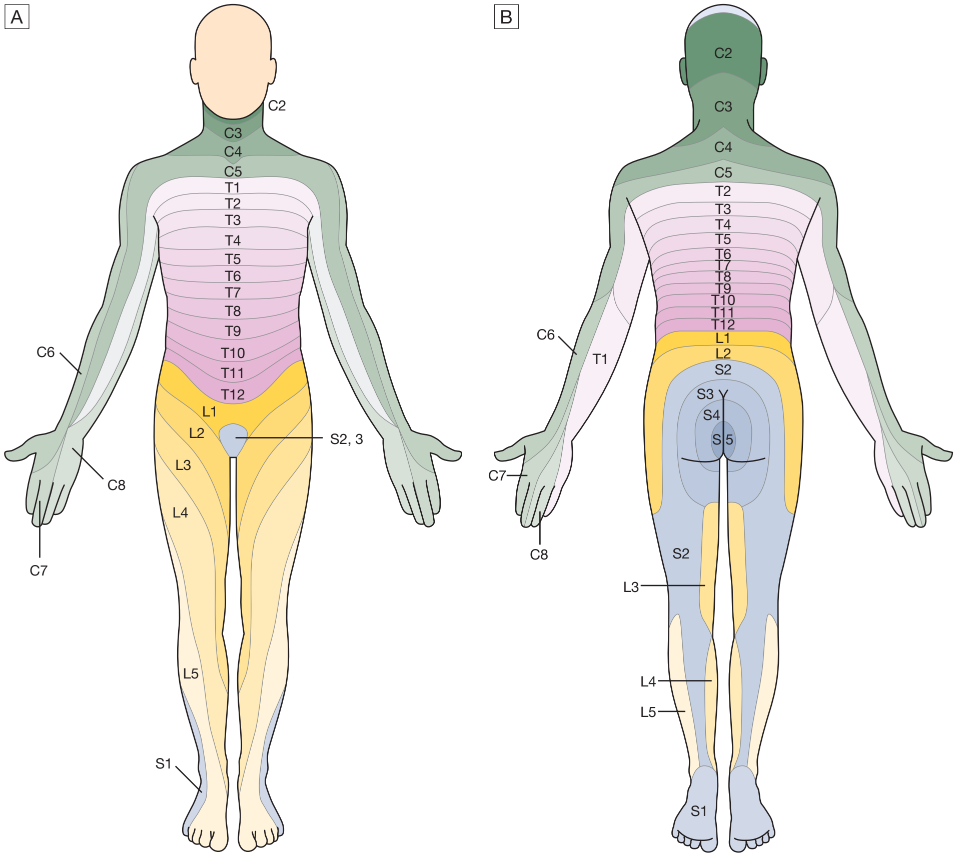

Fig. 25.10 The areas supplied by specific levels of the spinal cord. These are approximations and in practice there is much overlap. The clinical utility of these dermatomes has diminished somewhat with the advent of good magnetic resonance imaging of the spinal cord but it remains important to ascertain the presence of a 'spinal level' of sensation, to remember the supply of saddle area, and to note the cervical descent of some facial spinothalamic pathways. **A** Anterior. **B** Posterior.

Storage of urine is maintained by inhibiting parasympathetic activity and thus relaxing the detrusor muscle of the bladder wall. Continence is also helped by simultaneous sympathetic- and somatic-mediated tonic contraction of the urethral sphincters. Voiding in adults is usually carried out under conscious control, which triggers relaxation of tonic inhibition on the pontine micturition centre from higher centres, leading to relaxation of the pelvic floor muscles and external and internal urethral sphincters, along with parasympathetic-mediated detrusor contraction.

Personality and mood

The physiology and pathology of mood disorders are discussed elsewhere (Ch. 28) but it is important to remember that any process affecting brain function may influence mood and affect. Conversely, mood disorder may have a significant effect on perception and function. It can be difficult to disentangle whether psychological and psychiatric changes are the cause or the effect of any neurological symptoms.

Sleep

The function of sleep is unknown but it is required for health. Sleep is controlled by the reticular activating system in the upper brainstem and diencephalon. It is composed of different stages that can be visualised on electroencephalography (EEG). As drowsiness occurs, normal EEG background alpha rhythm disappears and activity becomes dominated by deepening slow-wave activity. As sleep deepens and dreaming begins, the limbs become flaccid, movements are 'blocked' and EEG signs of rapid eye movements (REM) are superimposed on the slow wave. REM sleep persists for a short spell before another slow-wave spell starts, the cycle repeating several times throughout the night. REM phases lengthen as sleep progresses. REM sleep seems to be the most important part of the sleep cycle for refreshing cognitive processes, and REM sleep deprivation causes tiredness, irritability and impaired judgement.

Localising lesions in the central nervous system

After taking a history and examining the patient, the clinician should have an idea of the nature and site of any pathology (see Box 25.10). Given the intricate anatomy of the brainstem, this section will dwell on the possible localisation in more detail (see Fig. 25.5).

Brainstem lesions typically present with symptoms due to cranial nerve, cerebellar and upper motor neuron dysfunction and are most commonly caused by vascular disease. Since the anatomy of the brainstem is very precisely organised, it is usually possible to localise the site of a lesion on the basis of careful history and examination in order to determine exactly

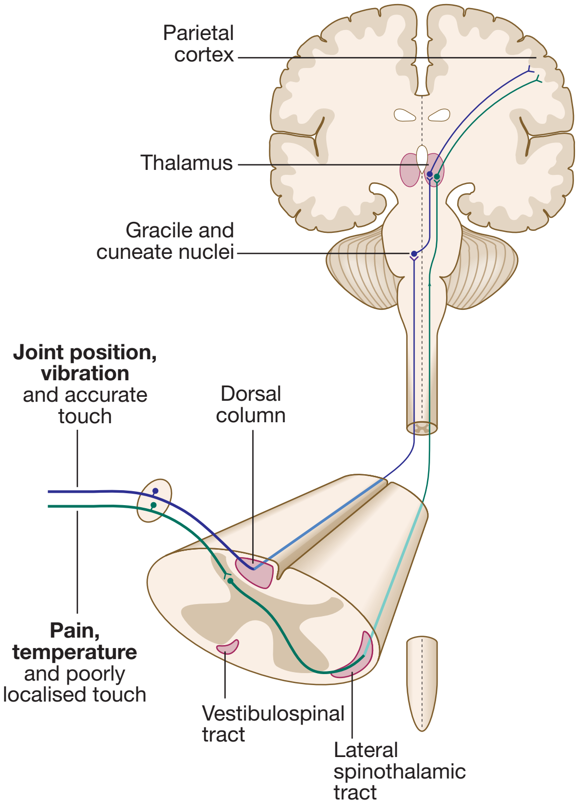

Fig. 25.11 **The main somatic sensory pathways.**

25.3 Major focal brainstem syndromes

Name of syndrome	Site of lesions	Clinical features
Weber	Anterior cerebral peduncle (mid-brain)	Ipsilateral 3rd palsy Contralateral upper motor neuron 7th palsy Contralateral hemiplegia
Claude	Cerebral peduncle Involving red nucleus	Ipsilateral 3rd palsy Contralateral cerebellar signs
Parinaud	Dorsal mid-brain (tectum)	Vertical gaze palsy Convergence disorders Convergence retraction nystagmus Pupillary and lid disorders
Millard–Gubler	Ponto-medullary junction	Ipsilateral 6th palsy Ipsilateral lower motor neuron 7th palsy Contralateral hemiplegia
Wallenberg	Lateral medulla	Ipsilateral 5th, 9th, 10th, 11th palsy Ipsilateral Horner's syndrome Ipsilateral cerebellar signs Contralateral spinothalamic sensory loss Vestibular disturbance

which tracts/nuclei are affected, usually invoking the fewest number of lesions.

For example, in a patient presenting with sudden onset of upper motor neuron features affecting the right face, arm and leg in association with a left 3rd nerve palsy, the lesion will be in the left cerebral peduncle in the brainstem and the pathology is likely to have been a discrete stroke, as the onset was sudden. This combination of symptoms and signs is known as Weber's syndrome, and is one of several well-described brainstem syndromes, which are listed in Box 25.3. The effects of individual cranial nerve deficits are discussed in the sections on eye movements (p. 1088) and on facial weakness, sensory loss in brainstem lesions, dysphonia and dysarthria, and bulbar symptoms (pp. 1082, 1083, 1087 and 1093).

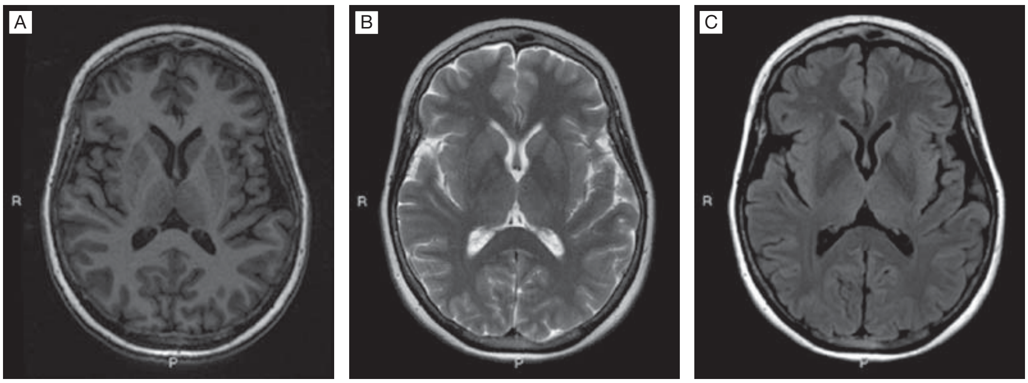
Investigation of neurological disease

Experienced clinicians make most neurological diagnoses on history alone, with a lesser contribution from examination and investigation. As investigations become more complex and more easily available, it is tempting to adopt a 'scan first, think later' approach to neurological symptoms. The frequency of 'false-positive' results, the wide range of normality, and the negative implications for patients (unnecessary expense, inconvenience, discomfort and worry) necessitate a more thoughtful approach. Investigation may include assessment of structure (imaging) and function (neurophysiology). Neurophysiological testing has become so complex that in some countries it constitutes a separate specialty focusing on electroencephalography, evoked potentials, nerve conduction studies and electromyography.

Neuroimaging

Neurological imaging has traditionally allowed only assessment of structure but advances are allowing much more sophistication. Imaging modalities can use X-rays (plain X-rays, computed tomography (CT), CT angiography, myelography and angiography), magnetic resonance (MR imaging (MRI), MR angiography (MRA)), ultrasound (Doppler imaging of blood vessels) and nuclear medicine techniques (single photon emission computed tomography (SPECT) and positron emission tomography (PET)). The uses and limitations of each of these are shown in Box 25.4. Different sequences for analysing MRI signals can provide helpful information for characterising tissues and pathologies (Box 25.5).

Specialist MR techniques, such as functional MRI (fMRI), MR spectroscopy or diffusion tensor imaging (DTI), can be used to assess brain metabolism and chemical compositions. This may be dynamic and can provide 'maps' of cortical function to help plan lesionectomy and epilepsy surgery. Similarly, MR spectroscopy can outline the chemical composition of specific regions, providing notions of whether lesions are ischaemic, neoplastic or inflammatory.



Some degenerative neurological conditions cause functional rather than structural abnormalities that make metabolic and neurochemical assessment increasingly useful. PET scanning can display glucose metabolism in dementia and epilepsy. SPECT scanning uses the lipid-soluble properties of radioactive tracers to mark cerebral blood flow at the time of injection to help in investigating seizures. Dopaminergic pathway tracers can assess the integrity of the nigrostriatal pathway in patients with possible parkinsonism.

i 25.4 Imaging techniques for the nervous system

Technique	Applications	Advantages	Disadvantages	Comments
X-ray/CT	Plain X-rays, CT, CTA Radiculography Myelography Intra-arterial angiography	Widely available Relatively cheap Relatively quick	Ionising radiation Contrast reactions Invasive (myelography and angiography)	X-rays: used for fractures or foreign bodies CT: first line for stroke Intra-arterial angiography: gold standard for vascular lesions
MRI	Structural imaging MRA Functional MRI MR spectroscopy	High-quality soft tissue images, useful for posterior fossa and temporal lobes No ionising radiation Non-invasive	Expensive Less widely available MRA images blood flow, not vessel anatomy Claustrophobic Pacemakers are a contraindication Contrast (gadolinium) reactions	Functional MR and spectroscopy: mainly research tools
Ultrasound	Doppler Duplex scans	Cheap Quick Non-invasive	Operator-dependent Poor anatomical definition	Screening tool to assess need for carotid endarterectomy
Radioisotope	Isotope brain scan SPECT PET	In vivo imaging of functional anatomy (ligand binding, blood flow)	Poor spatial resolution Ionising radiation Expensive Not widely available	Isotope scans: obsolete SPECT: useful in movement disorders, epilepsy and dementias PET: mainly research tool

(CT = computed tomography; CTA = computed tomographic angiography; MRA = magnetic resonance angiography; MRI = magnetic resonance imaging; PET = positron emission tomography; SPECT = single photon emission computed tomography)

Head and orbit

Plain skull X-rays now have a very limited role in neurological disease. CT or MRI is needed for intracranial imaging. CT is good for demonstrating bone and calcification well. It will also detect abnormalities of the brain and ventricles, such as atrophy, tumours, cysts, abscesses, vascular lesions and hydrocephalus. Diagnostic yield may be improved by the use of intravenous contrast and thinner slicing but CT is not optimal for lesions of meninges, cranial nerves or subtle parenchymal changes.

MRI resolution is unaffected by bone and so is more useful in posterior fossa disease. Its sensitivity for cortical and white matter changes makes it the modality of choice in inflammatory conditions such as multiple sclerosis and in the investigation of epilepsy. Different MRI techniques can selectively suppress

signal from fluid or fat, for example, and so increase sensitivity for more subtle pathologies.

Examples of brain imaged by the various techniques are shown in Figure 25.12.

Cervical, thoracic and lumbar spine

X-rays are useful for imaging bony structures and can show destruction or damage to vertebrae, for example, but will provide no information about non-bony tissues, such as intervertebral discs, spinal cord and nerve roots. They have some usefulness in dynamic imaging, e.g. flexion/extension of the spine, in the assessment of instability. MRI has transformed spinal investigation, as it can give information not only about vertebrae and intervertebral discs but also about their effects on the spinal cord and nerve roots. Myelography (usually with CT) is an invasive technique requiring injection of contrast into the lumbar theca. While outlining the nerve roots and spinal cord provides some detail about abnormal structure, the accuracy and availability of MRI have reduced the need for it. Myelography may still be used where MRI is unavailable, contraindicated, or precluded by a patient's claustrophobia. Examples of the cervical spine imaged by plain X-rays, myelography and MRI are shown in Figure 25.13.

Blood vessels

Imaging of the extra- and intracranial blood vessels and disturbance of arterial or venous blood flow is described on page 1161.

Neurophysiological testing

Electroencephalography

The electroencephalogram (EEG) detects electrical activity arising in the cerebral cortex via electrodes placed on the scalp to record the amplitude and frequency of the resulting waveforms. With closed eyes, the normal background activity is 8–13 Hz (known as alpha rhythm), most prominent occipitally and suppressed on eye opening. Other frequency bands seen over different parts of the brain in different circumstances are beta (faster than 13/sec), theta (4–8/sec) and delta (slower than 4/sec). Normal EEG patterns evolve with age and alertness; lower frequencies predominate in the very young and during sleep.

In recent years, digital technology has allowed longer, cleaner EEG recordings that can be analysed in a number of ways and recorded alongside contemporaneous video of any clinical 'event'. Meanwhile, the development of intracranial recording allows more sensitive monitoring via surgically placed electrodes in and around lesions to help increase the efficacy and safety of epilepsy surgery.

Abnormal EEGs result from a number of conditions. Examples include an increase in fast frequencies (beta) seen with sedating drugs such as benzodiazepines, or marked focal slowing noted over a structural lesion such as a tumour or an infarct. Improved quality and accessibility of imaging have made EEG redundant in lesion localisation, except in the specialist investigation of epilepsy (p. 1100). EEG remains useful in progressive and continuous disorders such as reduced consciousness (p. 194), encephalitis

(p. 1121), and certain dementias such as Creutzfeldt–Jakob disease (p. 1127).

Since sleep induces marked changes in cerebral activity, EEG can be useful in diagnosis of sleep disturbances. In paroxysmal disorders such as epilepsy, EEG is at its most useful when it captures activity during one of the events in question. Over 50% of patients with epilepsy have a normal 'routine' EEG but, conversely, the presence of epileptiform features does not of itself make a diagnosis. Up to 5% of some normal populations may demonstrate epileptiform discharges on EEG, preventing its use as a screening test for epilepsy, most notably in younger patients with a family history of epilepsy. In view of this, the EEG should not be used where epilepsy is merely 'possible'.

25

Therefore the EEG in epilepsy is predominantly used for classification and prognostication, but in some patients can help localise the seat of epileptiform discharges when surgery is being considered. During a seizure, high-voltage disturbances of background activity ('discharges') are often noted. These may be generalised, as in the 3 Hz 'spike and wave' of childhood absence epilepsy, or more focal, as in localisation-related epilepsies (Fig. 25.14). Techniques such as hyperventilation or photic stimulation can be used to increase the yield of epileptiform changes, particularly in the generalised epilepsy syndromes. While some argue that it is possible to detect 'spikes' and 'sharp waves' to lend support to a clinical diagnosis, these are non-specific and therefore not diagnostic, and can lead an unwary clinician to err in ascribing other symptoms to epilepsy.

Nerve conduction studies

Electrical stimulation of a nerve causes an impulse to travel both efferently and afferently along the underlying axons. Nerve conduction studies (NCS) make use of this, recording action potentials as they pass along peripheral nerves and (with motor nerves) as they pass into the muscle belly. Digital recording has enhanced sensitivity and reproducibility of these tiny potentials. By measuring the time taken to traverse a known distance, it is possible to calculate nerve conduction velocities (NCVs). Healthy nerves at room temperature will conduct at a speed of 40–50 m/sec. If the recorded potential is smaller than expected, this provides evidence of a reduction in the overall number of functioning axons. Significant slowing of conduction velocity, in contrast, suggests impaired conduction due to peripheral nerve demyelination. Such changes in NCS may be diffuse (as in a hereditary demyelinating peripheral neuropathy, p. 1138), focal (as in pressure palsies, p. 1139) or multifocal (e.g. Guillain–Barré syndrome, p. 1140; mononeuritis multiplex, p. 1140). The information gained can allow the disease responsible for peripheral nerve dysfunction to be better deduced (see Box 25.84, p. 1139).

Stimulation of motor nerves allows for the recording of compound muscle action potentials (CMAPs) over muscles (Fig. 25.15). These are around 500 times larger than sensory nerve potentials, typically around 1–20 millivolts. Since a proportion of stimulated impulses in motor nerves will 'reflect' back from the anterior horn cell body (forming the 'F' wave), it is also possible to obtain some information about the condition of nerve roots.

Repetitive nerve stimulation (RNS) at 3–15/sec provides consistent CMAPs in healthy muscle. In myasthenia gravis (p. 1141), however, where there is partial blockage of acetylcholine receptors, there is a diagnostic fall (decrement) in CMAP amplitude. In contrast, an increasing CMAP with high-frequency RNS is seen in Lambert–Eaton myasthenic syndrome (p. 1143).

Electromyography

Electromyography (EMG) is usually performed alongside NCS and involves needle recording of muscle electrical potential during rest and contraction. At rest, muscle is electrically silent but loss of nerve supply causes muscle membrane to become unstable, manifest as fibrillations, positive sharp waves ('spontaneous activity') or fasciculations. Motor unit action potentials are recorded during muscle contraction. Axonal loss or destruction will result in fewer motor units. Resultant sprouting of remaining units will lead to increasing size of each individual unit on EMG. Myopathy, in contrast, causes muscle fibre splitting, which results in a large number of smaller units on EMG. Other abnormal activity, such as myotonic discharges, may signify abnormal ion channel conduction, as in myotonic dystrophy or myotonia congenita.

Specialised single-fibre electromyography (SFEMG) can be used to investigate neuromuscular junction transmission. Measuring 'jitter' and 'blocking' can identify the effect of antibodies in reducing the action of acetylcholine on the receptor.

Evoked potentials

The cortical response to visual, auditory or electrical stimulation can be measured on an EEG as an evoked potential (EP). If a stimulus is provided – e.g. to the eye, the tiny EEG response can be discerned when averaging 100–1000 repeated stimuli. Assessing the latency (the time delay) and amplitude can give

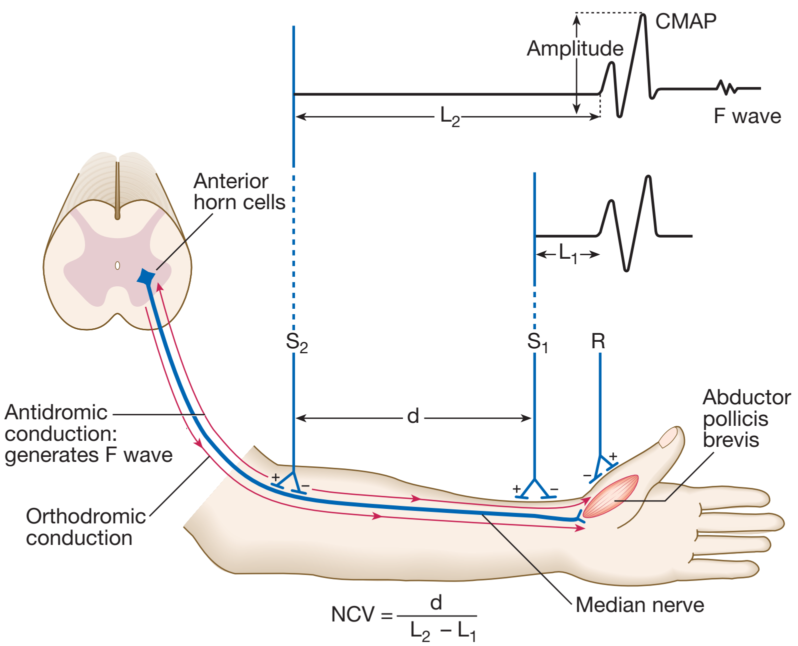

Fig. 25.15 Motor nerve conduction tests. Electrodes (R) on the muscle (abductor pollicis here) record the compound muscle action potential (CMAP) after stimulation at the median nerve at the wrist (S_1) and from the elbow (S_2). The velocity from elbow to wrist can be determined if the distance between the two stimulating electrodes (d) is known. A prolonged L_1 (L = latency) would be caused by dysfunction distally in the median nerve (e.g. in carpal tunnel syndrome). A prolonged L_2 is caused by slow nerve conduction (as in demyelinating neuropathy). The F wave is a small delayed response that appears when the electrical signal travels backwards to the anterior horn cell, sparking a second action potential in a minority of fibres (see text). (NCV = nerve conduction velocity)

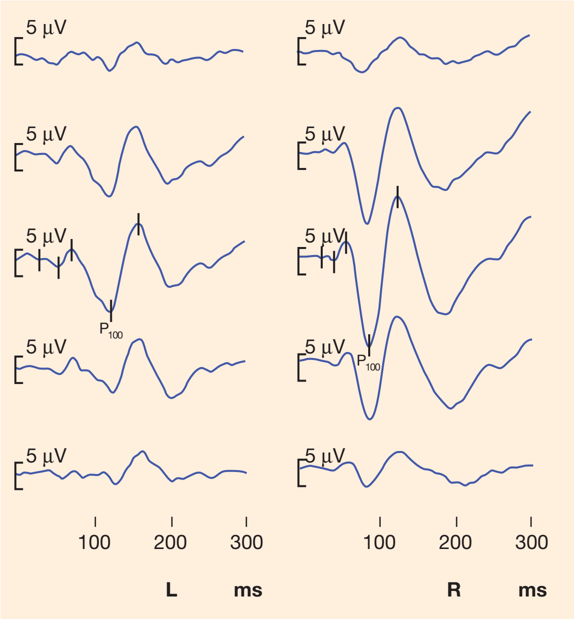

Fig. 25.16 Visual evoked potential (VEP) recording. The abnormality is in the left hemisphere, with delay in latency and a reduction in signal of the P_{100}.

information about the integrity of the relevant pathway. MRI now provides more information about CNS pathways, thus reducing reliance on EPs. In practice, visual evoked potentials (VEPs) are most commonly used to help differentiate CNS demyelination from small-vessel white-matter changes (Fig. 25.16).

Magnetic stimulation

Central conduction times can also be measured using electromagnetic induction of action potentials in the cortex or spinal cord by the local application of specialised coils. Again, MRI has made this technique largely redundant, other than for research.

Routine blood tests

Many systemic conditions that can affect the nervous system can be identified by simple blood tests. Nutritional deficiencies, metabolic disturbances, inflammatory conditions or infections may all present or be associated with neurological symptoms, and basic blood tests (full blood count, erythrocyte sedimentation rate, C-reactive protein, biochemical screening) may provide clues. Specific blood tests will be highlighted in the relevant subsections of this chapter. Human immunodeficiency virus (HIV) infection is increasingly recognised as a cause of neurological disease and the clinician should have a low threshold for checking this.

Immunological tests

Recent developments have seen a host of new immune-mediated conditions emerge in clinical neurology, with antibody targets ranging from muscle and neuromuscular junction disturbance (causing weakness and muscle pain) to specific neuronal ion channels (causing cognitive decline, epilepsy and psychiatric changes). The 21st century has seen the identification of many causative antibodies (see Boxes 25.52 and 25.53, p. 1111) and it is likely that further conditions will turn out to have an immune basis.

Genetic testing

This evolving field represents a huge untapped area for neurological exploration, particularly with the development of genome-wide association study (GWAS) and whole-genome sequencing. Relevant subsections will detail the increasing numbers of inherited neurological conditions that can now be diagnosed by DNA analysis (p. 56). These include diseases caused by increased numbers of trinucleotide repeats, such as Huntington's disease (p. 1114); myotonic dystrophy (p. 1143); and some types of spinocerebellar ataxia (p. 1115). Mitochondrial DNA can also be sequenced to diagnose relevant disorders (p. 1144).

Lumbar puncture

Lumbar puncture (LP) is the technique used to obtain both a CSF sample and an indirect measure of intracranial pressure. After local anaesthetic injection, a needle is inserted between lumbar spinous processes (usually between L3 and L4) through the dura and into the spinal canal. Intracranial pressure can be deduced (if patients are lying on their side) and CSF removed for analysis. CSF pressure measurement is important in the diagnosis and monitoring of idiopathic intracranial hypertension (p. 1133). In this condition, the LP itself is therapeutic.

CSF is normally clear and colourless, and the tests that are usually performed include a naked eye examination of the CSF and centrifugation to determine the colour of the supernatant (yellow, or xanthochromic, some hours after subarachnoid haemorrhage; p. 1160). Measurement of absorption of specific light wavelengths helps quantify the amount of haem metabolites in CSF. Routine analysis involves a cell count, as well as glucose and protein concentrations.

CSF assessment is important in investigating infections (meningitis or encephalitis), subarachnoid haemorrhage and inflammatory conditions (multiple sclerosis, sarcoidosis and cerebral lupus). Normal values and abnormalities found in specific conditions are shown in Box 25.6.

More sophisticated analysis allows measurement of antibody formation solely within the CNS (oligoclonal bands), genetic analysis (e.g. polymerase chain reaction (PCR) for herpes simplex or tuberculosis), immunological tests (paraneoplastic antibodies) and cytology (to detect malignant cells).

If there is a cranial space-occupying lesion causing raised intracranial pressure, LP presents a theoretical risk of downward shift of intracerebral contents, a potentially fatal process known as coning (p. 1128). Consequently, LP is contraindicated if there is any clinical suggestion of raised intracranial pressure (papilloedema), depressed level of consciousness, or focal neurological signs suggesting a cerebral lesion, until imaging (by CT or MRI) has excluded a space-occupying lesion or hydrocephalus. When there is a risk of local haemorrhage (thrombocytopenia, disseminated intravascular coagulation or anticoagulant treatment), then caution should be exercised or specific measures should be taken. LP can be safely performed in patients on antiplatelet drugs or low-dose heparin, but may be unsafe in patients who are fully anticoagulated due to the increased risk of epidural haematoma.

About 30% of LPs are followed by a postural headache, due to reduced CSF pressure. The frequency of headache

25.6 How to interpret cerebrospinal fluid results

	Normal	Subarachnoid haemorrhage	Acute bacterial meningitis	Viral meningitis	Tuberculous meningitis	Multiple sclerosis
Pressure	50–250 mm of water	Increased	Normal/increased	Normal	Normal/increased	Normal
Colour	Clear	Blood-stained Xanthochromic	Cloudy	Clear	Clear/cloudy	Clear
Red cell count ($\times 10^6$/L)	0–4	Raised	Normal	Normal	Normal	Normal
White cell count ($\times 10^6$/L)	0–4	Normal/slightly raised	1000–5000 polymorphs	10–2000 lymphocytes	50–5000 lymphocytes	0–50 lymphocytes
Glucose	>50–60% of blood level	Normal	Decreased	Normal	Decreased	Normal
Protein	<0.45 g/L	Increased	Increased	Normal/increased	Increased	Normal/increased
Microbiology	Sterile	Sterile	Organisms on Gram stain and/or culture	Sterile/virus detected	Ziehl–Neelsen/auramine stain or tuberculosis culture positive	Sterile
Oligoclonal bands	Negative	Negative	Can be positive	Can be positive	Can be positive	Often positive

can be reduced by using smaller or atraumatic needles. Rarer complications involve transient radicular pain, and pain over the lumbar region during the procedure. Aseptic technique renders secondary infections such as meningitis extremely rare.

Biopsy

Biopsies of nervous tissue (peripheral nerve, muscle, meninges or brain) are occasionally required for diagnosis.

Nerve biopsy can help in the investigation of peripheral neuropathy. Usually, a distal sensory nerve (sural or radial) is targeted. Histological examination can help identify underlying causes, such as vasculitides or infiltrative disorders like amyloid. Nerve biopsy should not be undertaken lightly since there is an appreciable morbidity; it should be reserved for cases where the diagnosis is in doubt after routine investigations and where it will influence management.

Muscle biopsy is performed more frequently and is indicated for the differentiation of myositis and myopathies. These conditions can usually be distinguished by histological examination, and enzyme histochemistry can be useful when mitochondrial diseases and storage diseases are suspected. The quadriceps muscle is most commonly biopsied but other muscles may also be sampled if they are involved clinically. Although pain and infection can follow the procedure, these are less of a problem than after nerve biopsy.

Brain biopsy is required when imaging fails to clarify the nature of intracerebral lesions, e.g. in unexplained degenerative diseases such as unusual cases of dementia and in patients with brain tumours. Most biopsies are performed stereotactically through a burr hole in the skull, which lowers complication rates. Nevertheless, haemorrhage, infection and death still occur and brain biopsy should be considered only if a diagnosis is otherwise elusive.

Biopsy of other organs can be useful in the diagnosis of systemic disorders presenting as neurological problems, such as tonsillar biopsy (diagnosis of prion diseases), or rectal or fat biopsy (for assessment of amyloid).

Presenting problems in neurological disease

While history is important in all medical specialties, it is especially key in neurology, where many neurological diagnoses have no confirmatory test. History-taking allows doctor and patient to get to know one another; many neurological diseases follow chronic paths and this may be the first of many such consultations. It also allows the clinician to obtain information about the patient's affect, cognition and psychiatric state.

History-taking is a highly active process. While there are generic templates (Box 25.7), each individual story will follow its own course, and diagnostic considerations during the history will guide further questioning.

It is important to be clear about what patients mean by certain words. They may find it difficult to describe symptoms: for instance, weakness may be called 'numbness', while there are many possible interpretations of 'dizziness'. These must be clarified; even in emergency situations, a clear, accurate history is the foundation of any management plan. While the story should come primarily from the patient, input from eye-witnesses and family members is crucial if the patient is unable to provide details or if there has been loss of consciousness. This need for corroboration and clarification means the telephone is as important as any investigation.

The aim of the history is to address two key issues: where is the lesion and what is the lesion (Box 25.8)? These should remain uppermost in the doctor's mind while the history is being elicited. Some common combinations of symptoms may suggest particular locations for a lesion (Box 25.10). Enquiry about handedness is important; lateralisation of the dominant hand helps designate the dominant hemisphere, which in turn may help to localise any pathologies, or to plan rehabilitation or treatment strategies in asymmetrical disorders such as stroke or Parkinson's disease.

Epidemiology must be borne in mind. How likely is it that this particular patient has any specific condition under consideration?

25.7 How to take a neurological history

Introduction

- Age and sex
- Handedness

Presenting complaint

- Symptoms (clarify: see text)
- Overall pattern: intermittent or persistent?
- If intermittent, how often do symptoms occur and how long do they last?
- Speed of onset: seconds, minutes, hours, days, weeks, months, years, decades?
- Better, worse or the same over time?
- Associated symptoms (including non-neurological)
- Disability caused by symptoms
- Change in walking
- Difficulty with fine hand movements, e.g. writing, fastening buttons, using cutlery
- Effect on work, family life and leisure

Background

- Previous neurological symptoms and whether similar to current symptoms
- Previous medical history
- Domestic situation
- Driving licence status
- Medications (current and at time of symptom onset)
- Alcohol/smoking habits
- Recreational drug and other toxin exposure
- Family history and developmental history
- What are patient's thoughts/fears/concerns?

25.8 The key diagnostic questions

Where is the lesion?

- Is it neurological?
- If so, to which part of the nervous system does it localise?
  - Central versus peripheral
  - Sensory versus motor versus both

What is the lesion?

- Hereditary or congenital
- Acquired:
  - Traumatic
  - Infective
  - Neoplastic
  - Degenerative
  - Inflammatory or immune-mediated
  - Vascular
  - Functional

25.9 Neurological examination in old age

- **Pupils**: tend to be smaller, making fundoscopy more difficult.
- **Limb tone**: more difficult to assess because of poor relaxation and concomitant joint disease.
- **Ankle reflexes**: may be absent.
- **Gait assessment**: more difficult because of concurrent musculoskeletal disease and pre-existing neurological deficits.
- **Sensory testing**: especially difficult when there is cognitive impairment.
- **Vibration sense**: may be reduced distally in the legs.

25.10 How to 'localise' neurological disease

Combination of symptoms/signs	Probable site	Possible pathology	Other important information
Painless loss of hemilateral function	Cerebral cortex	Usually vascular, inflammatory or neoplastic	Associated systemic symptoms Tempo of evolution
Pyramidal weakness of all four limbs or both legs, bladder signs, sensory loss	Spinal cord	Usually vascular, inflammatory or neoplastic	Associated systemic symptoms Tempo of evolution
Cranial nerve lesions, with limb pyramidal signs or sensory loss ± sphincter disturbance	Brainstem Mid-brain Pons Medulla	Usually vascular or inflammatory Rarely neoplastic	Associated systemic symptoms Tempo of evolution
Visual loss + pyramidal signs and/or cerebellar signs	Widespread cerebral lesions	Usually inflammatory Less commonly vasculitic	Tempo of evolution
Weakness and/or sensory loss in a combination of individual peripheral nerves	Several peripheral nerves ('mononeuritis multiplex')	Usually inflammatory or diabetic	Associated systemic symptoms
Widespread LMN and UMN signs	Upper and lower motor neurons	Motor neuron disease Cervical myeloradiculopathy	Associated localised cervical symptoms
Distal loss of sensation and/or weakness	Generalised peripheral nerves	See causes of neuropathy (p. 1138)	Associated systemic symptoms

(LMN/UMN = lower/upper motor neuron)

For example, a 20-year-old with right-sided headache and tenderness will not have temporal arteritis, but this is an important possibility if such symptoms present in a 78-year-old female.

Determining the evolution, speed of onset and progression of a disease is important (Box 25.11). For example, if right-hand weakness occurred overnight, it would suggest a stroke in an older person or an acute entrapment neuropathy in a younger one. Evolution over several days, however, might make demyelination (multiple sclerosis) a possible diagnosis, or perhaps a subdural haematoma if the weakness was preceded by a head injury in an older person taking warfarin. Progression over weeks might bring an intracranial mass lesion or motor neuron disease into the differential. Slow progression over a year or so, with difficulty in using the hand, could suggest a degenerative process such

25.11 The evolution of symptoms

Onset	Evolution	Possible causes
Sudden (minutes to hours)	Stable/improvement	Vascular (stroke/transient ischaemic attack (TIA)) Nerve entrapment syndromes Functional
Gradual	Progressive over days	Demyelination Infection
Gradual	Progressive over weeks to months	Neoplastic/paraneoplastic
Gradual	Progressive over months to years	Genetic Degenerative

as Parkinson's disease. The impact on day-to-day activities, such as walking, climbing stairs and carrying out fine hand movements, should also be established in order to gauge the level of associated disability.

Estimates of the frequency and duration of specific events are essential when taking details of a paroxysmal disorder such as migraine and epilepsy. Vague terms such as 'a lot' or 'sometimes' are unhelpful, and it can assist the patient if choices are given to estimate numbers, such as once a day, week or month.

Many neurological symptoms are not explained by disease. Describing these as 'functional' is less pejorative and more acceptable to patients than 'psychogenic' or 'hysterical'. Functional symptoms require considerable experience in diagnosis and are frequently missed (p. 1094).

Headache and facial pain

Most headaches are chronic disorders but acute presentation of headaches is an important aspect of emergency medical care. Headache may be divided into primary (benign) or secondary, and most patients, whether presenting in clinic or as emergencies, have primary syndromes (see Box 10.10, p. 184). The emergency clinical assessment of headaches is dealt with on page 185.

Ocular pain

Assuming that ocular disease (such as acute glaucoma) has been excluded, ocular pain may be due to trigeminal autonomic cephalalgias (TACs) or, rarely, inflammatory or infiltrative lesions at the apex of the orbit or the cavernous sinus, when 3rd, 4th, 5th or 6th cranial nerve involvement is usually evident. Ocular pain and headache are also discussed on page 1170.

Facial pain

Pain in the face can be due to dental or temporomandibular joint problems. Acute sinusitis is usually apparent from other features of sinus congestion/infection and may cause localised pain over the affected sinus, but is almost never the explanation for persistent facial pain or headache.

Facial pain is not uncommon in migraine but some syndromes can present solely with facial pain. The most common neurological causes of facial pain are trigeminal neuralgia, herpes zoster (shingles) and post-herpetic neuralgia, all characterised by their extreme severity. In trigeminal neuralgia, the patient describes bouts of brief (seconds), lancinating pain ('electric shocks'), most frequently felt in the second and third divisions of the nerve and often triggered by talking or chewing. Facial shingles most commonly affects the first (ophthalmic) division of the trigeminal nerve, and pain usually precedes the rash. Post-herpetic neuralgia may follow, typically a continuous burning pain throughout the affected territory, with marked sensitivity to light touch (allodynia) and resistance to treatment. Destructive lesions of the trigeminal nerve usually cause numbness rather than pain.

Persistent idiopathic facial pain is most frequently seen in middle-aged women, who report persistent pain, with no abnormal signs or investigations, and is similar to other forms of idiopathic chronic pain.

Dizziness, blackouts and 'funny turns'

Acute onset of dizziness or blackouts will present to the acute medical department. In neurological practice, it is common to deal with patients presenting with a history of multiple events. While detailed questioning will be dealt with in the relevant section (p. 181), the neurologist will have to tease out the pattern of each of the different attack types experienced by the patient to be able to form a treatment and investigation plan, one of the challenges of clinical neurology.

Status epilepticus

Status epilepticus is seizure activity not resolving spontaneously, or recurrent seizure with no recovery of consciousness in between. Persisting seizure activity has a recognised mortality and is a medical emergency.

Diagnosis is usually clinical and can be made on the basis of the description of prolonged rigidity and/or clonic movements with loss of awareness. As seizure activity becomes prolonged, movements may become more subtle. Cyanosis, pyrexia, acidosis and sweating may occur, and complications include aspiration, hypotension, cardiac arrhythmias and renal or hepatic failure.

In patients with pre-existing epilepsy, the most likely cause is a fall in antiepileptic drug levels. In de novo status epilepticus, it is essential to exclude precipitants such as infection (meningitis, encephalitis), neoplasia and metabolic derangement (hypoglycaemia, hyponatraemia or hypocalcaemia). Treatment and investigation are outlined in Box 25.12.

Coma

Coma and loss of consciousness usually present to the acute medical admissions department (p. 194). Clarification of cause and prognosis may require specialist neurological input.

Delirium

Delirium describes cortical dysfunction and replaces the older term 'acute confusional state'. It has a range of primary causes, and given its role in precipitating acute admission, it is covered in detail on page 183.

Amnesia

Memory disturbance is a common symptom. In the absence of significant functional impairment (e.g. inability to work, dyspraxias, loss of daily function), many patients will prove to have benign memory dysfunction related to age, mood or psychiatric disorders.

25.12 Management of status epilepticus

Initial

- Ensure airway is patent; give oxygen to prevent cerebral hypoxia
- Check pulse, blood pressure, BM stix and respiratory rate
- Secure intravenous access
- Send blood for:
  - Glucose, urea and electrolytes, calcium and magnesium, liver function, antiepileptic drug levels
  - Full blood count and coagulation screen
  - Storing a sample for future analysis (e.g. drug misuse)
- If seizures continue for >5 mins: give midazolam 10 mg bucally or nasally or lorazepam 4 mg IV if access available or diazepam 10 mg rectally or IV if necessary; repeat *once only* after 15 mins
- Correct any metabolic trigger, e.g. hypoglycaemia

Ongoing

If seizures continue after 30 mins

- IV infusion (with cardiac monitoring) with one of:
  - Phenytoin: 15 mg/kg at 50 mg/min
  - Sodium valproate: 20–30 mg/kg IV at 40 mg/min
  - Phenobarbital: 10 mg/kg at 100 mg/min
- Cardiac monitor and pulse oximetry:
  - Monitor neurological condition, blood pressure, respiration; check blood gases

If seizures still continue after 30–60 mins

- Transfer to intensive care:
  - Start treatment for refractory status with intubation, ventilation and general anaesthesia using propofol or thiopental
  - EEG monitor

Once status controlled

- Commence longer-term antiepileptic medication with one of:
  - Sodium valproate 10 mg/kg IV over 3–5 mins, then 800–2000 mg/day
  - Phenytoin: give loading dose (if not already used as above) of 15 mg/kg, infuse at <50 mg/min, then 300 mg/day
  - Carbamazepine 400 mg by nasogastric tube, then 400–1200 mg/day
- Investigate cause

The increasing publicity given to dementia, combined with a natural fear of losing one's mind, has led to an increase in patients presenting with memory loss but many will have benign symptoms. Investigation and treatment of the dementias are discussed elsewhere (p. 1191).

Temporary loss of memory may be due to a transient delirium related to infection, the post-ictal period after seizure, or transient global amnesia. These are usually distinguished on the basis of the history. Transient amnesia resulting directly from a seizure (transient epileptic amnesia) is a rare result of temporal lobe epilepsy.

Transient global amnesia

Transient global amnesia (TGA) predominantly affects middle-aged people, with an abrupt, discrete loss of anterograde memory function lasting up to a few hours. During the episode, patients are unable to record new memories, resulting in repetitive questioning, the hallmark of this condition. Consciousness is preserved and patients may perform even complex motor acts normally. During the attack there is retrograde amnesia for the events of the past few days, weeks or years. After 4–6 hours, memory function and behaviour return to normal but the patient has persistent, complete amnesia for the duration of the attack itself. There are no seizure markers and, unlike epileptic amnesia, transient global amnesia recurs in only around 10–20% of cases. A vascular aetiology is unlikely (TGA is not a risk factor for subsequent vascular disease) and amnesia may be due to a benign process similar to migraine, occurring in the hippocampus. TGA causes no physical signs and, provided there is a typical history (which requires a witness), no investigation is necessary and patients may be reassured.

Persistent amnesia

Serious neurological disease must be excluded in patients with persistent memory disturbance, although many will prove to have benign symptoms. Symptoms corroborated by relatives or colleagues are likely to be more significant than those noted by the patient only. Where poor concentration is at the heart of cognitive deterioration, it is more likely to be due to an underlying mood disorder.

It is important to assess the timing of onset and to establish which aspects of memory are affected. Complaints of getting lost or of losing complex abilities are more pathological than word-finding difficulties. Disturbance of episodic or working memory (previously called 'short-term memory') must be distinguished from semantic memory (memory for concept-based knowledge unrelated to specific experiences). Episodic memory is selectively impaired in Korsakoff's syndrome (often secondary to alcohol) or bilateral temporal lobe damage. It can also be seen in conjunction with other types of dementia. Progressive deterioration over months suggests an underlying dementia, and a full medical assessment must be performed to detect any underlying medical problem.

It is important to identify and treat depression (p. 1185) in patients with memory loss. Depression may present as a 'pseudo-dementia', with concentration and memory impairment as dominant features, and this is often reversible with antidepressant medication. Any patient with dementia (particularly of Alzheimer's type) may develop depression in the early stages of their illness, however. Specific causes of progressive dementia, with their investigation and treatment, are described elsewhere (p. 1191).

Weakness

The assessment of weakness requires the application of basic anatomy, physiology and some pathology to the interpretation of the history and clinical findings. Points to consider are shown on Figure 25.17 and in Boxes 25.13 and 25.14. The pattern and evolution of weakness and the clinical signs provide clues to the site and nature of the lesion.

It is important to establish whether the patient has loss of power rather than reduced sensation or generalised fatigue. Pain may restrict movement and thus mimic weakness. Paradoxically, sensory neglect (p. 1083) may leave patients unaware of severe weakness.

Patients with parkinsonism may complain of weakness; extrapyramidal signs of rigidity (cogwheel or lead pipe) and bradykinesia should be evident, and a resting tremor (usually asymmetrical) may provide a further clue (p. 1112). Simple observation of the patient walking into the consulting room may be diagnostic, and is as important as formal strength testing. Movement restricted by pain should be apparent, and other features (contractures, wasting, fasciculations, abnormal movements/postures) all provide diagnostic clues.

Weakness is a common symptom arising without an underlying degenerative or destructive cause (functional symptom). Functional

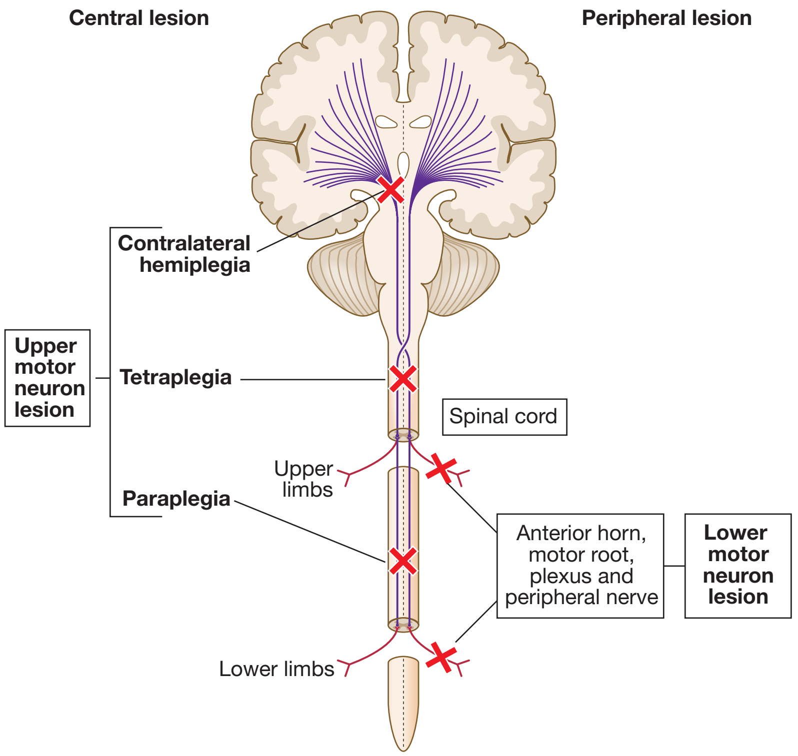

Fig. 25.17 Patterns of motor loss according to the anatomical site of the lesion.

25.13 Distinguishing signs in upper versus lower motor neuron syndromes

	Upper motor neuron lesion	Lower motor neuron lesion
Inspection	Normal (may be wasting in chronic lesions)	Wasting, fasciculation
Tone	Increased with clonus	Normal or decreased, no clonus
Pattern of weakness	Preferentially affects extensors in arms, flexors in leg Hemiparesis, paraparesis or tetraparesis	Typically focal, in distribution of nerve root or peripheral nerve, with associated sensory changes
Deep tendon reflexes	Increased	Decreased/absent
Plantar response	Extensor (Babinski sign)	Flexor

weakness does not conform to typical organic patterns, and the signs in Box 25.13 are absent. Clinical examination is often variable (e.g. the patient can walk but appears to have no leg movement when assessed on the couch), and strength may appear to 'give way', with the patient able to achieve full power for brief bursts, which does not occur in disease. Hoover's sign is useful to confirm functional weakness, and relies on eliciting the normal phenomenon of simultaneous hip extension when the contralateral hip flexes. In functional weakness, hip extension weakness may be seen; this then returns to full strength when contralateral hip flexion is tested. This sign may be demonstrated to the patient in a non-confrontational manner, to show that the potential limb power is intact.

25.14 How to assess weakness

Clinical finding	Likely level of lesion/diagnosis
Pattern and distribution	
Isolated muscles	Radiculopathy or mononeuropathy
Both limbs on one side (hemiparesis)	Cerebral hemisphere, less likely cord or brainstem
One limb	Neuronopathy, plexopathy, cord/brain
Both lower limbs (paraparesis)	Spinal cord; look for a sensory level
Fatigability	Myasthenia gravis
Bizarre, fluctuating, not following anatomical rules	Functional
Signs	
Upper motor neuron	Brain/spinal cord
Lower motor neuron	Peripheral nervous system
Evolution of the weakness	
Sudden and improving	Stroke/mononeuropathy
Evolving over months or years	Meningioma, cervical spondylotic myelopathy
Gradually worsening over days or weeks	Cerebral mass, demyelination
Associated symptoms	
Absence of sensory involvement	Motor neuron disease, myopathy, myasthenia

Facial weakness

Facial nerve palsy (Bell's palsy)

One of the most common causes of facial weakness is Bell's palsy, a lower motor neuron lesion of the 7th (facial) nerve, affecting all ages and both sexes. It is more common following upper respiratory tract infections, during pregnancy, and in patients with diabetes, immunosuppression and hypertension.

The lesion is within the facial canal. Symptoms usually develop subacutely over a few hours, with pain around the ear preceding the unilateral facial weakness. Patients often describe the face as 'numb' but there is no objective sensory loss (except to taste, if the chorda tympani is involved). Hyperacusis may occur if the nerve to stapedius is involved and impairment of parasympathetic fibres may cause diminished salivation and tear secretion. Examination reveals an ipsilateral lower motor neuron facial nerve palsy (no sparing of forehead muscles). Vesicles in the ear or on the palate may indicate primary herpes zoster infection (p. 239). A clinical search for signs of other causes of lower motor neuron facial nerve weakness, such as parotid or scalp lesions, trauma or skull base lesions, is justified.

Glucocorticoids improve recovery rates if started within 72 hours of onset but antiviral drugs are not effective. Artificial tears applied regularly prevent corneal drying, and taping the eye shut overnight helps prevent exposure keratitis and corneal abrasion. Patients unable to close the eye should be referred urgently to an ophthalmologist. About 80% of patients recover spontaneously within 12 weeks. Plastic surgery may be considered for the minority left with facial disfigurement after 12 months. Recurrence is unusual and should prompt further investigation. Aberrant re-innervation may occur during recovery, producing unwanted facial movements, such as eye closure when the mouth is moved (synkinesis) or 'crocodile tears' (tearing during salivation).

Unlike Bell's palsy, lesions with an upper motor neuron origin may spare the upper face. Cortical lesions may cause a facial weakness either in isolation or with associated hemiparesis and speech difficulties.

Sensory disturbance

Sensory symptoms are common and frequently benign. Patients often find sensory symptoms difficult to describe and sensory examination is difficult for both doctor and patient. While neurological disease can cause sensory symptoms, systemic disorders can also be responsible. Tingling in both hands and around the mouth can occur as the result of hyperventilation (p. 558) or hypocalcaemia (p. 662). When there is dysfunction of the relevant cerebral cortex, the patient's perception of the wholeness or actual presence of the relevant part of the body may be distorted.

Numbness and paraesthesia

The history may give the best clues to localisation and pathology. Certain common patterns are recognised: in migraine, the aura may consist of spreading tingling or paraesthesia, followed by numbness evolving over 20–30 minutes over one half of the body, often splitting the tongue. Sensory loss caused by a stroke or transient ischaemic attack (TIA) occurs much more rapidly and is typically negative (numbness) rather than positive (tingling). Rarely, unpleasant paraesthesia of sensory epilepsy spreads within seconds. The sensory alteration of inflammatory spinal cord lesions often ascends from one or both lower limbs to a distinct level on the trunk over hours to days. Psychogenic sensory change can occur as a manifestation of anxiety or as part of a conversion disorder (p. 1202). In such cases, the distribution usually neither conforms to a known anatomical pattern nor fits with any organic disease. Care must be taken in diagnosing non-organic sensory problems; a careful history and examination will ensure there is no other objective neurological deficit.

Sensory neurological examination needs to be undertaken and interpreted with care because the findings depend, by definition, on subjective reports. The reported distribution of sensory loss can be useful, however, when combined with the coexisting deficits of motor and/or cranial nerve function (Fig. 25.18).

Sensory loss in peripheral nerve lesions

Here the symptoms are usually of sensory loss and paraesthesia. Single nerve lesions cause disturbance in the sensory distribution of the nerve, whereas in diffuse neuropathies the longest neurons are affected first, giving a characteristic 'glove and stocking' distribution. If smaller nerve fibres are preferentially affected (e.g. in diabetic neuropathy), temperature and pin-prick (pain) are reduced, whilst vibration sense and proprioception (modalities served by the larger, well-myelinated, sensory nerves) may be relatively spared. In contrast, vibration and proprioception are particularly affected if the neuropathy is demyelinating in character (p. 1138), producing symptoms of tightness and swelling with impairment of proprioception and vibration sensation.

Sensory loss in nerve root lesions

These typically present with pain as a prominent feature, either within the spine or in the limb plexuses. Pain is often felt in the myotome rather than the dermatome. The nerve root involved may be deduced from the dermatomal pattern of sensory loss (p. 1071), although overlap may lead to this being smaller than expected.

Sensory loss in spinal cord lesions

Transverse lesions of the spinal cord produce loss of all sensory modalities below that segmental level, although the clinical level may only be manifest 2–3 segments lower than the anatomical site of the lesion. Very often, there is a band of paraesthesia or hyperaesthesia at the top of the area of sensory loss. Clinical examination may reveal dissociated sensory loss, i.e. different patterns in the spinothalamic and dorsal columnar pathways. If the transverse lesion is vascular due to anterior spinal artery thrombosis, the spinothalamic pathways may be affected while the posterior one-third of the spinal cord (the dorsal column modalities) may be spared.

Lesions damaging one side of the spinal cord will produce loss of spinothalamic modalities (pain and temperature) on the opposite side, and of dorsal column modalities (joint position and vibration sense) on the same side of the body – the Brown–Séquard syndrome (p. 1084).

Lesions in the centre of the spinal cord (such as syringomyelia: see Box 25.83 and Fig. 25.51, pp. 1138 and 1139) spare the dorsal columns but involve the spinothalamic fibres crossing the cord from both sides over the length of the lesion. There is no sensory loss in segments above and below the lesion; this is described as 'suspended' sensory loss. There is sometimes reflex loss at the level of the lesion if afferent fibres of the reflex arc are affected.

An isolated lesion of the dorsal columns is not uncommon in multiple sclerosis. This produces a characteristic unpleasant, tight feeling over the limb(s) involved and, while there is no loss of pin-prick or temperature sensation, the associated loss of proprioception may severely limit function of the affected limb(s).

Sensory loss in brainstem lesions

Lesions in the brainstem can be associated with sensory loss but the distribution depends on the site of the lesion. A lesion limited to the trigeminal nucleus or its sensory projections will cause

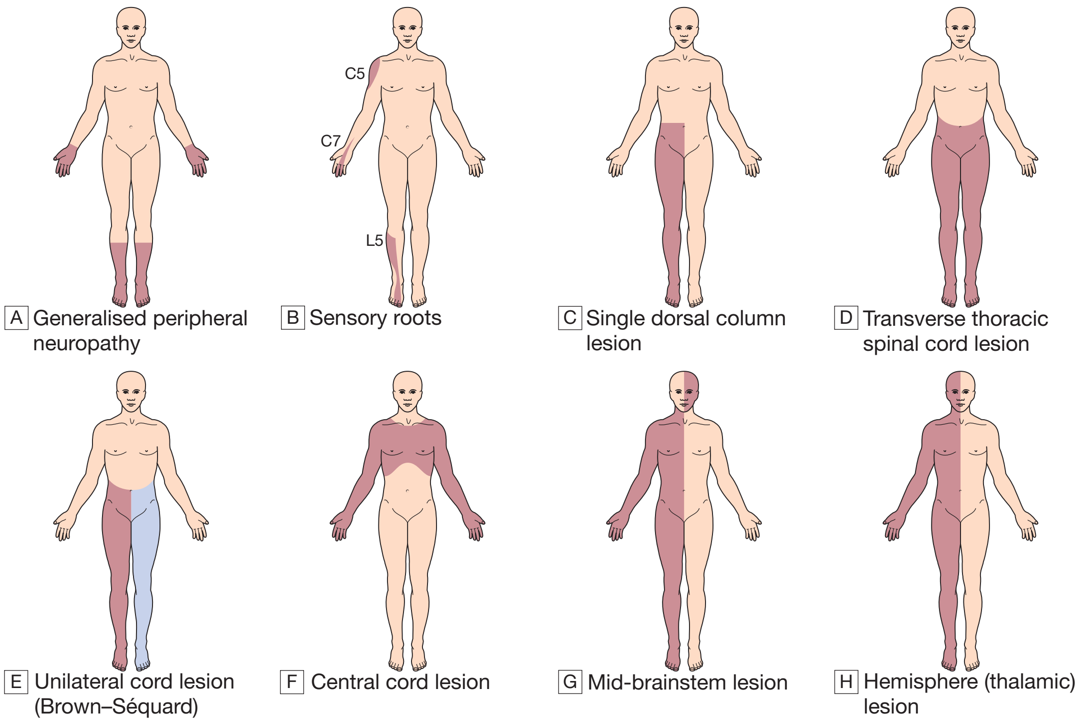

Fig. 25.18 Patterns of sensory loss. **A** Generalised peripheral neuropathy. **B** Sensory roots: some common examples. **C** Single dorsal column lesion (proprioception and some touch loss). **D** Transverse thoracic spinal cord lesion. **E** Unilateral cord lesion (Brown–Séquard): ipsilateral dorsal column (and motor) deficit and contralateral spinothalamic deficit. **F** Central cord lesion: 'cape' distribution of spinothalamic loss. **G** Mid-brainstem lesion: ipsilateral facial sensory loss and contralateral loss on body below the vertex. **H** Hemisphere (thalamic) lesion: contralateral loss on one side of face and body.

ipsilateral facial sensory disturbance. For example, pain resembling trigeminal neuralgia can be seen in patients with multiple sclerosis. The anatomy of the trigeminal connections means that lesions in the medulla or spinal cord can give rise to 'balaclava' patterns of sensory loss (p. 1070). Sensory pathways running up from the spinal cord can also be damaged in the brainstem, resulting in simultaneous sensory loss in arm(s) and/or leg(s).

Sensory loss in hemispheric lesions

The temporal, parietal and occipital lobes receive sensory information regarding the various modalities of touch, vision, hearing and balance (see Box 25.2, p. 1066). The initial points of entry into the cortex are the respective primary cortical areas (see Fig. 25.4, p. 1067). Damage to any of these primary areas will result in reduction or loss of the ability to perceive that particular modality: 'negative' symptomatology. Abnormal excitation of these areas can result in a false perception ('positive' symptoms), the most common of which is migrainous visual aura (flashing lights or teichopsia).

Cortical lesions are more likely to cause a mixed motor and sensory loss. Substantial lesions of the parietal cortex (as in large strokes) can cause severe loss of proprioception and may even abolish conscious awareness of the existence of the affected limb(s), known as neglect; this can be difficult to distinguish from paralysis. Pathways are so tightly packed in the thalamus that even small lacunar strokes can cause isolated contralateral hemisensory loss.

Neuropathic pain

Neuropathic pain is a positive neurological symptom caused by dysfunction of the pain perception apparatus, in contrast to nociceptive pain, which is secondary to pathological processes such as inflammation. Neuropathic pain has distinctive features and typically provokes a very unpleasant, persistent, burning sensation. There is often increased sensitivity to touch, so that light brushing of the affected area causes exquisite pain (allodynia). Painful stimuli are felt as though they arise from a larger area than that touched, and spontaneous bursts of pain may also occur. Pain may be elicited by other modalities (allodynia) and is considerably affected by emotional influences. The most common causes of neuropathic pain are diabetic neuropathies, trigeminal and post-herpetic neuralgias, and trauma to a peripheral nerve. Treatment of these syndromes can be difficult. Drugs that modulate various parts of the nociceptive system, such as gabapentin, carbamazepine or tricyclic antidepressants, may help. Localised treatment (topical treatment or nerve blocks) sometimes succeeds but may increase the sensory deficit and worsen the situation. Electrical stimulation has occasionally proved successful. For further information, see page 1347.

Abnormal movements

Disorders of movement lead to either extra, unwanted movement (hyperkinetic disorders) or too little movement (hypokinetic disorders) (Box 25.15). In either case, the lesion often localises to the basal ganglia, although some tremors are related to cerebellar or brainstem disturbance. Functional movement disorders are common and may mimic all of the organic syndromes below. The most important hypokinetic disorder is Parkinson's disease (p. 1112). Parkinsonism is a clinical description of a collection of symptoms, including tremor, bradykinesia and rigidity. While the history is always important, observation is clearly vital; much

of the skill in diagnosing movement disorders lies in pattern recognition. Once it is established whether the problem is hypo- or hyperkinetic, the next task is to categorise the movements further, accepting that there is often overlap. Videoing the movements (with the patient's consent), so that they can be shown to a movement disorder expert, may provide a quick diagnosis in cases of uncertainty.

Tremor

Tremor is caused by alternating agonist/antagonist muscle contractions and produces a rhythmical oscillation of the body part affected. In the assessment of tremor, the position, body part affected, frequency and amplitude should be considered, as these provide diagnostic clues (Box 25.16).

25.15 Movement disorders

Description	Features	Examples
Hypokinetic disorders		
Parkinsonism	Akinesia Rigidity Tremor Loss of postural reflexes Other features depending on cause	Idiopathic Parkinson's disease Other degenerative syndromes Drug-induced (See Box 25.54)
Catatonia	Mutism Sustained posturing and waxy flexibility	Usually psychiatric; if neurological, is most commonly of vascular origin
Hyperkinetic disorders		
Tremor	Rhythmical oscillation of body part (see Box 25.16)	Essential tremor Parkinson's disease Drug-induced
Chorea	Jerky, brief, involuntary movements	Huntington's disease Drug-induced
Tics	Stereotyped, repetitive movements, briefly suppressible	Tourette's syndrome
Myoclonus	Shock-like muscle jerks	Epilepsy Hypnic jerks (p. 1086) Focal cortical disease
Dystonia	Sustained muscle contraction causing abnormal postures ± tremor	Genetic Generalised dystonic syndromes Focal dystonias in adults (e.g. torticollis)
Others	Various	Paroxysmal hyperkinetic dyskinesias Hemifacial spasm Tardive syndromes

Other hyperkinetic syndromes

Non-rhythmic involuntary movements include chorea, athetosis, ballism, dystonia, myoclonus and tics. They are categorised by clinical appearance, and coexistence and overlap are common, such as in choreoathetosis.

Chorea

Chorea refers to jerky, brief, purposeless involuntary movements, appearing fidgety and affecting different areas. They suggest disease in the caudate nucleus (as in Huntington's disease, p. 1114) and are a common complication of levodopa treatment for Parkinson's disease. Other causes are shown in Box 25.17.

25.17 Causes of chorea

Hereditary
- Huntington's disease (HD) and HD-like syndromes
- Wilson's disease
- Neuroacanthocytosis
- Dentato-rubro-pallidoluysian atrophy
- Benign hereditary chorea
- Paroxysmal dyskinesias

Cerebral birth injury (including kernicterus)

Cerebral trauma

Drugs
- Levodopa (long-term with Parkinson's disease)
- Antipsychotics
- Antiepileptics
- Oral contraceptive

Metabolic
- Disorders affecting thyroid, parathyroid, glucose, sodium, calcium and magnesium balance
- Pregnancy

Autoimmune
- Post-streptococcal (Sydenham's chorea)
- Antiphospholipid antibody syndrome
- Autoimmune encephalitis
- Systemic lupus erythematosus

Structural lesions of basal ganglia (usually caudate)
- Vascular
- Demyelination
- Brain tumour

25.16 Causes and characteristics of tremors

	Body part affected	Position	Frequency	Amplitude	Character
Physiological	Both arms > legs	Posture, movement	High	Small (fine)	Enhanced by anxiety, emotion, drugs, toxins
Parkinsonism	Unilateral or asymmetrical Arm > leg, chin, never head	Rest Postural and re-emergent may occur	Low (3–4 Hz)	Moderate	Typically pill-rolling, thumb and index finger, other features of parkinsonism
Essential tremor	Bilateral arms, head	Movement	High (8–10 Hz)	Low to moderate	Family history; 50% respond to alcohol
Dystonic	Head, arms, legs	Posture	Variable	Variable	Other features of dystonia, often jerky tremors
Functional	Any	Any	Variable	Variable	Distractible

Athetosis

Slower, writhing movement of the limbs are often combined with chorea and have similar causes.

Ballism

This more dramatic form of chorea causes often violent flinging movements of one limb (monoballism) or one side of the body (hemiballism). The lesion localises to the contralateral subthalamic nucleus and the most common cause is stroke.

Dystonia

Sustained involuntary muscle contraction causes abnormal postures or movement. It may be generalised (usually in childhood-onset genetic syndromes) or, more commonly, focal/segmental (such as in torticollis, when the head is twisted repeatedly to one side). Some dystonias occur only with specific tasks, such as writer's cramp or other occupational 'cramps'. Dystonic tremor is associated, and is asymmetrical and of large amplitude.

Myoclonus

Myoclonus consists of brief, isolated, random jerks of muscle groups. This is physiological at the onset of sleep (hypnic jerks). Similarly, a myoclonic jerk is a component of the normal startle response, which may be exaggerated in some rare (mostly genetic) disorders. Myoclonus may occur in disorders of the cerebral cortex, such as some forms of epilepsy. Alternatively, myoclonus can arise from subcortical structures or, more rarely, from segments of the spinal cord.

Tics

Tics are stereotyped repetitive movements, such as blinking, winking, head shaking or shoulder shrugging. Unlike dyskinesias, the patient may be able to suppress them, although only for a short time. Isolated tics are common in childhood and usually disappear. Tourette's syndrome is defined by the presence of multiple motor and vocal tics that may evolve over time; it is frequently associated with psychiatric disease, including obsessive compulsions, depression, self-harm or attention deficit disorder. Tics may also occur in Huntington's and Wilson's diseases, or after streptococcal infection.

Abnormal perception

The parietal lobes are involved in the higher processing and integration of primary sensory information. This takes place in areas referred to as 'association' cortex, damage to which gives rise to sensory (including visual) inattention, disorders of spatial perception, and disruption of spatially orientated behaviour, leading to apraxia. Apraxia is the inability to perform complex, organised activity in the presence of normal basic motor, sensory and cerebellar function (after weakness, numbness and ataxia have been excluded as causes). Examples of complex motor activities include dressing, using cutlery and geographical orientation. Other abnormalities that can result from damage to the association cortex involve difficulty reading (dyslexia) or writing (dysgraphia), or the inability to recognise familiar objects (agnosia). The results of damage to particular lobes of the brain are given in Box 25.2 (p. 1066).

Altered balance and vertigo

Balance is a complicated dynamic process that requires ongoing modification of both axial and limb muscles to compensate for the effects of gravity and alterations in body position and load (and hence centre of gravity) in order to prevent a person from falling. This requires input from a variety of sensory modalities (visual, vestibular and proprioceptive), processing by the cerebellum and brainstem, and output via a number of descending pathways (e.g. vestibulospinal, rubrospinal and reticulospinal tracts).

Disorders of balance can therefore arise from any part of this process. Disordered input (loss of vision, vestibular disorders or lack of joint position sense), processing (damage to vestibular nuclei or cerebellum) or motor function (spinal cord lesions, leg weakness of any cause) can all impair balance. The patient may complain of different symptoms, depending on the location of the lesion. For example, loss of joint position sense or cerebellar function may result in a sensation of unsteadiness, while damage to the vestibular nuclei or labyrinth may result in an illusion of movement, such as vertigo (see below). A careful history is vital. Since vision can often compensate for lack of joint position sense, patients with peripheral neuropathies or dorsal column loss will often find their problem more noticeable in the dark.

Examination of such patients may yield physical signs that again depend on the site of the lesion. Sensory abnormalities may be manifest as altered visual acuities or visual fields, possibly with abnormalities on fundoscopy, altered eye movements (including nystagmus, p. 1090), impaired vestibular function (p. 1104) or lack of joint position sense. Disturbance of cerebellar function may be manifest as nystagmus, dysarthria or ataxia, or difficulty with gait (unsteadiness or inability to perform tandem gait; see below). Leg weakness, if present, will be detectable on examination of the limbs.

Vertigo

Vertigo is defined as an abnormal perception of movement of the environment or self, and occurs because of conflicting visual, proprioceptive and vestibular information about a person's position in space. Vertigo commonly arises from imbalance of vestibular input and is within the experience of most people, since this is the 'dizziness' that occurs after someone has spun round vigorously and then stops. Bilateral labyrinthine dysfunction often causes some unsteadiness. Labyrinthine vertigo usually lasts days at a time, though it may recur, while vertigo arising from central (brainstem) disorders is often persistent and accompanied by other brainstem signs. Benign paroxysmal positional vertigo (p. 1104) lasts a few seconds on head movement. A careful history will reveal the likely cause in most patients.

Abnormal gait

Many neurological disorders can affect gait. Observing patients as they walk into the consulting room can be very informative, although formal examination is also important. Neurogenic gait disorders need to be distinguished from those due to skeletal abnormalities, usually characterised by pain producing an antalgic gait, or limp. Gait alteration incompatible with any anatomical or physiological deficit may be due to functional disorders.

Pyramidal gait

Upper motor neuron lesions cause characteristic extension of the affected leg. The resultant tendency for the toes to strike the ground on walking requires the leg to swing outwards at the hip (circumduction). Nevertheless, a shoe on the affected side worn down at the toes may provide evidence of this type of

gait. In hemiplegia, the asymmetry between affected and normal sides is obvious on walking, but in paraparesis both lower limbs swing slowly from the hips in extension and are dragged stiffly over the ground – described as ‘walking in mud’.

Foot drop

In normal walking, the heel is the first part of the foot to hit the ground. A lower motor neuron lesion affecting the leg will cause weakness of ankle dorsiflexion, resulting in a less controlled descent of the foot, which makes a slapping noise as it hits the ground. In severe cases, the foot will have to be lifted higher at the knee to allow room for the inadequately dorsiflexed foot to swing through, resulting in a high-stepping gait.

Myopathic gait

During walking, alternating transfer of the body’s weight through each leg requires adequate hip abduction. In proximal muscle weakness, usually caused by muscle disease, the hips are not properly fixed by these muscles and trunk movements are exaggerated, producing a rolling or waddling gait.

Ataxic gait

An ataxic gait can result from lesions in the cerebellum, vestibular apparatus or peripheral nerves. Patients with lesions of the central portion of the cerebellum (the vermis) walk with a characteristic broad-based gait ‘as if drunk’ (cerebellar function is particularly sensitive to alcohol). Patients with acute vestibular disturbances walk similarly but the accompanying vertigo is characteristic. Inability to walk heel to toe may be the only sign of less severe cerebellar dysfunction.

Proprioceptive defects can also cause an ataxic gait. The impairment of joint position sense makes walking unreliable, especially in poor light. The feet tend to be placed on the ground with greater emphasis, presumably to enhance proprioceptive input, resulting in a ‘stamping’ gait.

Apraxic gait

In an apraxic gait, power, cerebellar function and proprioception are normal on examination of the legs. The patient may be able to carry out complex motor tasks (e.g. bicycling motion) while recumbent and yet cannot formulate the motor act of walking. In this higher cerebral dysfunction, the feet appear stuck to the floor and the patient cannot walk. Gait apraxia is a sign of diffuse bilateral hemisphere disease (such as normal pressure hydrocephalus) or diffuse frontal lobe disease.

Marche à petits pas

This gait is characterised by small, slow steps and marked instability. It differs from the festination found in Parkinson’s disease (see below), in that it lacks increasing pace and freezing. The usual cause is small-vessel cerebrovascular disease and there may be accompanying bilateral upper motor neuron signs.

Extrapyramidal gait

The rigidity and bradykinesia of basal ganglia dysfunction (p. 1112) lead to a stooped posture and characteristic gait difficulties, with problems initiating walking and controlling the pace of the gait. Patients may become stuck while trying to start walking or when walking through doorways (‘freezing’). The centre of gravity will be moved forwards to aid propulsion, which, with poor axial control, can lead to an accelerating pace of shuffling and difficulty stopping. This produces the festinant gait: initial stuttering steps that quickly increase in frequency while decreasing in length.

Abnormal speech and language

Speech disturbance may be isolated to disruption of sound output (dysarthria) or may involve language disturbance (dysphasia). Dysphonia (reduction in the sound/volume) is usually due to mechanical laryngeal disruption, whereas dysarthria is more typically neurological in origin. Dysphasia is always neurological and localises to the dominant cerebral hemisphere (usually left, regardless of handedness). Combinations of speech and swallowing problems are explained below (p. 1093).

Dysphonia

Dysphonia describes hoarse or whispered speech. The most common cause is laryngitis, but dysphonia can also result from a lesion of the 10th cranial nerve or disease of the vocal cords, including laryngeal dystonia. Parkinsonism may cause hypophonia with marked reduction in speech volume, often in association with dysarthria, making speech difficult to understand.

Dysarthria

Dysarthria is characterised by poorly articulated or slurred speech and can occur in association with lesions of the cerebellum, brainstem and lower cranial nerves, as well as in myasthenia or myopathic disease. Language function is not affected. The quality of the speech tends to differ, depending on the cause, but

25.18 Causes of dysarthria

Type	Site	Characteristics	Associated features
Myopathic	Muscles of speech	Indistinct, poor articulation	Weakness of face, tongue and neck
Myasthenic	Motor end plate	Indistinct with fatigue and dysphonia Fluctuating severity	Ptosis, diplopia, facial and neck weakness
Bulbar	Brainstem	Indistinct, slurred, often nasal	Dysphagia, diplopia, ataxia
‘Scanning’	Cerebellum	Slurred, impaired timing and cadence, ‘sing-song’	Ataxia of limbs and gait, tremor of head/limbs Nystagmus
Spastic (‘pseudo-bulbar’)	Pyramidal tracts	Indistinct, nasal tone, mumbling	Poor rapid tongue movements, increased reflexes and jaw jerk
Parkinsonian	Basal ganglia	Indistinct, rapid, stammering, quiet	Tremor, rigidity, slow shuffling gait
Dystonic	Basal ganglia	Strained, slow, high-pitched	Dystonia, athetosis

it can be very difficult to distinguish the different types clinically (Box 25.18). Dysarthria is discussed further in the section on bulbar symptoms (p. 1093).

Dysphasia

Dysphasia (or aphasia) is a disorder of the language content of speech. It can occur with lesions over a wide area of the dominant hemisphere (Fig. 25.19). Dysphasia may be categorised according to whether the speech output is fluent or non-fluent. Fluent aphasias, also called receptive aphasias, are impairments related mostly to the input or reception of language, with difficulties either in auditory verbal comprehension or in the repetition of words, phrases or sentences spoken by others. Speech is easy and fluent but there are difficulties related to the output of language as well, such as paraphasia (either substitution of similar-sounding non-words, or incorrect words) and neologisms (non-existent words). Examples include Wernicke's aphasia (which localises to the superior posterior temporal lobe), transcortical sensory aphasia, conduction aphasia and anomic aphasia.

Non-fluent aphasias, also called expressive aphasias, are difficulties in articulating, but in most cases there is relatively good auditory verbal comprehension. Examples include Broca's aphasia (associated with pathologies in the inferior frontal region), transcortical motor aphasia and global aphasia.

'Pure' aphasias are selective impairments in reading, writing or the recognition of words. These disorders may be quite selective. For example, a person is able to read but not write, or is able to write but not read. Examples include pure alexia, agraphia and pure word deafness.

Dysphasia (a focal symptom) is frequently misinterpreted as disorientation (which is non-focal) and it is important always to consider dysphasia as an alternative explanation for the apparently 'confused' patient. Dysphasia can be misheard/misspelt as dysphagia, and for this reason some prefer to use 'aphasia' to avoid confusion.

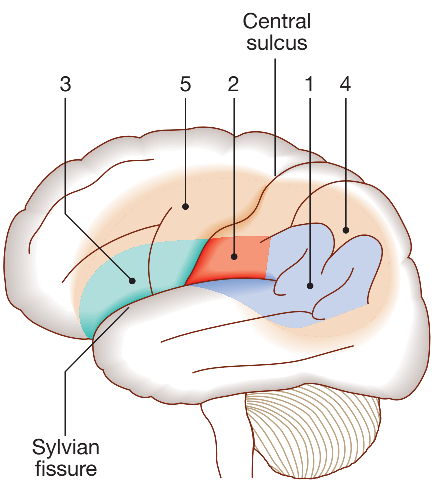

Fig. 25.19 Classification of cortical speech problems. (1) Wernicke's aphasia: fluent dysphasia with poor comprehension and poor repetition. (2) Conduction aphasia: fluent aphasia with good comprehension and poor repetition. (3) Broca's aphasia: non-fluent aphasia with good comprehension and poor repetition. (4) Transcortical sensory aphasia: fluent aphasia with poor comprehension and good repetition. (5) Transcortical motor aphasia: non-fluent aphasia with good comprehension and good repetition. Large lesions affecting all of regions 1–5 cause global aphasia.

Disturbance of smell

Symptomatic olfactory loss is most commonly due to local causes (nasal obstruction) but may follow head injury. Hyposmia may predate motor symptoms in Parkinson's disease by many years, although it is rarely noticed by the patient. Frontal lobe lesions are a rare cause. Positive olfactory symptoms may arise in Alzheimer's disease or epilepsy.

Visual disturbance and ocular abnormalities

Disturbances of vision may be due to primary ocular disease or to disorders of the central connections and visual cortex. Visual symptoms are usually negative (loss of vision) but sometimes positive, most commonly in migraine. Eye movements may be disturbed, giving rise to double vision (diplopia) or blurred vision. Loss of vision is also discussed on page 1170.

Visual loss

Visual loss can occur as the result of lesions in any areas between the retina and the visual cortex. Patterns of visual field loss are explained by the anatomy of the visual pathways (see Fig. 25.7, p. 1069). Associated clinical manifestations are described in Box 25.19. Visual symptoms affecting one eye only are due to lesions anterior to the optic chiasm.

Transient visual loss is quite common and sudden-onset visual loss lasting less than 15 minutes is likely to have a vascular origin. It may be difficult to know whether the visual loss was monocular (carotid circulation) or binocular (vertebrobasilar circulation), and it is important to ask if the patient tried closing each eye in turn to see whether the symptom affected one eye or both. Visual field testing is an important part of the examination, either at the bedside or formally with perimetry. Field defects become more symmetrical (congruous), the closer the lesion comes to the visual cortex.

Migrainous visual symptoms are very common and, when associated with typical headache and other migraine features, rarely pose a diagnostic challenge. They may occur in isolation, however, making distinction from TIA difficult, but TIAs typically cause negative (blindness) symptoms, whereas migraine causes positive phenomena (see below). TIAs often last for a shorter time (a few minutes), compared to the 10–60-minute duration of migraine aura, and have an abrupt onset and end, unlike the gradual evolution of a migraine aura.

Positive visual phenomena

The most common cause is migraine; patients may describe silvery zigzag lines (fortification spectra) or flashing coloured lights (teichopsia), usually preceding the headache. Simple flashes of light (phosphenes) may indicate damage to the retina (e.g. detachment) or to the primary visual cortex. Formed visual hallucinations may be caused by drugs or may be due to epilepsy or 'release phenomena' in a blind visual field (Charles Bonnet syndrome).

Double vision

Diplopia arises from misalignment of the eyes, meaning that the image is not projected to the same points on the two retinas. At its most subtle it may be reported as blurred rather than

25.19 Clinical manifestations of visual field loss

Site of lesion	Common causes	Complaint	Visual field loss	Associated physical signs
Retina/optic disc	Vascular disease (including vasculitis) Glaucoma Inflammation	Partial/complete visual loss depending on site, involving one or both eyes	Altitudinal field defect Arcuate scotoma	Reduced acuity Visual distortion (macula) Abnormal retinal appearance
Optic nerve	Optic neuritis Sarcoidosis Tumour Leber's hereditary optic neuropathy	Partial/complete loss of vision in one eye Often painful Central vision particularly affected	Central or paracentral scotoma Monocular blindness	Reduced acuity Reduced colour vision Relative afferent pupillary defect Optic atrophy (late)
Optic chiasm	Pituitary tumour Craniopharyngioma Sarcoidosis	May be none Rarely, diplopia ('hemifield slide')	Bitemporal hemianopia	Pituitary function abnormalities
Optic tract	Tumour Inflammatory disease	Disturbed vision to one side of midline	Incongruous contralateral homonymous hemianopia	
Temporal lobe	Stroke Tumour Inflammatory disease	Disturbed vision to one side of midline	Contralateral homonymous upper quadrantanopia	Memory/language disorders
Parietal lobe	Stroke Tumour Inflammatory disease	Disturbed vision to one side of midline Bumping into things	Contralateral homonymous lower quadrantanopia	Contralateral sensory disturbance Asymmetry of optokinetic nystagmus
Occipital lobe	Stroke Tumour Inflammatory disease	Disturbed vision to one side of midline Difficulty reading Bumping into things	Homonymous hemianopia (may be macula-sparing)	Damage to other structures supplied by posterior cerebral circulation

25.20 Common causes of damage to cranial nerves 3, 4 and 6

Site	Common pathology	Nerve(s) involved	Associated features
Brainstem	Infarction	3 (mid-brain)	Contralateral pyramidal signs
	Haemorrhage Demyelination Intrinsic tumour	6 (ponto-medullary junction)	Ipsilateral lower motor neuron facial palsy Other brainstem/cerebellar signs
Intrameningeal	Meningitis (infective/malignant)	3, 4 and/or 6	Meningism, features of primary disease course
	Raised intracranial pressure	6 3 (uncal herniation)	Papilloedema Features of space-occupying lesion
	Aneurysms	3 (posterior communicating artery) 6 (basilar artery)	Pain Features of subarachnoid haemorrhage
	Cerebello-pontine angle tumour	6	8, 7, 5 nerve lesions (order of likelihood) Ipsilateral cerebellar signs
	Trauma	3, 4 and/or 6	Other features of trauma
Cavernous sinus	Infection/thrombosis Carotid artery aneurysm Caroticocavernous fistula	3, 4 and/or 6	May be 5th nerve involvement also Pupil may be fixed, mid-position (Sympathetic plexus on carotid may also be affected)
Superior orbital fissure	Tumour (e.g. sphenoid wing meningioma) Granuloma	3, 4 and/or 6	May be proptosis, chemosis
Orbit	Vascular (e.g. diabetes, vasculitis) Infections Tumour Granuloma Trauma	3, 4 and/or 6	Pain Pupil often spared in vascular 3rd nerve palsy

double vision. Monocular diplopia indicates ocular disease, while binocular diplopia suggests a neurological cause. Closing either eye in turn will abort binocular diplopia. Once the presence of binocular diplopia is confirmed, it should be established whether the diplopia is maximal in any particular direction of gaze, whether the images are separated horizontally or vertically, and whether there are any associated symptoms or signs, such as ptosis or pupillary disturbance.

Binocular diplopia may result from central disorders or from disturbance of the ocular motor nerves, muscles or the

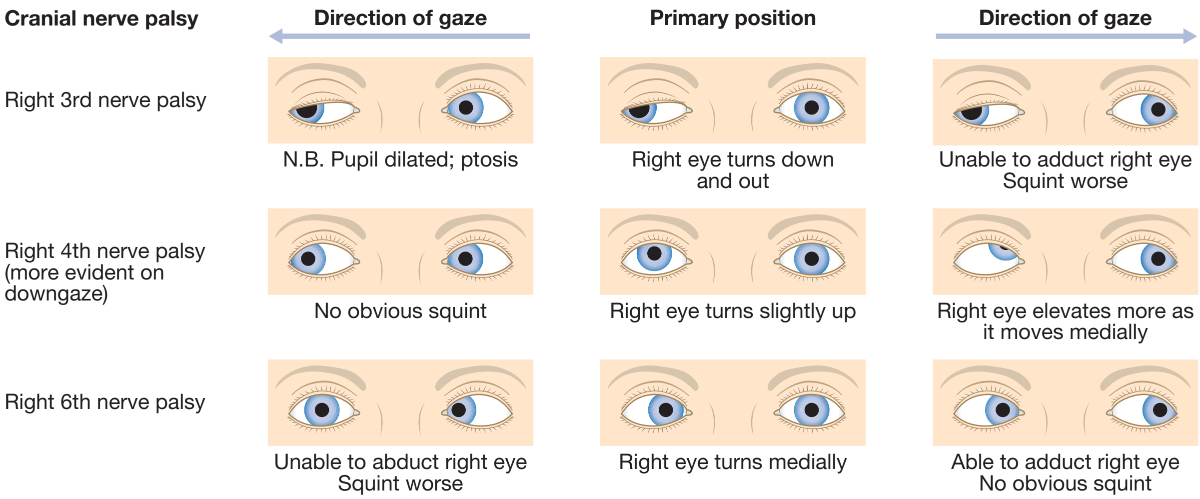

Fig. 25.20 Examination findings in 3rd, 4th and 6th nerve palsy. Diplopia tends to be more obvious on lateral gaze compared to primary position.

neuromuscular junction (see Fig. 25.8, p. 1070). The pattern of double vision, along with any associated features, usually allows the clinician to infer which nerves/muscles are affected, while the mode of onset and other features (e.g. fatigability in myasthenia) provide further clues to the cause.

The causes of ocular motor nerve palsies are listed in Box 25.20. Examination findings are illustrated in Figure 25.20.

Nystagmus

Nystagmus describes a repetitive to-and-fro movement of the eyes. In central lesions, the slow drifts are the primary abnormal movement, each followed by fast (corrective) phases. Nystagmus occurs because the control systems of the eyes are defective, causing them to drift off target; corrections then become necessary to return fixation to the object of interest, causing nystagmus. The direction of the fast phase is usually designated as the direction of the nystagmus because it is easier to see. Nystagmus may be horizontal, vertical or torsional, and usually involves both eyes synchronously. It may be a physiological phenomenon in response to sustained vestibular stimulation or movement of the visual world (optokinetic nystagmus). There are many causes of pathological nystagmus, the most common sites of lesions being the vestibular system, brainstem and cerebellum.

The brainstem and the cerebellum are involved in maintaining eccentric positions of gaze. Lesions will therefore allow the eyes to drift back in towards primary position, producing nystagmus with fast component beats in the direction of gaze (gaze-evoked nystagmus). This is the most common type of 'central' nystagmus; it is most commonly bidirectional and not usually accompanied by vertigo. Other signs of brainstem dysfunction may be evident. Brainstem disease may also cause vertical nystagmus.

Unilateral cerebellar lesions may result in gaze-evoked nystagmus when looking in the direction of the lesion, where the fast phases are directed towards the side of the lesion. Cerebellar hemisphere lesions also cause 'ocular dysmetria', an overshoot of target-directed, fast eye movements (saccades) resembling 'past-pointing' in limbs.

In vestibular lesions, damage to one of the horizontal canals or its connections will allow the tonic output from the healthy contralateral side to cause the eyes to drift towards the side of the lesion. This elicits recurrent compensatory fast movements away from the side of the lesion, manifest as unidirectional horizontal nystagmus. Vertical and torsional components can be seen with damage to other parts of the vestibular apparatus. The nystagmus of peripheral labyrinthine lesions is accompanied by vertigo and usually by nausea, vomiting and unsteadiness, but as the CNS habituates, the nystagmus disappears (fatigues) quite quickly. Central vestibular nystagmus is more persistent.

Nystagmus also occurs as a consequence of drug toxicity and nutritional deficiency (e.g. thiamin). The severity is variable, and it may or may not result in visual degradation, though it may be associated with a sensation of movement of the visual world (oscillopsia). Nystagmus may occur as a congenital phenomenon, in which case both phases are equal and 'pendular', rather than having alternating fast and slow components.

Ptosis

Various disorders may cause drooping of the eyelids (ptosis) and these are listed in Box 25.21 and shown on Figure 25.21.

Abnormal pupillary responses

Abnormal pupillary responses may arise from lesions at several points between the retina and brainstem. Lesions of the oculomotor nerve, ciliary ganglion and sympathetic supply produce characteristic ipsilateral disorders of pupillary function. 'Afferent' defects result from damage to an optic nerve, impairing the direct response of a pupil to light, although leaving the consensual response from stimulation of the normal eye intact. Structural damage to the iris itself can also result in pupillary abnormalities. Causes are given in Box 25.22. An example is shown in Figure 25.22.

Papilloedema

There are several causes of swelling of the optic disc but the term 'papilloedema' is reserved for swelling secondary to raised intracranial pressure, when obstructed axoplasmic flow from retinal ganglion cells results in swollen nerve fibres, which in turn cause capillary and venous congestion, producing papilloedema.

25.21 Common causes of ptosis

Mechanism	Causes	Associated clinical features
3rd nerve palsy	Isolated palsy (see Box 25.20) Central/supranuclear lesion	Ptosis is usually complete Extraocular muscle palsy (eye 'down and out') Depending on site of lesion, other cranial nerve palsies (e.g. 4, 5 and 6) or contralateral upper motor neuron signs
Sympathetic lesion (**Horner's syndrome**: see Fig. 25.22)	Central (hypothalamus/brainstem) Peripheral (lung apex, carotid artery pathology) Idiopathic	Ptosis is partial Lack of sweating on affected side Depending on site of lesion, brainstem signs, signs of apical lung/brachial plexus disease, or ipsilateral carotid artery stroke
Myopathic	Myasthenia gravis Dystrophia myotonica	Extraocular muscle palsies Usually bilateral More widespread muscle weakness, with fatigability in myasthenia Progressive external ophthalmoplegia Other characteristic features of individual causes
Other	Functional ptosis Pseudo-ptosis (e.g. blepharospasm) Local orbital/lid disease Age-related levator dehiscence	Resistance to eye opening Eyebrows depressed rather than raised May be local orbital abnormality

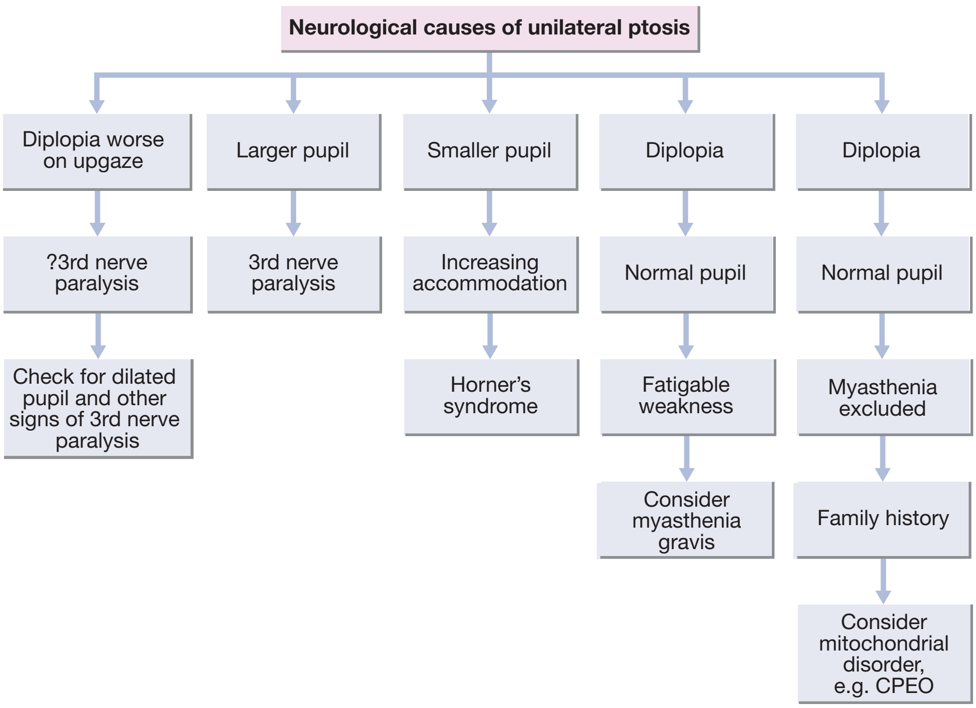

Fig. 25.21 Differential diagnosis of unilateral ptosis. (CPEO = chronic progressive external ophthalmoplegia)

Fig. 25.22 Right-sided Horner's syndrome due to paravertebral metastasis at T1. There is ipsilateral partial ptosis and a small pupil.

The earliest sign is the cessation of venous pulsation seen at the disc, progression causing the disc margins to become red (hyperaemic). Disc margins become indistinct and haemorrhages may occur in the retina (Fig. 25.23). Lack of papilloedema never excludes raised intracranial pressure. Other causes of optic disc swelling are listed in Box 25.23. Some normal variations of disc appearance (e.g. optic nerve drusen, p. 1178) can mimic disc swelling. Optic disc swelling is also discussed on page 1171.

Optic atrophy

Loss of nerve fibres causes the optic disc to appear pale, as the choroid becomes visible (Fig. 25.24). A pale disc (optic

i 25.22 Pupillary disorders

Disorder	Cause	Ophthalmological features	Associated features
3rd nerve palsy	See Box 25.21	Dilated pupil (especially with external compression) Extraocular muscle palsy (eye is typically 'down and out') Complete ptosis	Other features of 3rd nerve palsy (see Box 25.21)
Horner's syndrome (see Fig. 25.22)	Lesion to sympathetic supply	Small pupil Partial ptosis Iris heterochromia (if congenital)	Ipsilateral failure of sweating (anhidrosis)
Holmes–Adie syndrome (tonic pupil)	Lesion of ciliary ganglion (usually idiopathic)	Dilated pupil Light-near dissociation (accommodate but do not react to light) Vermiform movement of iris during contraction Disturbance of accommodation	Generalised areflexia
Argyll Robertson pupil	Dorsal mid-brain lesion (syphilis or diabetes)	Small, irregular pupils Light-near dissociation	Other features of tabes dorsalis (p. 1125)
Local pupillary damage	Trauma/inflammatory disease	Irregular pupils, often with adhesions to lens (synechiae) Variable degree of reactivity	Other features of trauma/underlying inflammatory disease (e.g. cataract, blindness etc.)
Relative afferent pupillary defect (Marcus Gunn pupil)	Damage to optic nerve	Pupils symmetrical – swinging torch test reveals dilatation in abnormal eye	Decreased visual acuity/colour vision Central scotoma Optic disc swelling or pallor

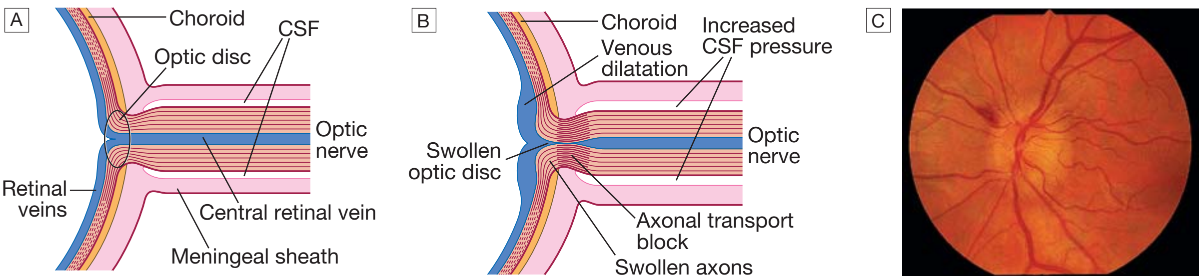

Fig. 25.23 Mechanism of optic disc oedema (papilloedema). A Normal. B Disc oedema (e.g. due to cerebral tumour). C Fundus photograph of the left eye showing optic disc oedema with a small haemorrhage on the nasal side of the disc. (CSF = cerebrospinal fluid) *C, Courtesy of Dr B. Cullen.*

i 25.23 Common causes of optic disc swelling

Raised intracranial pressure (papilloedema)

- Cerebral mass lesion (tumour, abscess)
- Obstructive hydrocephalus
- Idiopathic intracranial hypertension

Obstruction of ocular venous drainage

- Central retinal vein occlusion
- Cavernous sinus thrombosis

Systemic disorders affecting retinal vessels

- Hypertension
- Vasculitis
- Hypercapnia

Optic nerve damage

- Demyelination (optic neuritis/papillitis)
- Leber's hereditary optic neuropathy
- Anterior ischaemic optic neuropathy
- Toxins (e.g. methanol)
- Infiltration of optic disc
- Sarcoidosis
- Glioma
- Lymphoma

Fig. 25.24 Fundus photograph of the left eye of a patient with familial optic atrophy. Note the marked pallor of the optic disc.

atrophy) follows optic nerve damage; causes include previous optic neuritis or ischaemic damage, long-standing papilloedema, optic nerve compression, trauma and degenerative conditions (e.g. Friedreich's ataxia, p. 1116).

Hearing disturbance

Each cochlear organ has bilateral cortical representation, so unilateral hearing loss is a result of peripheral organ damage. Bilateral hearing dysfunction is usual and is most commonly due to age-related degeneration or noise damage, although infection and drugs (particularly diuretics and aminoglycoside antibiotics) can be a primary cause. Prominent deafness may suggest a mitochondrial disorder (see Box 25.93, p. 1144).

Bulbar symptoms – dysphagia and dysarthria

Swallowing is a complex activity involving the coordinated action of lips, tongue, soft palate, pharynx and larynx, which are innervated by cranial nerves 7, 9, 10, 11 and 12. Structural causes of dysphagia are considered on page 778. Neurological mechanisms are vulnerable to damage at different points, resulting in dysphagia that is usually accompanied by dysarthria. Tempo is again crucial: acute onset of dysphagia may occur as a result of brainstem stroke or a rapidly developing neuropathy, such as Guillain–Barré syndrome or diphtheria. Intermittent fatigable muscle weakness (including dysphagia) would suggest myasthenia gravis. Dysphagia developing over weeks or months may be seen in motor neuron disease, basal meningitis and inflammatory brainstem disease. More slowly developing dysphagia suggests a myopathy or possibly a brainstem or skull-base tumour.

Pathologies affecting lower cranial nerves (9, 10, 11 and 12) frequently manifest bilaterally, producing dysphagia and dysarthria. The term 'bulbar palsy' is used to describe lower motor neuron lesions, either within the medulla or outside the brainstem. The tongue may be wasted and fasciculating, and palatal movement is reduced.

Upper motor neuron innervation of swallowing is bilateral, so persistent dysphagia is unusual with a unilateral upper motor lesion (the exception being in the acute stages of, for example, a hemispheric stroke). Widespread lesions above the medulla will cause upper motor neuron bulbar paralysis, known as 'pseudobulbar palsy'. Here the tongue is small and contracted, and moves slowly; the jaw jerk is brisk, and there may be associated emotional variability. Causes of these are shown in Box 25.24.

i 25.24 Causes of pseudobulbar and bulbar palsy

Type	Pseudobulbar	Bulbar
Genetic	–	Kennedy's disease (X-linked bulbospinal neuronopathy)
Vascular	Bilateral hemisphere (lacunar) infarction	Medullary infarction (see Box 25.3, p. 1072)
Degenerative	Motor neuron disease (p. 1116)	Motor neuron disease Syringobulbia
Inflammatory/ infective	Multiple sclerosis (p. 1106) Cerebral vasculitis	Myasthenia (p. 1140) Guillain–Barré syndrome (p. 1140) Poliomyelitis (p. 1123) Lyme disease (p. 255) Vasculitis
Neoplastic	High brainstem tumours	Brainstem glioma Malignant meningitis

Bladder, bowel and sexual disturbance

While isolated disturbances of bladder, bowel and sexual function are rarely the sole presenting features of neurological disease, they are common complications of many chronic disorders such as multiple sclerosis, stroke and dementia, and are frequently found post head injury. Abnormalities in these functions considerably reduce quality of life for patients. Incontinence and its management are discussed elsewhere (pp. 397, 835 and 1309).

Bladder dysfunction

The anatomy and physiology involved in controlling bladder functions are discussed on page 386 but it is worth emphasising the role of the pontine micturition centre, which is itself under higher control via inputs from the pre-frontal cortex, mid-brain and hypothalamus.

In the absence of conscious control (e.g. in coma or dementia), distension of the bladder to near capacity evokes reflex detrusor contraction (analogous to the muscle stretch reflex), and reciprocal changes in sympathetic activation and relaxation of the distal sphincter result in coordinated bladder emptying.

Damage to the lower motor neuron pathways (the pelvic and pudendal nerves) produces a flaccid bladder and sphincter with overflow incontinence, often accompanied by loss of pudendal sensation. Such damage may be due to disease of the conus medullaris or sacral nerve roots, either within the dura (as in inflammatory or carcinomatous meningitis) or as they pass through the sacrum (trauma or malignancy), or due to damage to the nerves themselves in the pelvis (infection, haematoma, trauma or malignancy).

Damage to the pons or spinal cord results in an 'upper motor neuron' pattern of bladder dysfunction due to uncontrolled over-activity of the parasympathetic supply. The bladder is small and highly sensitive to being stretched. This results in frequency, urgency and urge incontinence. Loss of the coordinating control of the pontine micturition centre will also result in the phenomenon of detrusor–sphincter dyssynergia, in which detrusor contraction and sphincter relaxation are not coordinated; the spastic bladder will often try to empty against a closed sphincter. This manifests as both urgency and an inability to pass urine, which is distressing and painful. The resultant incomplete bladder emptying predisposes to urinary infection, and the prolonged high intravesical pressure may result in obstructive uropathy and renal failure; post-micturition bladder ultrasound may confirm incomplete bladder emptying. More severe lesions of the spinal cord, as in spinal cord compression or trauma, can result in painless urinary retention as bladder sensation, normally carried in the lateral spinothalamic tracts, will be disrupted.

Damage to the frontal lobes gives rise to loss of awareness of bladder fullness and consequent incontinence. Coexisting cognitive impairment may result in inappropriate micturition. These features may be seen in hydrocephalus, frontal tumours, dementia and bifrontal subdural haematomas.

When a patient presents with bladder symptoms, it is important to localise the lesion on the basis of history and examination, remembering that most bladder problems are not neurological

25.25 Neurogenic bladder: clinical features and treatment

Type	Site of lesion	Result	Treatment
Atonic (lower motor neuron)	Sacral segments of cord (conus medullaris) Sacral roots and nerves	Loss of detrusor contraction Difficulty initiating micturition Bladder distension with overflow	Intermittent self-catheterisation In-dwelling catheterisation
Hypertonic (upper motor neuron)	Pyramidal tract in spinal cord or brainstem	Urgency with urge incontinence Bladder sphincter incoordination (dyssynergia) Incomplete bladder emptying	Anticholinergics: Solifenacin Tolterodine Imipramine Intermittent self-catheterisation
Cortical	Post-central Pre-central Frontal	Loss of awareness of bladder fullness Difficulty initiating micturition Inappropriate micturition Loss of social control	Intermittent or in-dwelling catheterisation

unless there are overt neurological signs. Clinical features and management are summarised in Box 25.25.

Rectal dysfunction

The rectum has an excitatory cholinergic input from the parasympathetic sacral outflow, and inhibitory sympathetic supply similar to the bladder. Continence depends largely on skeletal muscle contraction in the puborectalis and pelvic floor muscles supplied by the pudendal nerves, as well as the internal and external anal sphincters. Damage to the autonomic components usually causes constipation (a common early symptom in Parkinson's disease) but diabetic neuropathy can be associated with diarrhoea. Lesions affecting the conus medullaris, the somatic S2–4 roots and the pudendal nerves may cause faecal incontinence.

Erectile failure and ejaculatory failure

These related functions are under autonomic control via the pelvic nerves (parasympathetic, S2–4) and hypogastric nerves (sympathetic, L1–2). Descending influences from the cerebrum are important for erection but it can occur as a reflex phenomenon in response to genital stimulation. Erection is largely parasympathetic and may be impaired by a number of drugs, including anticholinergic, antihypertensive and antidepressant agents. Sympathetic activity is important for ejaculation and may be inhibited by α-adrenoceptor antagonists (α-blockers). For further information on erectile dysfunction, see page 440.

Personality change

While this is often due to psychiatric illness, neurological conditions that alter the function of the frontal lobes can cause personality change and mood disorder (see Box 25.2, p. 1066). Personality change due to a frontal lobe disorder may occur as the result of structural damage due to stroke, trauma, tumour or hydrocephalus. The nature of any change may help localise the lesion.

Patients with mesial frontal lesions become increasingly withdrawn, unresponsive and mute (abulic), often in association with urinary incontinence, gait apraxia and an increase in tone known as gegenhalten, in which the patient varies the resistance to movement in proportion to the force exerted by the examiner.

Patients with lesions of the dorsolateral pre-frontal cortex develop a dysexecutive syndrome, which involves difficulties with speech, motor planning and organisation. Those with orbitofrontal lesions of the frontal lobes, in contrast, become disinhibited, displaying grandiosity or irresponsible behaviour. Memory is substantially intact but frontal release signs may emerge, such as a grasp reflex, palmomental response or pout. Proximity to the olfactory bulb and tracts means that inferior frontal lobe tumours may be associated with anosmia.

Disturbance to the cortical areas responsible for speech or memory can result in changes that may be interpreted as changes in personality.

Sleep disturbance

Disturbances of sleep are common and are not usually due to neurological disease. Patients may complain of insomnia (difficulty sleeping), excessive daytime sleepiness, disturbed behaviour during night-time sleep, parasomnia (sleep walking and talking, or night terrors) or disturbing subjective experiences during sleep and/or its onset (nightmares, hypnagogic hallucinations, sleep paralysis). A careful history (from bed partner as well as patient) usually allows specific causes of sleep disturbance to be identified and these are discussed in more detail on page 1105.

Psychiatric disorders

Psychiatric disorders are described in Chapter 28 but may cause or result from neurological problems. Care is needed in their identification, as effective management will help the underlying neurological illness.

Functional symptoms

Many patients presenting with neurological symptoms do not have a defined neurological disease and are best described as having functional symptoms (p. 1187). Some of these are psychogenic (or conversion) disorders. Such patients often have symptoms affecting multiple systems and an impressively long list of consultations and negative tests from other medical specialties when they present. Considering the possibility of a functional origin may save the patient some further anxiety and further investigation (which will be unnecessary, expensive, possibly invasive, and inconvenient).

i 25.26 Clinical features suggestive of functional disorder

- Inconsistent examination findings (e.g. Hoover's sign, p. 1082)
- Situational provocation of events (e.g. in medical settings)
- Associated mental health disorders:
  - Anxiety
  - Depression
- Lack of anatomical coherence to neurological symptoms
- Florid or bizarre descriptions of individual symptoms
- History of multiple other systemic symptoms inadequately explained by disease (asthma/breathlessness, fatigue, pain, gastrointestinal symptoms)

Weakness and sensory change predominate among patients with functional neurological disorders but pain or loss of consciousness can also occur. Associated symptoms, such as tiredness, lethargy, poor concentration, bowel upset (irritable bowel syndrome) and gynaecological complaints, are common. A functional cause should always be considered, as it can allow for more rapid diagnosis and minimise investigation. Some clinical features may hint at a functional origin for symptoms (Box 25.26). It is the clinician's (rewarding, albeit sometimes challenging) job to elicit the context of the patient's symptoms in a sensitive and non-judgemental manner. Whatever the cause of the illness, it is important to acknowledge that mood and sleep disturbance will exacerbate neurological symptoms, thus increasing disability. The best practitioners have the skill to carry the patient with them when describing the patterns of behaviour contributing to worsening symptoms.

Assessment to detect an underlying or exacerbating mood disorder is vital in all patients, ensuring that depression and anxiety are managed to minimise their secondary effects on neurological symptoms.

Headache syndromes

Acute management of headache is dealt with on page 184 but management of chronic, complex, or refractory headaches may require specialist input. Headaches may be classified as primary or secondary, depending on the underlying cause (see Box 10.10, p. 184). Secondary headache may be due to structural, infective, inflammatory or vascular conditions, discussed later in this chapter. Primary headache syndromes are described here.

Tension-type headache

This is the most common type of headache and is experienced to some degree by the majority of the population.

Pathophysiology

Tension-type headache is incompletely understood, and some consider that it is simply a milder version of migraine; certainly, the original notion that it is due primarily to muscle tension (hence the unsatisfactory name) has long since been dismissed. Anxiety about the headache itself may lead to continuation of symptoms, and patients may become convinced of a serious underlying condition.

Clinical features

The pain of tension headache is characterised as 'dull', 'tight' or like a 'pressure', and there may be a sensation of a band round the head or pressure at the vertex. It is of constant character and generalised, but often radiates forwards from the occipital region. It may be episodic or persistent, although the severity may vary, and there is no associated vomiting or photophobia. Tension-type headache is rarely disabling and patients appear well. The pain often progresses throughout the day. Tenderness may be present over the skull vault or in the occiput but is easily distinguished from the triggered pains of trigeminal neuralgia and the exquisite tenderness of temporal arteritis. Analgesics may be taken with chronic regularity, despite little effect, and may perpetuate the symptoms (see 'Medication overuse headache' below).

Management

Most benefit is derived from a careful assessment, followed by discussion of likely precipitants and reassurance that the prognosis is good. The concept of medication overuse headache needs careful explanation. An important therapeutic step is to allow patients to realise that their problem has been taken seriously and rigorously assessed. Physiotherapy (with muscle relaxation and stress management) may help and low-dose amitriptyline can provide benefit. Investigation is rarely required. The reassurance value of brain imaging needs careful assessment: the pick-up rate of structural abnormalities is exceedingly low, and significantly outweighed by the likelihood of identifying an incidental and irrelevant finding (e.g. an arachnoid cyst, Chiari I malformation or vascular abnormality). The value of such 'reassurance' is usually over-estimated by doctors and patients alike.

Migraine

Migraine usually appears before middle age, or occasionally in later life; it affects about 20% of females and 6% of males at some point in life. Migraine is usually readily identifiable from the history, although unusual variants can cause uncertainty.

Pathophysiology

The cause of migraine is unknown but there is increasing evidence that the aura (see below) is due to dysfunction of ion channels causing a spreading front of cortical depolarisation (excitation) followed by hyperpolarisation (depression of activity). This process (the 'spreading depression of Leão') spreads over the cortex at a rate of about 3 mm/min, corresponding to the aura's symptomatic spread. The headache phase is associated with vasodilatation of extracranial vessels and may be relayed by hypothalamic activity. Activation of the trigeminovascular system is probably important. A genetic contribution is implied by the frequently positive family history, and similar phenomena occurring in disorders such as CADASIL (p. 1052) or mitochondrial disease (p. 1144). The female preponderance and the frequency of migraine attacks at certain points in the menstrual cycle also suggest hormonal influences. Oestrogen-containing oral contraception sometimes exacerbates migraine and increases the very small risk of stroke in patients who suffer from migraine with aura. Doctors and patients often over-estimate the role of dietary precipitants such as cheese, chocolate or red wine. When psychological factors contribute, the migraine attack often occurs after a period of stress, being more likely on Friday evening at the end of the working week or at the beginning of a holiday.

Clinical features

Some patients report a prodrome of malaise, irritability or behavioural change for some hours or days. Around 20% of

patients experience an aura and are said to have migraine with aura (previously known as classical migraine). The aura may manifest as almost any neurological symptom but is most often visual, consisting of fortification spectra, which are usually positive phenomena such as shimmering, silvery zigzag lines marching across the visual fields for up to 40 minutes, sometimes leaving a trail of temporary visual field loss (scotoma). Sensory symptoms characteristically spreading over 20–30 minutes, from one part of the body to another, are more common than motor ones, and language function can be affected, leading to similarities with TIA/stroke. Isolated aura may occur (i.e. the neurological symptoms are not followed by headache).

The 80% of patients with characteristic headache but no 'aura' are said to have migraine without aura (previously called 'common' migraine).

Migraine headache is usually severe and throbbing, with photophobia, phonophobia and vomiting lasting from 4 to 72 hours. Movement makes the pain worse and patients prefer to lie in a quiet, dark room.

In a small number of patients the aura may persist, leaving more permanent neurological disturbance. This persistent migrainous aura may occur with or without evidence of brain infarction.

Management

Avoidance of identified triggers or exacerbating factors (such as the combined contraceptive pill) may prevent attacks. Treatment of an acute attack consists of simple analgesia with aspirin, paracetamol or non-steroidal anti-inflammatory agents. Nausea may require an antiemetic such as metoclopramide or domperidone. Severe attacks can be aborted by one of the 'triptans' (e.g. sumatriptan), which are potent 5-hydroxytryptamine (5-HT, serotonin) agonists. These can be administered via the oral, subcutaneous or nasal route. Caution is needed with ergotamine preparations because they may lead to dependence. Overuse of any analgesia, including triptans, may contribute to medication overuse headache.

If attacks are frequent (more than two per month), prophylaxis should be considered. Many drugs can be chosen but the most frequently used are vasoactive drugs (β-blockers), antidepressants (amitriptyline, dosulepin) and antiepileptic drugs (valproate, topiramate). Women with aura should avoid oestrogen treatment for either oral contraception or hormone replacement, although the increased risk of ischaemic stroke is minimal.

Medication overuse headache

With increasing availability of over-the-counter medication, headache syndromes perpetuated by analgesia intake are becoming much more common. Medication overuse headache (MOH) can complicate any headache syndrome but is especially common with migraine and chronic tension-type headache. The most frequent culprits are compound analgesics (particularly codeine and other opiate-containing preparations) and triptans, and MOH is usually associated with use on more than 10–15 days per month.

Management is by withdrawal of the responsible analgesics. Patients should be warned that the initial effect will be to exacerbate the headache, and migraine prophylactics may be helpful in reducing the rebound headaches. Relapse rates are high, and patients often need help and support in withdrawing from analgesia; a careful explanation of this paradoxical concept is vital.

Cluster headache

Cluster headaches (also known as migrainous neuralgia) are much less common than migraine. Unusually for headache syndromes, there is a significant male predominance and onset is usually in the third decade.

Pathophysiology

The cause is unknown but this type of headache differs from migraine in many ways, suggesting a different pathophysiological basis. Although uncommon, it is the most common of the trigeminal autonomic cephalalgia syndromes. Functional imaging studies have suggested abnormal hypothalamic activity. Patients are more often smokers with a higher than average alcohol consumption.

Clinical features

Cluster headache is strikingly periodic, featuring runs of identical headaches beginning at the same time for weeks at a stretch (the 'cluster'). Patients may experience either one or several attacks within a 24-hour period, and typically are awoken from sleep by symptoms ('alarm clock headache'). Cluster headache causes severe, unilateral periorbital pain with autonomic features, such as ipsilateral tearing, nasal congestion and conjunctival injection (occasionally with the other features of a Horner's syndrome). The pain, though severe, is characteristically brief (30–90 minutes). In contrast to the behaviour of those with migraine, patients are highly agitated during the headache phase. The cluster period is typically a few weeks, followed by remission for months to years, but a small proportion do not experience remission.

Management

Acute attacks can usually be halted by subcutaneous injections of sumatriptan or inhalation of 100% oxygen. The brevity of the attack probably prevents other migraine therapies from being effective. Migraine prophylaxis is often ineffective too but attacks can be prevented in some patients by verapamil, sodium valproate, or short courses of oral glucocorticoids. Patients with severe debilitating clusters can be helped with lithium therapy, although this requires monitoring (p. 1200).

Trigeminal neuralgia

This is characterised by unilateral lancinating facial pain, most commonly involving the second and/or third divisions of the trigeminal nerve territory, usually in patients over the age of 50 years.

Pathophysiology

For most, trigeminal neuralgia remains an idiopathic condition but there is a suggestion that it may be due to an irritative lesion involving the trigeminal root zone, in some cases an aberrant loop of artery. Other compressive lesions, usually benign, are occasionally found. Trigeminal neuralgia associated with multiple sclerosis may result from a plaque of demyelination in the brainstem.

Clinical features

The pain is repetitive, severe and very brief (seconds or less). It may be triggered by touch, a cold wind or eating. Physical signs are usually absent, although the spasms may make the patient wince and sit silently (tic douloureux). There is a tendency for the condition to remit and relapse over many years. Rarely, there

may be combined features of trigeminal neuralgia and cluster headache ('cluster–tic').

Management

The pain often responds to carbamazepine. It is wise to start with a low dose and increase gradually, according to effect. In patients who cannot tolerate carbamazepine, oxcarbazepine, gabapentin, pregabalin, amitriptyline or glucocorticoids may be effective alternatives, but if medication is ineffective or poorly tolerated, surgical treatment should be considered. Decompression of the vascular loop encroaching on the trigeminal root is said to have a 90% success rate. Otherwise, localised injection of alcohol or phenol into a peripheral branch of the nerve may be effective.

Headaches associated with specific activities

These usually affect men in their thirties and forties. Patients develop a sudden, severe headache with exertion, including sexual activity. There is usually no vomiting or neck stiffness, and the headache lasts less than 10–15 minutes, though a less severe dullness may persist for some hours. Subarachnoid haemorrhage needs to be excluded by CT and/or CSF examination (see Fig. 26.14, p. 1162) after a first event. The pathogenesis of these headaches is unknown. Although frightening, attacks are usually brief and patients may need only reassurance and simple analgesia for the residual headache. The syndrome may recur, and prevention may be necessary with propranolol or indometacin.

Other headache syndromes

A number of rare headache syndromes produce pains about the eye similar to cluster headaches (Box 25.27). These include chronic paroxysmal hemicrania and SUNCT (short-lasting unilateral neuralgiform headaches with conjunctival injection and tearing). The recognition of these syndromes is useful because they often respond to specific treatments such as indometacin.

Epilepsy

A seizure can be defined as the occurrence of signs and/or symptoms due to abnormal, excessive or synchronous neuronal activity in the brain. The lifetime risk of an isolated seizure is about 5%, although incidence is highest at the extremes of age. Epilepsy is the tendency to have unprovoked seizures. While the prevalence of active epilepsy in European countries is about 0.5%, the figure in developing countries may be higher because of parasitic illnesses such as cysticercosis (p. 298). A recent change in definition allows the diagnosis of epilepsy to be made after a single seizure with a high risk of recurrence (e.g. a single seizure in the presence of a cortical lesion). Such changes may lead to an observed increase in epilepsy incidence.

Historical terms such as 'grand mal' (implying tonic–clonic seizures) and 'petit mal' (intended originally to mean 'absence seizures' but commonly misused to describe 'anything other than grand mal') have been superseded. Subsequent revisions, including terms such as 'complex partial' and 'simple partial', have been imprecise and carry little information about underlying pathology, treatment or prognosis. The modern equivalents for these terms will be given below, but it is preferable to adhere to the 2010 iteration of the International League Against Epilepsy's classification (Box 25.28).

Pathophysiology

To function normally, the brain must maintain a continual balance between excitation and inhibition, remaining responsive to the environment while avoiding continued unrestrained spontaneous activity. The inhibitory transmitter gamma-aminobutyric acid (GABA) is particularly important, acting on ion channels to enhance chloride inflow and reducing the chances of action potential formation. Excitatory amino acids (glutamate and aspartate) allow influx of sodium and calcium, producing the opposite effect. It is likely that many seizures result from an imbalance

25.27 Benign paroxysmal headaches

Type	Character of pain	Duration	Location	Comment
Ice pick	Stabbing	Very brief (split-second)	Variable, usually temporoparietal	Benign, more common in migraine
Ice cream	Sharp, severe	30–120 secs	Bitemporal/occipital	Obvious trigger by cold stimuli
Exertional/sexual activity	Bursting, thunderclap	Severe for mins, then less severe for hours	Generalised	Subarachnoid haemorrhage needs to be excluded
Cough	Bursting	Secs to mins	Occipital or generalised	Intracranial pathology needs to be excluded (especially craniocervical junction)
Cluster headache (migrainous neuralgia)	Severe unilateral, with ptosis, tearing, conjunctival injection, unilateral nasal congestion	30–90 mins 1–3 times per day	Periorbital	Usually in men, occurring in clusters over weeks/months
Chronic paroxysmal hemicrania	Severe unilateral with cluster headache-like autonomic features (see above)	5–20 mins, frequently through day	Periorbital/temporal	Usually in women, responds to indometacin
SUNCT*	Severe, sharp, triggered by touch or neck movements	15–120 secs, repetitive through day	Periorbital	May respond to carbamazepine

*__S__hort-lasting, __u__nilateral, __n__euralgiform headache with __c__onjunctival injection, __t__earing, rhinorrhoea and forehead sweating.

25

25.28 Classification of seizures (2010 International League Against Epilepsy classification)

Generalised seizures

- Tonic–clonic (in any combination)
- Absence:
  - Typical
  - Atypical
  - Absence with special features
- Myoclonic absence
- Eyelid myoclonia
- Myoclonic:
  - Myoclonic
  - Myoclonic–atonic
  - Myoclonic–tonic
- Clonic
- Tonic
- Atonic

Focal seizures

- Without impairment of consciousness or awareness (was 'simple partial'):
  - Focal motor
  - Focal sensory
- With impairment of consciousness or awareness (was 'complex partial')
- Evolving to a bilateral, convulsive seizure (was 'secondarily generalised seizure'):

  - Clonic
  - Tonic–clonic

Unknown

- Epileptic spasms

between this excitation and inhibition. Intracellular recordings during seizures demonstrate a paroxysmal depolarisation shift in neuronal membrane potential, an upshift in internal potential predisposing to recurrent action potentials. In vivo, epileptic cortex shows repetitive discharges involving large groups of neurons.

Focal epilepsy

Seizures may be related to a localised disturbance in the cortex, becoming manifest in the first instance as focal seizures. Any disturbance of cortical architecture and function can precipitate this, whether focal infection, tumour, hamartoma or trauma-related scarring. If focal seizures remain localised, the symptoms experienced depend on which cortical area is affected. If areas in the temporal lobes become involved, then awareness of the environment becomes impaired but without associated tonic–clonic movements. When both hemispheres become involved, the seizure becomes generalised (Fig. 25.25).

Generalised epilepsies

The new terminology is genetic generalised epilepsies (GGEs) (previously idiopathic generalised epilepsies) to reflect their likely cause. These seizures are generalised at onset, abnormal activity probably originating in the central mechanisms controlling cortical activation (Fig. 25.25) and spreading rapidly. This group constitutes around 30% of all epilepsy and is likely to reflect widespread disturbance of structure or function. GGEs almost always become apparent before the age of 35.

Seizure activity is usually apparent on EEG as spike and wave discharges (see Fig. 25.14, p. 1075). Other generalised seizures may involve merely brief loss of awareness (absence seizures), single jerks (myoclonus) or loss of tone (atonic seizures), as detailed in Box 25.28.

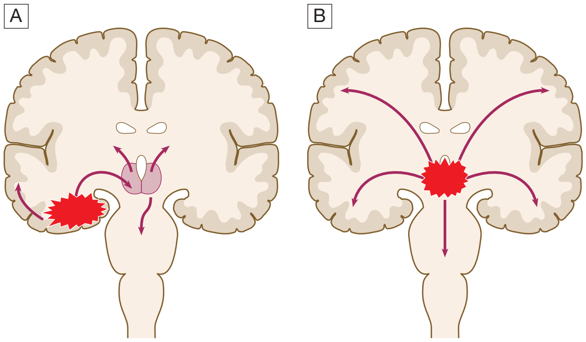

Fig. 25.25 The pathophysiological classification of seizures. **A** A focal seizure originates from a paroxysmal discharge in a focal area of the cerebral cortex (often the temporal lobe); the seizure may subsequently spread to the rest of the brain (secondary generalisation) via diencephalic activating pathways. **B** In genetic generalised epilepsies (GGEs) the abnormal electrical discharges originate from the diencephalic activating system and spread simultaneously to all areas of the cortex.

25.29 Trigger factors for seizures

- Sleep deprivation
- Missed doses of antiepileptic drugs in treated patients
- Alcohol (particularly withdrawal)
- Recreational drug misuse
- Physical and mental exhaustion
- Flickering lights, including TV and computer screens (generalised epilepsy syndromes only)
- Intercurrent infections and metabolic disturbances
- Uncommon: loud noises, music, reading, hot baths

Clinical features

Seizure type and epilepsy type

Patients can experience more than one type of seizure attack, and it is important to document each attack type and the patient's age at its onset, along with its frequency, duration and typical features. Any triggers should be identified (Box 25.29). The type of seizure, other clinical features and investigations can then be used to determine the epilepsy syndrome, as discussed below. Where there is doubt about the type, this is best stated and a full classification should be deferred until the evolution of the clinical features clarifies the picture.

To classify seizure type, the clinician should ask firstly whether there is a focal onset, and secondly whether the seizures conform to one of the recognised patterns (see Box 25.28). Epilepsy that starts in patients beyond their mid-thirties will almost invariably reflect a focal cerebral event. Where activity remains focal, the classification will be obvious. With generalised tonic–clonic seizures, a focal onset will be heralded by positive neurological symptoms and signs corresponding to the normal function of that area. Occipital onset causes visual changes (lights and blobs of colour), temporal lobe onset causes false recognition (déjà vu), sensory strip involvement causes sensory alteration (burning, tingling), and motor strip involvement causes jerking.

Alternatively, patients report a previous local cortical insult, and it may be reasonably (but not invariably) inferred that this is the seat of epileptogenesis.

Focal seizures

The classification of focal seizures is shown in Box 25.28. They are caused by localised cortical activity with retained awareness. The localisation of such symptoms is described above. A spreading pattern of seizure may occur, the abnormal sensation spreading much faster (in seconds) than a migrainous focal sensory attack.

Awareness may become impaired if spread occurs to the temporal lobes (previously 'complex partial seizure'). Patients stop and stare blankly, often blinking repetitively, making smacking movements of their lips or displaying other automatisms, such as picking at their clothes. After a few minutes consciousness returns but the patient may be muddled and feel drowsy for a period of up to an hour. The age of onset, preceding aura, longer duration and post-ictal symptoms usually make these easy to differentiate from childhood absence seizures (see below).

Seizures arising from the anterior parts of the frontal lobe may produce bizarre behaviour patterns, including limb posturing, sleep walking or even frenetic, ill-directed motor activity with incoherent screaming. Video EEG may be necessary to differentiate these from psychogenic attacks (which are more common) but abruptness of onset, stereotyped nature, relative brevity and nocturnal preponderance may indicate a frontal origin. Causes of focal seizures are given in Box 25.30.

Generalised seizures

Tonic–clonic seizures An initial 'aura' may be experienced by the patient, depending on the cortical area from which the seizure originates (as above). The patient then becomes rigid (tonic) and unconscious, falling heavily if standing ('like a log') and risking facial injury. During this phase, breathing stops and central cyanosis may occur. As cortical discharges reduce in frequency, jerking (clonic) movements emerge for 2 minutes at most. Afterwards, there is a flaccid state of deep coma, which can persist for some minutes, and on regaining awareness the patient may be confused, disorientated and/or amnesic. During the attack, urinary incontinence and tongue-biting may occur. A severely bitten, bleeding tongue after an attack of loss of consciousness is pathognomonic of a generalised seizure but less marked lingual injury can occur in syncope. Subsequently, the patient usually feels unwell and sleepy, with headache and myalgia. Witnesses are usually frightened by the event, often believe the person to be dying, and may struggle to give a clear account of the episode. Some may not describe the tonic or clonic phase and may not mention cyanosis or tongue-biting. In less typical episodes, post-ictal delirium, or sequelae such as headache or myalgia, may be the main pointers to the diagnosis. Causes of generalised tonic–clonic seizures are listed in Box 25.31.

Absence seizures Absence seizures (previously 'petit mal') always start in childhood. The attacks are rarely mistaken for focal seizures because of their brevity. They can occur so frequently (20–30 times a day) that they are mistaken for daydreaming or poor concentration in school.

Myoclonic seizures These are typically brief, jerking movements, predominating in the arms. In epilepsy, they are more marked

i 25.30 Causes of focal seizures

Idiopathic

- Benign Rolandic epilepsy of childhood
- Benign occipital epilepsy of childhood

Focal structural lesions

Genetic

- Tuberous sclerosis (p. 1264)
- Autosomal dominant nocturnal frontal lobe epilepsy
- Autosomal dominant partial epilepsy with auditory features (ADPEAF)
- von Hippel–Lindau disease (p. 1132)
- Neurofibromatosis (p. 1131)
- Cerebral migration abnormalities

Infantile hemiplegia

Dysembryonic

- Cortical dysgenesis
- Sturge–Weber syndrome

Mesial temporal sclerosis (associated with febrile convulsions)

Cerebrovascular disease (Ch. 26)

- Intracerebral haemorrhage
- Cerebral infarction
- Arteriovenous malformation
- Cavernous haemangioma

Tumours (primary and secondary) (p. 1129)

Trauma (including neurosurgery)

Infective (p. 1117)

- Cerebral abscess (pyogenic)
- Toxoplasmosis
- Cysticercosis
- Tuberculoma
- Subdural empyema
- Encephalitis
- Human immunodeficiency virus (HIV)

Inflammatory

- Autoimmune encephalopathies (e.g. anti-voltage-gated potassium channel antibodies, anti-NMDA receptor antibodies, anti-glycine receptor antibodies)
- Sarcoidosis
- Vasculitis

i 25.31 Causes of generalised tonic–clonic seizures

Generalisation from focal seizures

- See Box 25.30

Genetic

- Inborn errors of metabolism (p. 1144)
- Storage diseases
- Phakomatoses (e.g. tuberous sclerosis, p. 1264)

Cerebral birth injury

Hydrocephalus

Cerebral anoxia

Drugs

- Antibiotics: penicillin, isoniazid, metronidazole
- Antimalarials: chloroquine, mefloquine
- Ciclosporin
- Amphetamines (withdrawal)
- Cardiac anti-arrhythmics: lidocaine, disopyramide
- Psychotropic agents: phenothiazines, tricyclic antidepressants, lithium

Alcohol (especially withdrawal)

Toxins

- Organophosphates (sarin)
- Heavy metals (lead, tin)

Metabolic disease

- Hypocalcaemia
- Hyponatraemia
- Hypomagnesaemia
- Hypoglycaemia
- Renal failure
- Liver failure

Infective

- Post-infectious encephalopathy
- Meningitis (p. 1118)

Inflammatory

- Multiple sclerosis (uncommon; (p. 1106)
- Systemic lupus erythematosus (p. 1034)

Diffuse degenerative diseases

- Alzheimer's disease (uncommonly; p. 1992)
- Creutzfeldt–Jakob disease (rarely; p. 1127)

in the morning or on awakening from sleep, and tend to be provoked by fatigue, alcohol, or sleep deprivation.

Atonic seizures These are seizures involving brief loss of muscle tone, usually resulting in heavy falls with or without loss of consciousness. They occur only in the context of epilepsy syndromes that involve other forms of seizure.

Tonic seizures These are associated with a generalised increase in tone and an associated loss of awareness. They are usually seen as part of an epilepsy syndrome and are unlikely to be isolated.

Clonic seizures Clonic seizures are similar to tonic–clonic seizures. The clinical manifestations are similar but there is no preceding tonic phase.

Seizures of uncertain generalised or focal nature

Epileptic spasms While these are highlighted in the classification system, they are unusual in adult practice and occur mainly in infancy. They signify widespread cortical disturbance and take the form of marked contractions of the axial musculature, lasting a fraction of a second but recurring in clusters of 5–50, often on awakening.

Epilepsy syndromes

Many patients with epilepsy fall into specific patterns, depending on seizure type(s), age of onset and treatment responsiveness: the so-called electroclinical syndromes (Box 25.32). It is anticipated that genetic testing will ultimately demonstrate similarities in molecular pathophysiology.

Box 25.33 highlights the more common epilepsy syndromes, which are largely of early onset and are sensitive to sleep deprivation, hyperventilation, alcohol and photic stimulation. Epilepsies that do not fit into any of these diagnostic categories can be delineated firstly on the basis of the presence or absence of a known structural or metabolic condition (presumed cause), and then on the basis of the primary mode of seizure onset (generalised versus focal).

Investigations

Single seizure

All patients with transient loss of consciousness should have a 12-lead ECG. Where seizure is suspected or definite, patients should have cranial imaging with either MRI or CT, although the yield is low unless focal signs are present. EEG may help to assess prognosis once a firm diagnosis has been made. The recurrence rate after a first seizure is approximately 40% and most recurrent attacks occur within a month or two of the first. Further seizures are less likely if an identified trigger can be avoided (see Box 25.29).

Other investigations for infective, toxic and metabolic causes (Box 25.34) may be appropriate. An EEG performed immediately after a seizure may be more helpful in showing focal features than if performed after a delay.

25.32 Electroclinical epilepsy syndromes

Adolescence to adulthood
- Juvenile absence epilepsy (JAE)
- Juvenile myoclonic epilepsy (JME)
- Epilepsy with generalised tonic–clonic seizures alone
- Progressive myoclonus epilepsies (PMEs)
- Autosomal dominant epilepsy with auditory features (ADEAF)
- Other familial temporal lobe epilepsies

Less specific age relationship
- Familial focal epilepsy with variable foci (childhood to adult)
- Reflex epilepsies

Distinctive constellations
- Mesial temporal lobe epilepsy with hippocampal sclerosis (MTLE with HS)
- Rasmussen's syndrome
- Gelastic (from the Greek word for laughter) seizures with hypothalamic hamartoma
- Hemiconvulsion–hemiplegia–epilepsy

Epilepsies with structural–metabolic causes
- Malformations of cortical development (hemimegalencephaly, heterotopias etc.)
- Neurocutaneous syndromes (tuberous sclerosis complex, Sturge–Weber etc.)
- Tumour
- Infection
- Trauma
- Angioma
- Perinatal insults
- Stroke etc.

Epilepsies of unknown cause

Conditions with epileptic seizures not needing long-term treatment
- Benign neonatal seizures (BNS)
- Febrile seizures (FS)

25.33 Common generalised epilepsy syndromes

Syndrome	Age of onset	Type of seizure	EEG features	Treatment	Prognosis
Childhood absence epilepsy	4–8 years	Frequent brief absences	3/sec spike and wave	Ethosuximide Sodium valproate Levetiracetam	40% develop GTCS, 80% remit in adulthood
Juvenile absence epilepsy	10–15 years	Less frequent absences than childhood absence	Poly-spike and wave	Sodium valproate Levetiracetam	80% develop GTCS, 80% seizure-free in adulthood
Juvenile myoclonic epilepsy	15–20 years	GTCS, absences, morning myoclonus	Poly-spike and wave, photosensitivity	Sodium valproate Levetiracetam	90% remit with AEDs but relapse if AED withdrawn
GTCS on awakening	10–25 years	GTCS, sometimes myoclonus	Spike and wave on waking and sleep onset	Sodium valproate Levetiracetam	65% controlled with AEDs but relapse off treatment

(AED = antiepileptic drug; GTCS = generalised tonic–clonic seizure)

25.34 Investigation of epilepsy

From where is the epilepsy arising?

- Standard EEG
- Sleep EEG
- EEG with special electrodes (foramen ovale, subdural)

What is the cause of the epilepsy?

Structural lesion?

- CT
- MRI

Metabolic disorder?

- Urea and electrolytes
- Liver function tests
- Blood glucose
- Serum calcium, magnesium

Inflammatory or infective disorder?

- Full blood count, erythrocyte sedimentation rate, C-reactive protein
- Chest X-ray
- Serology for syphilis, HIV, collagen disease
- CSF examination

Are the attacks truly epileptic?

- Ambulatory EEG
- Videotelemetry

(CSF = cerebrospinal fluid; CT = computed tomography; EEG = electroencephalography; HIV = human immunodeficiency virus; MRI = magnetic resonance imaging)

25.35 Indications for brain imaging in epilepsy

- Epilepsy starting after the age of 16 years
- Seizures having focal features clinically
- Electroencephalogram showing a focal seizure source
- Control of seizures difficult or deteriorating

Epilepsy

The same investigations are required in a patient with epilepsy (Box 25.34). The EEG may help to establish the type of epilepsy and guide therapy. Investigations should be revisited if the epilepsy is intractable to treatment.

Inter-ictal EEG is abnormal in only about 50% of patients with recurrent seizures, so it cannot be used to exclude epilepsy. The sensitivity can be increased to about 85% by prolonging recording time and including a period of natural or drug-induced sleep, but this does not replace a well-taken history. Ambulatory EEG recording or video EEG monitoring may help with differentiation of epilepsy from other disorders if attacks are sufficiently frequent.

Indications for imaging are summarised in Box 25.35. Imaging cannot establish a diagnosis of epilepsy but identifies any structural cause. It is not required if a confident diagnosis of a recognised GGE syndrome (e.g. juvenile myoclonic epilepsy) is made. While CT excludes a major structural cause of epilepsy, MRI is required to demonstrate subtle changes such as hippocampal sclerosis, which may direct or inform surgical intervention.

Management

It is important to explain the nature and cause of seizures to patients and their relatives, and to instruct relatives in the first aid management of seizures (Box 25.36). Many people with epilepsy feel stigmatised and may become unnecessarily isolated from work and social life. It is important to emphasise that epilepsy is a common disorder that affects 0.5–1% of the population, and that full control of seizures can be expected in approximately 70% of patients (Box 25.37).

25.36 How to administer first aid for seizures

- Move the person away from danger (fire, water, machinery, furniture)
- After convulsions cease, turn the person into the ‘recovery’ position (semi-prone)
- Ensure the airway is clear but do **NOT** insert anything in the mouth (tongue-biting occurs at seizure onset and cannot be prevented by observers)
- If convulsions continue for more than 5 mins or recur without the person regaining consciousness, summon urgent medical attention
- Do not leave the person alone until fully recovered (drowsiness and delirium can persist for up to 1 hr)

25.37 Epilepsy: outcome after 20 years

- 50% are seizure-free, without drugs, for the previous 5 years
- 20% are seizure-free for the previous 5 years but continue to take medication
- 30% continue to have seizures in spite of antiepileptic therapy

Immediate care

Little can or needs to be done for a person during a convulsive seizure except for first aid and common-sense manœuvres to limit damage or secondary complications (see Box 25.36). Advice should be given that on no account should anything be inserted into the patient’s mouth. The management of status epilepticus is described on page 1080.

Lifestyle advice

Patients should be advised to avoid activities where they might place themselves or others at risk if they have a seizure. This applies at work, at home and at leisure. At home, only shallow baths (or showers) should be taken. Prolonged cycle journeys should be discouraged until reasonable freedom from seizures has been achieved. Activities involving prolonged proximity to water (swimming, fishing or boating) should always be carried out in the company of someone who is aware of the risks and the potential need for rescue measures. Driving regulations vary between countries and the patient should be made aware of these (Box 25.38). Certain occupations, such as firefighter or airline pilot, are not open to those with a previous or active diagnosis of epilepsy; further information is available from epilepsy support organisations.

The risk of harm from epilepsy should be discussed around the time of diagnosis. This should be done with care and sensitivity, and with the aim of motivating the patient to adapt habits and lifestyle to optimise epilepsy control and minimise risks of serious complications.

Antiepileptic drugs

Antiepileptic drugs (AEDs) should be considered where risk of seizure recurrence is high. A diagnosis of two or more seizures is justification enough but a prolonged inter-seizure interval may deter some patients and physicians. Treatment decisions should always be shared with the patient, to enhance adherence. A wide range of drugs is available. These agents either increase inhibitory neurotransmission in the brain or alter neuronal sodium channels to prevent abnormally rapid transmission of impulses. In the majority of patients, full control is achieved with a single drug. Dose regimens should be kept as simple as possible. Guidelines

25.38 UK driving regulations

The physician's prime duty is to ensure the patient is aware of the legal obligation to inform the driving authority

Private use

Single seizure
- Cease driving for 6 months; a longer period may be required if risk of recurrence is high

Epilepsy (i.e. more than one seizure over the age of 5 years)
- Cease driving immediately
- Licence restored when patient is seizure-free for 1 year, *or* an initial sleep seizure is followed by exclusively sleep seizures for 1 year, *or* mixed awake and sleep seizures are followed by 3 years of exclusively sleep seizures
- Licence will require renewal every 3 years thereafter until patient is seizure-free for 10 years

Withdrawal of antiepileptic drugs
- Cease driving during withdrawal period and for 6 months thereafter

Vocational drivers (heavy goods and public service vehicles)
- No licence permitted if any seizure has occurred after the age of 5 years until patient is off medication and seizure-free for more than 10 years, and has no potentially epileptogenic brain lesion

25.39 Guidelines for antiepileptic drug therapy*

- Start with one first-line drug (see Box 25.40)
- Start at a low dose; gradually increase dose until effective control of seizures is achieved or side-effects develop
- Optimise adherence (use minimum number of doses per day)
- If first drug fails (seizures continue or side-effects develop), start second first-line drug, followed if possible by gradual withdrawal of first
- If second drug fails (seizures continue or side-effects develop), start second-line drug in combination with the preferred baseline drug at maximum tolerated dose (beware interactions)
- If this combination fails (seizures continue or side-effects develop), replace second-line drug with alternative second-line drug
- If this combination fails, check adherence and reconsider diagnosis (Are events seizures? Occult lesion? Treatment adherence/alcohol/drugs confounding response?)
- Consider alternative, non-drug treatments (e.g. epilepsy surgery, vagal nerve stimulation)
- Use minimum number of drugs in combination at any one time

*See Scottish Intercollegiate Guidelines Network SIGN 143 – Diagnosis and management of epilepsy in adults (May 2015).

are listed in Box 25.39. For focal epilepsies, one large study suggests that lamotrigine is the best-tolerated monotherapy, which, alongside its favourable adverse-effect profile and relative lack of pharmacokinetic interactions, makes it a good first-line drug, although caution must be exercised with oral contraceptive use. Unclassified or genetic generalised epilepsies respond best to valproate, although pregnancy-related problems mean that valproate should not be used in women of reproductive age unless the benefits outweigh the risks. The initial choice should be an established first-line drug (Box 25.40), with more recently introduced drugs as second choice.

Monitoring therapy

Some practitioners confuse epilepsy care with serum level monitoring. The newer drugs have much more predictable pharmacokinetics than the older ones and the only indication for measuring serum levels is if there is doubt about adherence. Blood levels need to be interpreted carefully and dose changes made to treat the patient rather than to bring a serum level into the 'therapeutic range'. Some centres advocate serum level monitoring during pregnancy (notably with lamotrigine) but the evidence of benefit for this is not strong.

25.40 Guidelines for choice of antiepileptic drug[1]

Epilepsy type	First-line	Second-line	Third-line
Focal onset and/or secondary GTCS	Lamotrigine	Carbamazepine Levetiracetam Sodium valproate Topiramate Zonisamide Lacosamide	Clobazam Gabapentin Oxcarbazepine Phenobarbital Phenytoin Pregabalin Primidone Tiagabine
GTCS[2]	Sodium valproate Levetiracetam	Lamotrigine Topiramate Zonisamide	Carbamazepine Phenytoin Primidone Phenobarbital Acetazolamide
Absence[2]	Ethosuximide	Sodium valproate	Lamotrigine Clonazepam
Myoclonic[2]	Sodium valproate	Levetiracetam Clonazepam	Lamotrigine Phenobarbital

[1]See Scottish Intercollegiate Guidelines Network SIGN 143 – Diagnosis and management of epilepsy in adults (May 2015). [2]Genetic generalised epilepsies.
N.B. Use as few drugs as possible at the lowest possible dose.
(GTCS = generalised tonic–clonic seizure)

Epilepsy surgery

Some patients with drug-resistant epilepsy benefit from surgical resection of epileptogenic brain tissue. Less invasive treatments, including vagal nerve stimulation or deep brain stimulation, may also be helpful in some patients. All those who continue to experience seizures despite appropriate drug treatment should be considered for surgical treatment. Planning such interventions requires intensive specialist assessment and investigation to identify the site of seizure onset and the dispensability of any target areas for resection, i.e. whether the area of brain involved is necessary for a critical function such as vision or motor function.

Withdrawing antiepileptic therapy

Withdrawal of medication may be considered after a patient has been seizure-free for more than 2 years. Childhood-onset epilepsy, particularly classical absence seizures, carries the best prognosis for successful drug withdrawal. Other epilepsy syndromes, such as juvenile myoclonic epilepsy, have a marked tendency to recur after drug withdrawal.

Focal epilepsies that begin in adult life are also likely to recur, especially if there is an identified structural lesion. Overall, the recurrence rate after drug withdrawal depends on the individual's epilepsy history. An individualised estimate may be gained from the SIGN guideline tables (see 'Further information', p. 1146).

Patients should be advised of the risks of recurrence, to allow them to decide whether or not they wish to withdraw. If undertaken, withdrawal should be done slowly, reducing the drug dose gradually over weeks or months. Withdrawal

may necessitate precautions around driving or occupation (see Box 25.38).

Contraception

Some AEDs induce hepatic enzymes that metabolise synthetic hormones, increasing the risk of contraceptive failure. This is most marked with carbamazepine, phenytoin and barbiturates, but clinically significant effects can be seen with lamotrigine and topiramate. If the AED cannot be changed, this can be overcome by giving higher-dose preparations of the oral contraceptive. Sodium valproate and levetiracetam have no interaction with hormonal contraception.

Pregnancy and reproduction

Epilepsy presents specific management problems during pregnancy (Box 25.41). There is usually concern about teratogenesis associated with AEDs. It is important to recognise proportionate risks: background risk of severe fetal malformation in the general population is around 2–3%, while the AED most associated with teratogenesis is sodium valproate, which, at high dose, increases the risk to around 6–7%. Long-term observational studies show that most of the commonly used AEDs can be given safely in pregnancy.

Pre-conception treatment with folic acid (5 mg daily), along with use of the smallest effective doses of as few AEDs as possible, may reduce the risk of fetal abnormalities. The risks of abrupt AED withdrawal to the mother should be stressed.

Seizures may become more frequent during pregnancy, particularly if pharmacokinetic changes decrease serum levels of AEDs (see Box 25.41).

Menstrual irregularities and reduced fertility are more common in women with epilepsy, and are also increased by sodium valproate. Patients with epilepsy are at greater risk of osteoporosis, apparently independently of the drug used. Some centres advocate vitamin D supplementation in any patient with epilepsy but the higher female risk of osteoporosis makes this most important in women. Oral contraception can interact with individual AEDs (Box 25.41).

25.41 Epilepsy in pregnancy

- **Provision of pre-conception counselling is best practice**: start folic acid (5 mg daily for 2 months) before conception to reduce the risk of fetal malformations.
- **Fetal malformation**: risk is minimised if a single drug is used.
  Carbamazepine and lamotrigine have the lowest incidence of major fetal malformations.
  The risk with sodium valproate is higher but should be carefully balanced against its benefits.
  Levetiracetam may be safe but avoid other newer drugs if possible.
- **Learning difficulties in children**: IQ may be lower when children are exposed to valproate in utero, so its use should always be considered carefully.
- **Haemorrhagic disease of the newborn**: enzyme-inducing antiepileptic drugs increase risk. Give oral vitamin K (20 mg daily) to the mother during the last month of pregnancy and IM vitamin K (1 mg) to the infant at birth.
- **Increased frequency of seizures**: where breakthrough seizures occur, monitor antiepileptic drug levels and adjust the dose regimen accordingly.
- **Pharmacokinetic effects of pregnancy**: carbamazepine levels may fall in the third trimester. Lamotrigine and levetiracetam levels may fall early in pregnancy. Some advocate monitoring of levels.

25.42 Epilepsy in old age

- **Incidence and prevalence**: late-onset epilepsy is very common and the annual incidence in those over 60 years is rising.
- **Fits and faints**: the features that usually differentiate these may be less definitive than in younger patients.
- **Non-convulsive status epilepticus**: can present as delirium in the elderly.
- **Cerebrovascular disease**: the underlying cause of seizures in 30–50% of patients over the age of 50 years. A seizure may occur with an overt stroke or with occult vascular disease.
- **Antiepileptic drug regimens**: keep as simple as possible and take care to avoid interactions with other drugs being prescribed.
- **Carbamazepine-induced hyponatraemia**: increases significantly with age; this is particularly important in patients on diuretics or those with heart failure.
- **Withdrawal of antiepileptic therapy**: drug withdrawal should be attempted only where benefits exceed risk of harm from seizures.

25.43 Epilepsy in adolescence

- **Effect on school/education**: seizures, antiepileptic drugs (AEDs) and psychological complications of epilepsy may hamper education. Fear may make some educational institutions unduly restrictive.
- **Effect on family relationships**: parents may adopt a protective role, which can lead to epilepsy (and AEDs) becoming a point of assertion and rebellion.
- **Effect on career choice**: epilepsy may exclude or restrict employment in the emergency services and armed forces.
- **Alcohol**: may affect sleep pattern; excess may be associated with poor AED adherence.
- **Illicit drugs**: may affect seizure threshold and be associated with poor AED adherence.
- **Sleep disturbance**: may be worsened by social activities and computer games.
- **Oral contraception**: interactions with AED can occur. Use may not always be disclosed to parents.

Prognosis

The outcome of newly diagnosed epilepsy is generally good. Overall, generalised epilepsies and generalised seizures are more readily controlled than focal seizures. The presence of a structural lesion reduces the chances of freedom from seizures. The overall prognosis for epilepsy is shown in Box 25.37. The particular problems that epilepsy poses in the elderly and in adolescents are summarised in Boxes 25.42 and 25.43, respectively.

Status epilepticus

Presentation and management are described on page 1080. While generalised status epilepticus is most easily recognised, non-convulsive status may be less dramatic and less easily diagnosed. It may cause only altered awareness, delirium or wandering with automatisms. In an intensive care unit setting, EEG monitoring is essential to ensure that diagnosis and treatment are optimised.

Non-epileptic attack disorder ('dissociative attacks')

The difficulty with nomenclature is discussed on page 1097. Patients may present with attacks that resemble epileptic seizures but are caused by psychological phenomena and

have no abnormal EEG discharges. Such attacks may be very prolonged, sometimes mimicking status epilepticus. Epileptic and non-epileptic attacks may coexist and time and effort are needed to clarify the relative contribution of each, allowing more accurate and comprehensive treatment.

Non-epileptic attack disorder (NEAD) may be accompanied by dramatic flailing of the limbs and arching of the back, with side-to-side head movements and vocalising. Cyanosis and severe biting of the tongue are rare but incontinence can occur. Distress and crying are common following non-epileptic attacks. The distinction between epileptic attacks originating in the frontal lobes and non-epileptic attacks may be especially difficult, and may require videotelemetry with prolonged EEG recordings. Non-epileptic attacks are three times more common in women than in men and have been linked with a history of past or ongoing life trauma. They are not necessarily associated with formal psychiatric illness. Patients and carers may need reassurance that hospital admission is not required for every attack. Prevention requires psychotherapeutic interventions rather than drug therapy (p. 1202).

Vestibular disorders

Vertigo is the typical symptom caused by vestibular dysfunction, and most patients with vertigo have acute vestibular failure, benign paroxysmal positional vertigo or Ménière's disease. Central (brain) causes of vertigo are rare by comparison, with the exception of migraine (p. 1095).

Acute vestibular failure

Although commonly called 'labyrinthitis' or 'vestibular neuronitis', acute vestibular failure is a more accurate term, as most cases are idiopathic. It usually presents as isolated severe vertigo with vomiting and unsteadiness. It begins abruptly, often on waking, and many patients are initially bed-bound. The vertigo settles within a few days, though head movement may continue to provoke transient symptoms (positional vertigo) for some time. During the acute attack, nystagmus (p. 1090) will be present for a few days.

Cinnarizine, prochlorperazine or betahistine provide symptomatic relief but should not be used long-term, as this may delay recovery. A small proportion of patients fail to recover fully and complain of ongoing imbalance and dysequilibrium rather than vertigo; vestibular rehabilitation by a physiotherapist may help.

Benign paroxysmal positional vertigo

Benign paroxysmal positional vertigo (BPPV) is due to the presence of otolithic debris from the saccule or utricle affecting the free flow of endolymph in the semicircular canals (cupulolithiasis). It may follow minor head injury but typically is spontaneous. The history is diagnostic, with transient (seconds) vertigo precipitated by movement (typically, rolling over in bed or getting into or out of bed). Although it is benign, and usually self-limiting after weeks or months, patients are often alarmed by the symptoms. The diagnosis can be confirmed by the 'Hallpike manœuvre' to demonstrate positional nystagmus (Fig. 25.26). Treatment comprises explanation and reassurance, along with positioning procedures designed to return otolithic debris from the semicircular canal to saccule or utricle (such as the Epley manœuvre) and/or to re-educate the brain to cope with the inappropriate signals from the labyrinth (such as Cawthorne–Cooksey exercises: see 'Further information', p. 1146).

Ménière's disease

This is due to an abnormality of the endolymph that causes episodes of vertigo accompanied by tinnitus and fullness in the ear, each attack typically lasting a few hours. Over the years, patients may develop progressive deafness (typically low-tone on audiometry). Examination is typically normal in between attacks. The diagnosis is clinical, supported by abnormal audiometry. Ménière's disease is idiopathic but a similar syndrome may

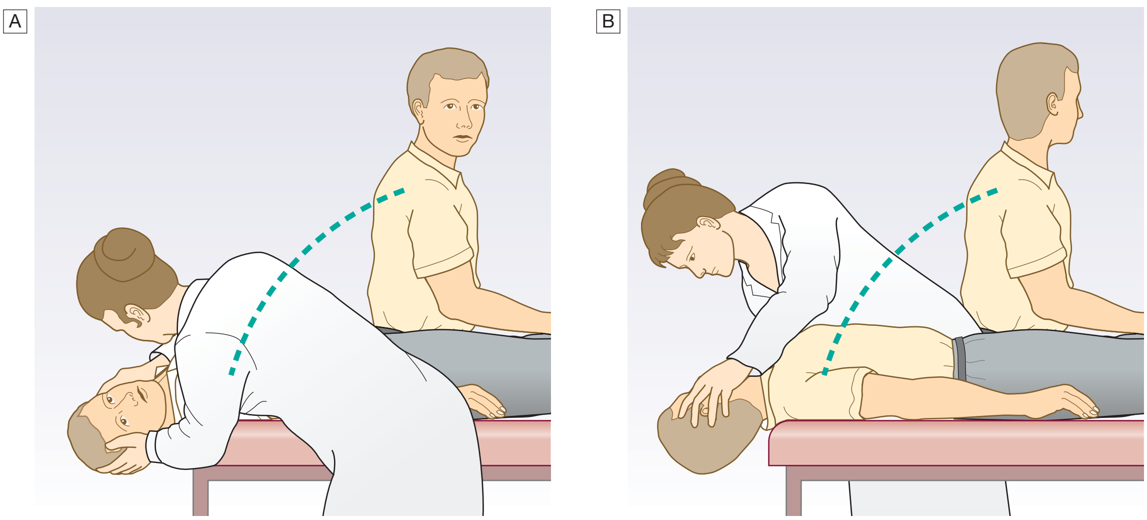

Fig. 25.26 The Hallpike manœuvre for diagnosis of benign paroxysmal positional vertigo (BPPV). Patients are asked to keep their eyes open and look at the examiner as their head is swung briskly backwards through 120° to overhang the edge of the couch. **A** Perform first with the right ear down. **B** Perform next with the left ear down. The examiner looks for nystagmus (usually accompanied by vertigo). In BPPV, the nystagmus typically occurs in A or B only and is torsional, the fast phase beating towards the lower ear. Its onset is usually delayed a few seconds and it lasts 10–20 seconds. As the patient is returned to the upright position, transient nystagmus may occur in the opposite direction. Both nystagmus and vertigo typically decrease (fatigue) on repeat testing.

be caused by middle ear trauma or infection. Imaging may be indicated to exclude other focal brainstem or cerebellopontine angle pathology but will be normal in Ménière's disease. Management includes a low-salt diet, vestibular sedatives for acute attacks (e.g. cinnarizine or prochlorperazine), and occasionally surgery to increase endolymphatic drainage from the vestibular system. Migraine may also cause episodic vertigo, and can be confused with Ménière's disease, although usually other migrainous features will appear in the history.

Disorders of sleep

Sleep disturbances include too much sleep (hypersomnolence or excessive daytime sleepiness), insufficient or poor-quality sleep (insomnia), and abnormal behaviour during sleep (parasomnias). Insomnia is usually caused by psychological or psychiatric disorders, shift work and other environmental causes, pain and so on, and will not be discussed further. Many symptoms and disorders may affect sleep and sleep quality (e.g. pain, depression/anxiety, parkinsonism).

Excessive daytime sleepiness (hypersomnolence)

There are primary and secondary causes (Box 25.44). The most common causes are impaired sleep due to lifestyle issues or sleep-disordered breathing (p. 622). Sleepiness may be measured using the Epworth Sleepiness Score (see Box 17.86, p. 623). Most causes will be identified by a detailed history from the patient and their bed partner, and a 2-week sleep diary.

Narcolepsy

This has a prevalence of about 1 in 2000, with peak onset in adolescence and early middle age. The key symptom is sudden, irresistible 'sleep attacks', often in inappropriate circumstances such as while eating or talking. Other characteristic features help distinguish this from excessive daytime sleepiness (Box 25.45). Symptoms may be due to loss of hypocretin-secreting hypothalamic neurons. Diagnosis requires sleep study with sleep latency testing (demonstrating rapid onset of REM sleep). Narcolepsy may respond to stimulants such as modafinil but more severe cases may require sodium oxybate, dexamfetamine, methylphenidate or selective serotonin reuptake inhibitor (SSRIs). Cataplexy can be debilitating and can respond to sodium oxybate or to antidepressants, such as clomipramine or venlafaxine.

i 25.44 Causes of hypersomnolence

Primary causes

- Narcolepsy
- Idiopathic hypersomnolence
- Brain injury

Secondary causes (due to poor-quality sleep)

- Obstructive sleep apnoea
- Pain
- Restless legs/periodic limb movements of sleep
- Parkinsonism and other neurodegenerative diseases
- Depression/anxiety
- Medication
- Environmental factors (noise, temperature etc.)

i 25.45 Narcolepsy symptoms

Sleep attacks

- Brief, frequent and unlike normal somnolence

Cataplexy

- Sudden loss of muscle tone triggered by surprise, laughter, strong emotion etc.

Hypnagogic or hypnopompic hallucinations

- Frightening hallucinations experienced during sleep onset or waking due to intrusion of REM sleep during wakefulness (can occur in normal people)

Sleep paralysis

- Brief paralysis on waking (can occur in normal people)

Parasomnias

Parasomnias are abnormal motor behaviours that occur around sleep. They may arise in either REM or non-REM sleep, with characteristic features and timing. Non-REM parasomnias tend to occur early in sleep. Parasomnias should be distinguished from other motor disturbances (such as periodic limb movements, hypnic jerks or sleep talking) and sleep-onset epileptic seizures (p. 1101). History from a sleeping partner or other witness is essential.

Non-REM parasomnias

These are due to incomplete arousal from non-REM sleep and manifest as night terrors, sleep walking and confusional arousals (sleep drunkenness). They typically occur within an hour or two of sleep onset, and are common in children and usually of no pathological significance. Rarely, they persist into adulthood and may become increasingly complex, including dressing, moving objects, eating, drinking or even acts of violence. Patients have little or no recollection of the episodes, even though they appear 'awake'. The episodes may be triggered by alcohol or unfamiliar sleeping situations, and can be familial. Treatment is usually not required but clonazepam can be used.

REM sleep behaviour disorder

In REM sleep behaviour disorder (RBD), patients 'act out' their dreams during REM sleep, due to failure of the usual muscle atonia. Sleep partners provide typical histories of patients 'fighting' or 'struggling' in their sleep, sometimes causing injury to themselves or to their partner. They are easily roused from this state, with recollection of their dream, unlike in non-REM states. RBD is more common in men and may be an early symptom of neurodegenerative diseases such as alpha synucleinopathies (p. 1111), perhaps preceding more typical symptoms of these conditions by years. Polysomnography will confirm absence of atonia during REM sleep. Clonazepam is the most successful treatment.

Restless legs syndrome

Restless legs syndrome (RLS) is common, with a prevalence of up to 10%, but many patients never seek medical attention. It is characterised by unpleasant leg (rarely, arm) sensations that are eased by movement (motor restlessness); the diagnosis is

i 25.46 Diagnostic criteria for restless legs syndrome

A need to move the legs, usually accompanied or caused by uncomfortable, unpleasant sensations in the legs, with the following features:

- only present or worse during periods of rest or inactivity such as lying or sitting
- partially or totally relieved by movement such as walking or stretching, at least as long as the activity continues
- generally worse or occurs only in the evening or night.

clinical (Box 25.46). It has a strong familial tendency and can present with daytime somnolence due to poor sleep. It is usually idiopathic but may be associated with iron deficiency, pregnancy, peripheral neuropathy, Parkinson's disease or uraemia. It should be distinguished from akathisia, the daytime motor restlessness that is an adverse effect of antipsychotic drugs. Treatment, if required, is with dopaminergic drugs (dopamine agonists or levodopa, p. 1113) or benzodiazepines.

Periodic limb movements in sleep

Unlike RLS, periodic limb movements in sleep (PLMS) only occur during sleep and cause repetitive flexion movements of the limbs, usually in the early (non-REM) stages of sleep. Although patients are unaware of the symptoms, they may disrupt sleep quality and often disturb partners. The pathological significance of PLMS is uncertain and it often occurs in normal health. There is an overlap with RLS. Treatment is most successful with clonazepam or dopaminergic drugs.

Neuro-inflammatory diseases

Multiple sclerosis

Multiple sclerosis (MS) is an important cause of long-term disability in adults, especially in the UK, where the prevalence is approximately 120 per 100 000. The annual incidence is around 7 per 100 000, while the lifetime risk of developing MS is about 1 in 400. The incidence of MS is higher in Northern Europeans and the disease is about twice as common in females.

Pathophysiology

There is evidence that both genetic and environmental factors play a causative role. The prevalence of MS is low near the equator and increases in the temperate zones of both hemispheres. People retain the risk of developing the disease in the zone in which they grew up, indicating that environmental exposures during growth and development are important. Prevalence also correlates with environmental factors, such as sunlight exposure, vitamin D (a controversial association) and exposure to Epstein–Barr virus (EBV), although causative mechanisms remain unclear. Genetic factors are also relevant; the risk of familial occurrence in MS is 15%, with highest risk in first-degree relatives (age-adjusted risk 4–5% for siblings and 2–3% for parents or offspring). Monozygotic twins have a concordance rate of 30%. The genes that predispose to MS are incompletely defined but inheritance appears to be polygenic, with influences from genes for human leucocyte antigen (HLA) typing, interleukin receptors, *CLEC16A* (C-type lectin domain family 16 member A) and *CD226* genes. An immune hypothesis is supported by increased levels of activated T lymphocytes in the CSF and increased immunoglobulin synthesis within the CNS.

Initial CNS inflammation in MS involves entry of activated T lymphocytes across the blood–brain barrier. These recognise myelin-derived antigens on the surface of the nervous system's antigen-presenting cells, the microglia, and undergo clonal proliferation. The resulting inflammatory cascade releases cytokines and initiates destruction of the oligodendrocyte–myelin unit by macrophages. Histologically, the resultant lesion is a plaque of inflammatory demyelination, most commonly in the periventricular regions of the brain, the optic nerves and the subpial regions of the spinal cord (Fig. 25.27). This begins as a circumscribed area of disintegration of the myelin sheath, accompanied by infiltration by activated lymphocytes and macrophages, often with conspicuous perivascular inflammation. After the acute attack, gliosis follows, leaving a shrunken scar.

Much of the initial acute clinical deficit is caused by the effect of inflammatory cytokines on transmission of the nervous impulse rather than structural disruption of myelin, and may explain the rapid recovery of some deficits and probably the acute benefit from glucocorticoids. In the long term, accumulating myelin loss reduces the efficiency of impulse propagation or causes complete conduction block, contributing to sustained impairment of CNS functions. Inflammatory mediators released during the acute attack (particularly nitric oxide) probably also initiate axonal damage, which is a feature of the latter stages of the disease. In established MS there is progressive axonal loss, probably due to the successive damage from acute attacks and the subsequent loss of neurotrophic factors from oligodendrocytes. This axonal loss may account for the phase of the disease characterised by progressive and persistent disability (Fig. 25.28).

Clinical features

The diagnosis of MS requires the demonstration of otherwise unexplained CNS lesions separated in time and space (Box 25.47); traditionally, this meant two or more clinical relapses affecting different parts of the nervous system, and the first ever episode was labelled 'clinically isolated syndrome' (CIS). Recent changes to diagnostic criteria mean that MS may be diagnosed after an isolated episode (i.e. at the CIS stage), provided that certain criteria are met (Box 25.47) The peak age of onset of MS is the fourth decade; onset before puberty or after the age of 60 years is rare. Symptoms and signs of MS usually evolve over days or weeks, resolving over weeks or months. Rarely, a more rapid stroke-like presentation may occur. About 85–90% of patients have an initial relapsing and remitting clinical course with variable intervening recovery, although the majority will eventually enter a secondary progressive phase. Most of the rest follow a slowly progressive clinical course (so-called primary progressive MS), while rare patients have a fulminant variety leading to early death (see Fig. 25.28). Frequent relapses with incomplete recovery indicate a poor prognosis. Some milder cases have an interval of years or even decades between attacks, while in others (particularly if optic neuritis is the initial manifestation) there is no recurrence of disease.

There are a number of clinical symptoms and syndromes suggestive of MS, occurring either at presentation or during the course of the illness (Box 25.48). The physical signs observed in MS are determined by the anatomical site of demyelination. Combined spinal cord and brainstem signs are common, although evidence of previous optic neuritis may be found in the form of an afferent pupillary deficit. Significant intellectual impairment

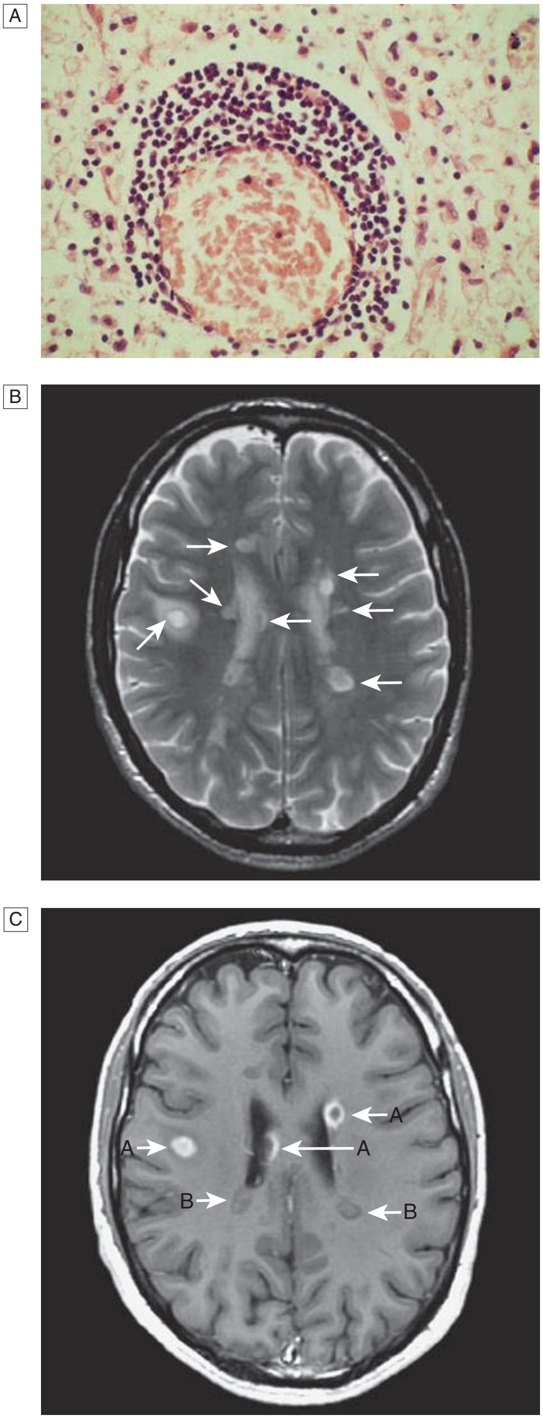

Fig. 25.27 Multiple sclerosis. **A** Photomicrograph from demyelinating plaque, showing perivascular cuffing of blood vessel by lymphocytes. **B** Brain magnetic resonance imaging in multiple sclerosis. Multiple high-signal lesions (arrows) seen particularly in the paraventricular region on T2 image. **C** In T1 image with gadolinium enhancement, recent lesions (A arrows) show enhancement, suggesting active inflammation (enhancement persists for 4 weeks); older lesions (B arrows) show no enhancement but low signal, suggesting gliosis.

25.47 The Macdonald criteria for the diagnosis of multiple sclerosis (2011)[1]

Clinical presentation[2]	Additional evidence required for diagnosis of MS
Two or more attacks with *either* objective clinical evidence of at least 2 lesions *or* Objective clinical evidence of 1 attack with reasonable evidence (on clinical history) of at least 1 prior attack	None
Two or more attacks with objective clinical evidence of 1 lesion	Dissemination in 'space' demonstrated by magnetic resonance imaging (MRI) ≥ 1 lesion in at least 2 of the MS-typical regions[3] (multiple lesions in different sites) *or* Await further clinical attack at different anatomical site
One attack with objective clinical evidence of ≥ 2 lesions	Dissemination in 'time' demonstrated by evolving MRI showing combined enhancing (new) and non-enhancing (old) lesions *or* New T2 or enhancing lesion on repeat MRI *or* Await further (second) clinical attack at different anatomical site
One attack with clinical evidence of only 1 lesion (clinically isolated syndrome)	Dissemination in 'space' demonstrated by ≥ 1 T2 lesion in at least 2 MS-typical regions *or* Dissemination in 'time', demonstrated by simultaneous enhancing and non-enhancing lesions *or* New T2 or enhancing lesions on repeat MRI *or* Await further (second) clinical attack
Insidious neurological progression suggestive of MS	1 year of progression plus 2 of the following: Evidence for dissemination in space with ≥ 1 T2 lesions in MS-typical regions Evidence for dissemination in space based on ≥ 2 lesions in the spinal cord Positive cerebrospinal fluid (evidence of oligoclonal band and/or elevated immunoglobulin G index)

[1]If the clinical presentation in the left-hand column is associated with the features in the right-hand column, the diagnosis is MS. If there is incomplete association, the diagnosis is 'possible MS'. [2]Assumes other possible causes for central nervous system inflammation (e.g. sarcoidosis, systemic lupus erythematosus) have been excluded. [3]MS-typical regions = periventricular, juxtacortical, infratentorial, spinal cord.

i 25.48 Clinical features of multiple sclerosis

Common presentations of multiple sclerosis

- Optic neuritis
- Relapsing/remitting sensory symptoms
- Subacute painless spinal cord lesion
- Acute brainstem syndrome
- Subacute loss of function of upper limb (dorsal column deficit)
- 6th cranial nerve palsy

Other symptoms and syndromes suggestive of central nervous system demyelination

- Afferent pupillary defect and optic atrophy (previous optic neuritis)
- Lhermitte's symptom (tingling in spine or limbs on neck flexion)
- Progressive non-compressive paraparesis
- Partial Brown–Séquard syndrome (p. 1083)
- Internuclear ophthalmoplegia with ataxia
- Postural ('rubral', 'Holmes') tremor
- Trigeminal neuralgia (p. 1096) under the age of 50
- Recurrent facial palsy

appears only late in the disease, when loss of frontal lobe functions and impairment of memory are common.

The prognosis for patients with MS is difficult to predict with confidence, especially early in the disease. Those with relapsing and remitting MS experience, on average, 1–2 relapses every 2 years, although this may decline with time. Approximately 5% of patients die within 5 years of disease onset, and slightly more have very good long-term outcome with little or no disability. Prognosis is good for patients with optic neuritis and only sensory relapses. Overall, about one-third of patients are disabled to the point of needing help with walking after 10 years, and this proportion rises to about half after 15 years. It would appear likely (though this is as yet unproven) that disease-modifying drugs will have an effect on long-term disability.

Investigations

There is no single diagnostic test that is definitive for MS and the results of investigation need to be combined with the clinical picture in order to make a diagnosis; MRI is the most important investigation (Fig. 25.29). MS mimics should be excluded (see below). Following the first clinical event (CIS), investigations may help prognosis by confirming the disseminated nature of the disease. MRI is the most sensitive technique for imaging lesions in brain and spinal cord (Fig. 25.30) and for excluding other causes that have provoked the neurological deficit. However, the MRI appearances in MS may be confused with those of small-vessel disease or cerebral vasculitis, and these diagnoses should be considered and excluded. Evoked potentials (visual, auditory or somatosensory) may detect clinically silent lesions but are rarely used nowadays with the advent of MRI.

The CSF may show a lymphocytic pleocytosis in the acute phase and unique (i.e. absent from the serum) oligoclonal bands of IgG in 70–90% of patients between attacks. Oligoclonal bands are not specific for MS and denote only intrathecal inflammation, provided they are unique for the CSF. These can appear in other disorders, which should be excluded by examination and investigation. It is important to exclude other potentially treatable conditions, such as infection, vitamin B_{12} deficiency and spinal cord compression.

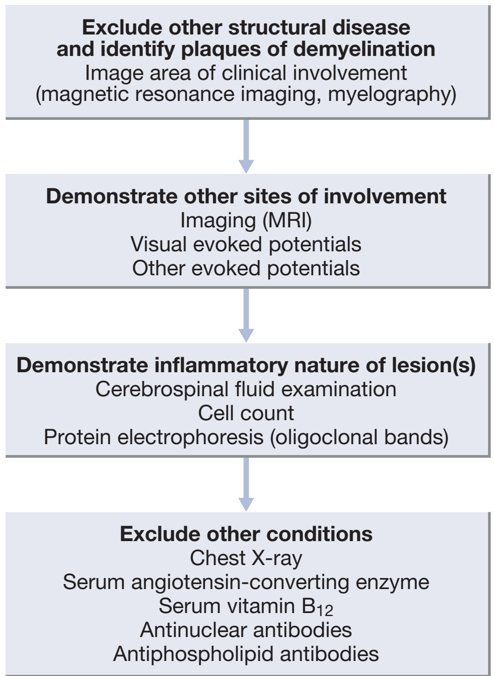

Fig. 25.29 **Investigations in a patient suspected of having multiple sclerosis.**

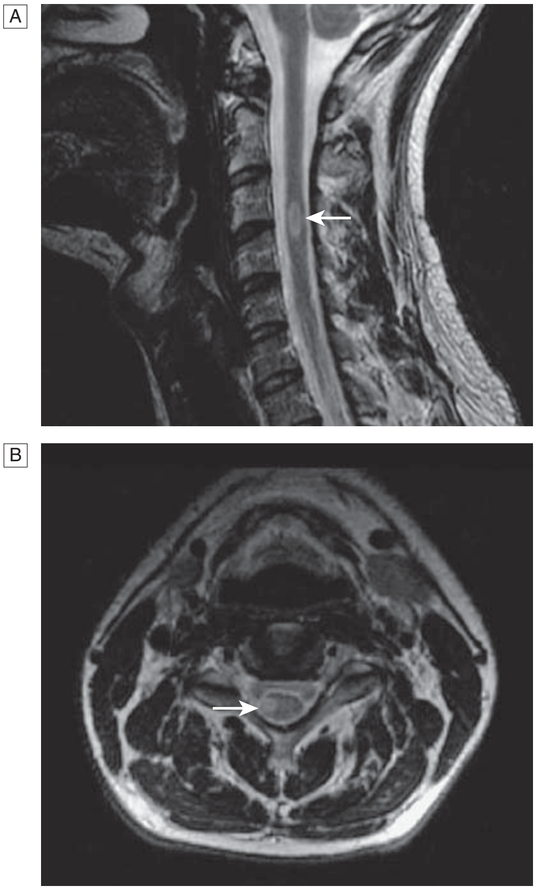

Fig. 25.30 Multiple sclerosis: demyelinating lesion in cervical spinal cord, high-signal T2 images (arrows). A Sagittal plane. B Axial plane.

Management

The management of MS involves four different strands: treatment of the acute episode, prevention of future relapses, treatment of complications, and management of the patient's disability.

The acute episode

In a disabling exacerbation of MS, pulses of high-dose glucocorticoid, given either intravenously or orally over 3–5 days, will shorten the duration of the acute episode. Prolonged administration of glucocorticoids does not alter the long-term outcome and is associated with severe adverse effects; it should therefore be avoided. Pulses of glucocorticoids can be given up to three times in a year but use should be restricted to those individuals with significant function-threatening deficits. Prophylaxis to prevent glucocorticoid-induced osteoporosis (p. 1045) should be considered in patients requiring multiple courses of glucocorticoids.

Disease-modifying treatment

Until the 1990s, there were no effective disease-modifying treatments (DMTs) for MS; azathioprine showed some promise but this was offset by adverse effects and the drug was rarely used. The introduction of, initially, beta-interferons and glatiramer acetate paved the way for a new and exciting era of DMTs, which is still evolving. All reduce annual relapse rates and the number and size of lesions on MRI, and some may reduce disability. They are not indicated for treatment of early or pre-clinical MS.

i 25.49 Disease-modifying treatments in multiple sclerosis

Treatment	Route of administration/dosing	Comment
Moderate efficacy for less severe cases: average relapse rate reduction 30–50%		
Interferon-beta	Alternate-day or weekly intramuscular or subcutaneous injection	In widespread use for reducing relapse rate
Glatiramer acetate	Alternate-day subcutaneous injection	Similar efficacy to interferon-beta
Teriflunomide	Daily oral	May cause diarrhoea, alopecia, hepatotoxicity Highly teratogenic
Dimethyl fumarate	Daily oral	May cause flushing and gastrointestinal disturbance Risk of PML
Fingolimod	Daily oral	Superior efficacy to interferon-beta in randomised trials Cardiac conduction defects, especially with first dose
High efficacy for severe cases: average relapse rate reduction >50%		
Alemtuzumab	Intravenous infusion over two courses separated by 12 months; 5-day infusion initially, second course 3 days	May precipitate autoimmune reactions, e.g. thyroid disease, ITP
Natalizumab	4-weekly intravenous infusion	Recently introduced; may be more effective than interferon-beta and glatiramer acetate Risk of PML

(ITP = idiopathic thrombocytopenic purpura; PML = progressive multifocal leucoencephalopathy)

These drugs – available orally, as regular subcutaneous injections or as pulsed intravenous treatments – may be divided into two groups (Box 25.49). All DMTs have strict licensing criteria and are associated with a range of adverse effects, some occasionally fatal, especially the more effective drugs. Careful selection and counselling of patients are necessary and these drugs should be supervised by teams experienced in their use, as recommended in national guidelines.

Clinical trials suggest that DMT options for primary and secondary progressive MS will be available in coming years. Clinical trials involving stem cells are ongoing.

Special diets, including gluten-free regimens or linoleic acid supplements, and hyperbaric oxygen therapy are popular with patients but their efficacy has not been demonstrated.

Treatment of symptoms, complications and disability

Treatments for the complications of MS are summarised in Box 25.50. It is important to provide patients with a careful explanation of the nature of the disease and its outcome. When and if disability occurs, patients and their relatives need appropriate support. Specialist nurses working in a multidisciplinary team of health-care professionals are of great value in managing the chronic phase of the disease. Periods of physiotherapy and occupational therapy may improve functional capacity in those who become disabled, and guidance can be provided on the

25.50 Treatment of complications in multiple sclerosis

Spasticity	
• Physiotherapy • Baclofen (usually oral) • Dantrolene • Gabapentin • Sativex	• Tizanidine • Intrathecal baclofen • Local (intramuscular) injection of botulinum toxin • Chemical neuronectomy
Dysaesthesia	
• Carbamazepine • Gabapentin	• Phenytoin • Amitriptyline
Bladder symptoms	
• See Box 25.25 (p. 1094)	
Fatigue	
• Amantadine • Modafinil	• Amitriptyline
Erectile dysfunction	
• Sildenafil 50–100 mg/day	• Tadalafil

25.51 Multiple sclerosis in pregnancy

- **Counselling**: provision of pre-conception counselling is best practice.
- **Relapse risk**: endocrine effects on the immune system ensure that relapse risk drops during pregnancy.
- **Disease-modifying drugs**: risk of teratogenicity means that all disease-modifying drugs should ideally be stopped 6–8 weeks before conception and recommenced after breastfeeding has stopped.
- **Post-partum relapse rate**: rebound of immune system activity means that the highest risk of relapse is in the first year after delivery.

provision of aids at home, reducing handicap. Bladder care is particularly important. Urgency and frequency can be treated pharmacologically (see Box 25.25, p. 1094) but this may lead to a degree of retention with an attendant risk of infection. Urinary retention can be managed initially by intermittent urinary catheterisation (performed by the patient, if possible) but an in-dwelling catheter may become necessary. Sexual dysfunction is a frequent source of distress. Sildenafil or tadalafil helps impotence in men, and skilled counselling and prosthetic aids may be beneficial. Pregnancy does not increase the risk of progression of MS but relapses may occur post-partum (Box 25.51).

Acute disseminated encephalomyelitis

This is an acute monophasic demyelinating condition in which areas of perivenous demyelination are widely disseminated throughout the brain and spinal cord. The illness may arise spontaneously but often occurs a week or so after a viral infection, especially measles or chickenpox, or following vaccination, suggesting that it is immunologically mediated.

Clinical features

Headache, vomiting, pyrexia, delirium and meningism may be presenting features, often with focal or multifocal brain and spinal cord signs. Seizures or coma may occur. A minority of patients who recover have further episodes.

Investigations

MRI shows multiple high-signal areas in a pattern similar to that of MS, although often with large confluent areas of abnormality. CSF may be normal or show an increase in protein and lymphocytes (occasionally > 100×10^6 cells/L). Oligoclonal bands may be found in the acute episode but, in contrast to MS, do not persist beyond clinical recovery. The clinical picture may be very similar to a first relapse of MS.

Management

The prognosis for acute disseminated encephalomyelitis is generally good, although occasionally it may be fatal (probably less than 10%). Treatment with high-dose intravenous methylprednisolone, using the same regimen as for a relapse of MS, is recommended.

Transverse myelitis

Transverse myelitis is an acute, usually monophasic, demyelinating disorder affecting the spinal cord. It is usually thought to be post-infectious in origin. It occurs at any age and presents with a subacute paraparesis with a sensory level, accompanied by severe pain in the neck or back at the onset. MRI should distinguish this from an external lesion affecting the spinal cord. CSF examination shows cellular pleocytosis, often with polymorphs at the onset. Oligoclonal bands are usually absent. Treatment is with high-dose intravenous methylprednisolone. The outcome is variable: one-third have static deficit, one-third go on to develop MS and one-third recover with no subsequent relapse. Some clinical features may suggest a higher risk of MS after transverse myelitis.

Neuromyelitis optica

Neuromyelitis optica (previously Devic's disease) is the occurrence of transverse myelitis and bilateral optic neuritis. The disease has been recognised for many years, particularly in Asia. The majority of cases are associated with an antibody to a neuronal membrane channel, aquaporin 4. If changes are seen on brain MRI (this is variable), they are typically high-signal lesions restricted to periventricular regions. Spinal MRI scans show lesions that are typically longer than three spinal segments (unlike the shorter lesions of MS). Clinical deficits tend to recover less well than in MS, and the disease may be more aggressive with more frequent relapses. Treatment with glucocorticoids, azathioprine or cyclophosphamide, and/or plasmapheresis seems to be more effective than in MS.

Paraneoplastic neurological disorders

Neurological disease may occur with systemic malignant tumours in the absence of cerebral metastases. It is now recognised that, in the majority of these cases, antigen production in the body of the tumour leads to development of antibodies to parts of the CNS. Paraneoplastic conditions are increasingly recognised and the number of antibodies identified is also growing (Boxes 25.52 and 25.53). These syndromes are particularly associated with small-cell carcinoma of lung, ovarian tumours and lymphomas. Autoantibodies are found in the serum and/or CSF, and biopsy will show a lymphocytic infiltrate of the neural tissue affected.

25.52 Paraneoplastic disorders of the central nervous system

Clinical presentation	Associated tumour	Antibodies demonstrated
Limbic encephalitis	SCLC	Anti-Hu, anti-CV2, PCA-2, anti-VGKC, anti-Ma1, anti-amphiphysin, anti-Ri, ANNA-3, anti-VGCC, anti-Zic4, anti-GluR1/2, anti-GABAR
	Testicular, breast	Anti-Ma2, anti-GluR1/2
	Thymoma	Anti-VGKC, anti-CV2, anti-GluR1/2
	Ovarian/testicular teratoma	Anti-NMDAR
Myelopathy	SCLC, thymoma, others	Anti-CV2, anti-amphiphysin, anti-aquaporin
Motor neuron disease	SCLC, others	Anti-Hu
Stiff person syndrome	Breast, SCLC, thymoma, others	Anti-amphiphysin, anti-Ri, anti-GAD, anti-GlyR
Cerebellar degeneration	Breast, ovarian, others	Anti-Yo, anti-Ma1, anti-Ri
	SCLC, others	Anti-Hu, anti-CV2, PCA-2, ANNA-3, anti-amphiphysin, anti-VGCC, anti-Ri, anti-Zic4, anti-GAD
	Lymphoma	Anti-Tr, anti-mGluR1
Multifocal encephalomyelitis	SCLC, thymoma	Anti-Hu, anti-CV2, anti-VGKC, anti-Ma1, anti-amphiphysin, anti-Ri, ANNA-3
Opsoclonus–myoclonus	Breast, ovarian	Anti-Ri, anti-Yo, anti-amphiphysin
	SCLC	Anti Hu, anti-Ri, anti-CV2, anti-amphiphysin, anti-VGCC
	Neuroblastoma	Anti-Hu
	Testicular	Anti-Ma1/2, anti-CV2
Extrapyramidal encephalitis	SCLC, thymoma, testicular	Anti-CV2, anti-Hu, anti-VGKC, anti-Ma
Optic neuritis	SCLC	Anti-CV2, anti-aquaporin
Retinal degeneration	SCLC	Anti-recoverin

(ANNA = anti-neuronal nucleolar antibody; GABAR = GABA receptor; GAD = glutamic acid decarboxylase; GluR = glutamate receptor; GlyR = glycine receptor; NMDAR = *N*-methyl-D-aspartate receptor; PCA = Purkinje cell antibody; SCLC = small-cell lung cancer; VGCC = voltage-gated calcium channel; VGKC = voltage-gated potassium channel)

25.53 Paraneoplastic disorders of the peripheral nervous system

Clinical presentation	Associated tumour	Antibodies demonstrated
Neuromyotonia	Thymoma, SCLC, others	Anti-VGKC
Myasthenia gravis	Thymoma	Anti-Achr, anti-MuSK
Sensorimotor polyneuropathy	Lymphoma, SCLC, others	Anti-Hu, anti-CV2, ANNA-3, anti-Ma1, anti-amphiphysin
Lambert–Eaton syndrome	SCLC	Anti-VGCC
Motor neuropathy	Lymphoma, SCLC, others	Anti-Hu, anti-Yo, anti-CV2
Sensory neuropathy	Lymphoma, SCLC, others	Anti-Hu, anti-Yo, anti-CV2
Polymyositis/dermatomyositis	Lung, breast	Anti-Jo1

(MuSK = muscle-specific kinase; for other abbreviations, see Box 25.52)

25

Clinical features

Clinical presentations are summarised in Boxes 25.52 and 25.53. In most instances, the neurological condition progresses quite rapidly over a few months, preceding the malignant disease in around half of cases. The range of clinical patterns is so wide that paraneoplastic disease should be considered in the diagnosis of any unusual progressive neurological syndrome. The paraneoplastic disorders of the peripheral nervous system particularly affect the synaptic cleft (p. 1065).

Investigations and management

The presence of characteristic autoantibodies in the context of a suspicious clinical picture may be diagnostic. The causative tumour may be very small and therefore CT of the chest or abdomen or PET scanning may be necessary to find it. These investigations should be pursued only when paraneoplastic disease has been proven, rather than when it is suspected. The CSF often shows an increased protein and lymphocyte count with oligoclonal bands.

Treatment is directed at the primary tumour. Occasionally, successful therapy of the tumour is associated with improvement of the paraneoplastic syndrome. Some improvement may occur following administration of intravenous immunoglobulin.

Neurodegenerative diseases

While MS is the most common cause of disability in young people in the UK, vascular and neurodegenerative diseases are increasingly important in later life. The neurodegenerative diseases are united in having a pathological process that leads to specific neuronal death, causing relentlessly progressive symptoms, with

incidence rising with age. The causes are not yet known, although genetic influences are important. Alzheimer's disease (p. 1192) and Parkinson's disease are the most common.

Movement disorders

Movement disorders present with a wide range of symptoms. They may be genetic or acquired, and the most important is Parkinson's disease. Most movement disorders are categorised clinically, with few confirmatory investigations available other than for those with a known gene abnormality.

Idiopathic Parkinson's disease

Parkinsonism is a clinical syndrome characterised primarily by bradykinesia (p. 1084), with associated increased tone (rigidity), tremor and loss of postural reflexes. There are many causes (Box 25.54) but the most common is Parkinson's disease (PD). PD has an annual incidence of about 18/100 000 in the UK and a prevalence of about 180/100 000. Age has a critical influence on incidence and prevalence, the latter rising to 300–500/100 000 after 80 years of age. Average age of onset is about 60 years and fewer than 5% of patients present under the age of 40. Genetic factors are increasingly recognised and several single genes causing parkinsonism have been identified, although they account for a very small proportion of cases overall. Having a first-degree relative with PD confers a 2–3 times increased risk of developing the disorder. It is progressive and incurable, with a variable prognosis. While motor symptoms are the most common presenting features, non-motor symptoms (particularly cognitive impairment, depression and anxiety) become increasingly prominent as the disease progresses, and significantly reduce quality of life.

Pathophysiology

Although mutations in several genes have been identified in a few cases, in most patients the cause remains unknown. The discovery that methyl-phenyl-tetrahydropyridine (MPTP) caused severe parkinsonism in young drug users suggested that PD might be due to an environmental toxin but none has been convincingly identified. The pathological hallmarks of PD are depletion of the pigmented dopaminergic neurons in the substantia nigra and the presence of α-synuclein and other protein inclusions in nigral cells (Lewy bodies; Fig. 25.31). It is thought that environmental or genetic factors alter the α-synuclein protein, rendering it toxic and leading to Lewy body formation within the nigral cells. Lewy bodies are also found in the basal ganglia, brainstem and cortex, and increase with disease progression. PD is recognised as a synucleinopathy alongside multiple system atrophy and dementia with Lewy bodies. The loss of dopaminergic neurotransmission is responsible for many of the clinical features.

Clinical features

Non-motor symptoms, including reduction in sense of smell (hyposmia), anxiety/depression, constipation and REM sleep behavioural disturbance (RBD), may precede the development of typical motor features by many years but patients rarely present at this stage. The motor symptoms are almost always initially asymmetrical. The hallmark is bradykinesia, leading to classic symptoms such as increasingly small handwriting ('micrographia'), difficulty tying shoelaces or buttoning clothes, and difficulty rolling over in bed. Tremor is an early feature but may not be present in at least 20% of people with PD. It is typically a unilateral rest tremor (p. 1085) affecting limbs, jaw and chin but not the head. In some patients, tremor remains the dominant symptom for many years. Rigidity causes stiffness and a flexed posture. Although postural righting reflexes are impaired early on in the disease, falls tend not to occur until later. As the disease advances, speech becomes softer and indistinct. There are a number of abnormalities on neurological examination (Box 25.55).

Although features are initially unilateral, gradual bilateral involvement evolves with time. Cognition is spared in early disease; if impaired, it should trigger consideration of alternative diagnoses, such as dementia with Lewy bodies.

Non-motor symptoms

While non-motor symptoms may precede the onset of more typical symptoms by many years, for most patients these features become increasingly common and disabling as PD progresses. Cognitive impairment, including dementia, is the symptom most likely to impair quality of life for patients and their carers. Estimates of dementia frequency range from 30% to 80%, depending on definitions and length of follow-up. Other distressing

25.54 Causes of parkinsonism

Idiopathic Parkinson's disease (at least 80% of parkinsonism)

Cerebrovascular disease

Drugs and toxins

- Antipsychotic drugs (older and 'atypical')
- Metoclopramide, prochlorperazine
- Tetrabenazine
- Sodium valproate
- Lithium
- Manganese
- MPTP

Other degenerative diseases

- Dementia with Lewy bodies
- Progressive supranuclear palsy
- Multiple system atrophy
- Corticobasal degeneration
- Alzheimer's disease

Genetic

- Huntington's disease
- Fragile X tremor ataxia syndrome
- Dopa-responsive dystonia
- Spinocerebellar ataxias (particularly SCA 3)
- Wilson's disease

Anoxic brain injury

(MPTP = methyl-phenyl-tetrahydropyridine)

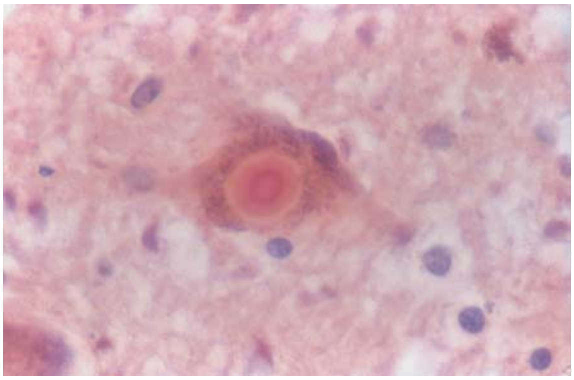

Fig. 25.31 Parkinson's disease. High power (×400) view of substantia nigra of a patient with Parkinson's disease showing classical Lewy body (haematoxylin and eosin). *Courtesy of Dr J. Xuereb.*

25.55 Physical signs in Parkinson's disease

General

- Expressionless face (hypomimia)
- Soft, rapid, indistinct speech (dysphonia)
- Flexed (stooped) posture
- Impaired postural reflexes

Gait

- Slow to start walking (failure of gait ignition)
- Rapid, short stride length, tendency to shorten (festination)
- Reduction of arm swing
- Impaired balance on turning

Tremor

Resting (3–4 Hz, moderate amplitude): most common
- Asymmetric, usually first in arm/hand ('pill rolling')
- May affect legs, jaw and chin but not head
- Intermittent, present at rest, often briefly abolished by movement of limb, exacerbated by walking

Postural (6–8 Hz, moderate amplitude)
- Present immediately on stretching out arms

Re-emergent tremor (3–4 Hz, moderate amplitude)
- Initially no tremor on stretching arms out, rest tremor re-emerges after a few seconds

Rigidity

- Cogwheel type, mostly upper limbs (due to tremor superimposed on rigidity)
- Lead pipe type

Akinesia (fundamental feature)

- Slowness of movement
- Fatiguing and decrease in size of repetitive movements

Normal findings (if abnormal, consider other causes)

- Power, deep tendon reflexes, plantar responses
- Eye movements
- Sensory and cerebellar examination

non-motor symptoms include neuropsychiatric features (anxiety, depression, apathy, hallucinosis/psychosis), sleep disturbance and hypersomnolence, fatigue, pain, sphincter disturbance and constipation, sexual problems (erectile failure, loss of libido or hypersexuality), drooling and weight loss.

Investigations

The diagnosis is clinical. Structural imaging (CT or MRI) is usually normal for age and thus rarely helpful, although it may support a suspected vascular cause of parkinsonism. Functional dopaminergic imaging (SPECT or PET) is abnormal, even in the early stages (Fig. 25.32), but does not differentiate between the different forms of degenerative parkinsonism (see Box 25.54) and so is not specific for PD. In younger patients, specific investigations may be appropriate (e.g. exclusion of Huntington's or Wilson's diseases). Some patients with family histories may wish to consider genetic testing, although the role of genetic counselling is uncertain at present.

Management

Drug therapy

Drug treatment for PD remains symptomatic rather than curative, and there is no evidence that any of the currently available drugs

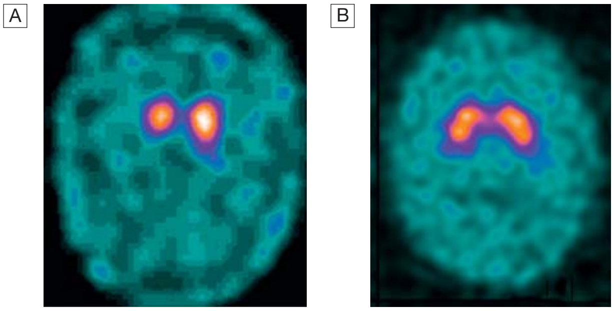

Fig. 25.32 Imaging in Parkinson's disease. A Single photon emission computed tomography (SPECT) in Parkinson's disease showing reduced dopamine activity in the basal ganglia. B Normal.

are neuroprotective. Levodopa (LD) remains the most effective treatment available but other agents include dopamine agonists, anticholinergics, inhibitors of monoamine oxidase (MAOI)-B and catechol-O-methyl-transferase (COMT), and amantadine. Debate continues about when and what treatment should be started. In general, most specialists recommend initiating treatment when symptoms are impacting on everyday life although some favour treatment as soon as the diagnosis is made. Whether it is best to start with LD, a dopamine agonist or MAOI-B remains unclear but most accept that the most effective, best-tolerated and cheapest drug is LD. Many motor symptoms, such as tremor, freezing, falling, head-drop and abnormal flexion, are quite resistant to treatment. Some non-motor symptoms, such as anxiety or depression, may respond to drug or non-drug treatments. In the UK, rivastigmine is licensed for use in PD-associated dementia, although its effect is modest. Many other non-motor symptoms are resistant to treatment. Drugs for PD should not be stopped abruptly, as this can precipitate malignant hyperthermia.

Levodopa Levodopa is the precursor to dopamine. When administered orally, more than 90% is decarboxylated to dopamine peripherally in the gastrointestinal tract and blood vessels, and only a small proportion reaches the brain. This peripheral conversion is responsible for the high frequency of adverse effects. To avoid this, LD is combined with a dopa decarboxylase inhibitor (DDI); the inhibitor does not cross the blood–brain barrier, thus avoiding unwanted decarboxylation-blocking in the brain. Two DDIs, carbidopa and benserazide, are available as combination preparations with LD (Sinemet and Madopar, respectively).

LD is most effective for relieving akinesia and rigidity; tremor response is often less satisfactory and it has no effect on many motor (posture, freezing) and non-motor symptoms. Failure of akinesia/rigidity to respond to LD (1000 mg/day) should prompt reconsideration of the diagnosis. Although controlled-release versions of LD exist, these are usually best reserved for use overnight, as their variable bioavailability makes them difficult to use throughout the day. Madopar is also available as a dispersible tablet for more rapid-onset effect.

Adverse effects include postural hypotension, nausea and vomiting, which may be offset by domperidone. LD may exacerbate or trigger hallucinations, and abnormal LD-seeking behaviour (dopamine dysregulation syndrome), in which the patient takes excessive doses of LD, may occur uncommonly.

As PD progresses, the response to LD becomes less predictable in many patients, leading to motor fluctuations. This end-of-dose deterioration is due to progressive loss of dopamine storage capacity by dwindling numbers of striatonigral neurons.

LD-induced involuntary movements (dyskinesia) may occur as a peak-dose phenomenon or as a biphasic phenomenon (occurring during both the build-up and wearing-off phases). More complex fluctuations present as sudden, unpredictable changes in response, in which periods of parkinsonism ('off' phases) alternate with improved mobility but with dyskinesias ('on' phases). Motor complication management is difficult; wearing-off effects may respond to increased dose or frequency of LD or the addition of a COMT inhibitor (see below). More complex fluctuations may be improved by the addition of dopamine agonists (including continuous infusion of apomorphine), use of intraintestinal LD via a percutaneous endoscopic jejunostomy, or deep brain stimulator implantation.

Dopamine receptor agonists Originally introduced in the hope of delaying the initiation of LD and thus delaying motor complications, several dopamine agonists are available, and may be delivered orally, transdermally or subcutaneously (Box 25.56).

The ergot-derived agonists are no longer recommended because of rare but serious fibrotic effects. With the exception of apomorphine, all the agonists are considerably less effective than LD in relieving parkinsonism, have more adverse effects (nausea, vomiting, disorientation and hallucinations, impulse control disorders) and are more expensive. Their role in the management of PD (monotherapy or adjunctive) remains uncertain, and evidence suggests that their usefulness as initial monotherapy is short-lasting.

MAOI-B inhibitors Monoamine oxidase type B facilitates breakdown of excess dopamine in the synapse. Two inhibitors are used in PD: selegiline and rasagiline. The effects of both are modest, although usually well tolerated. Neither is neuroprotective, despite initial hopes.

COMT inhibitors Catechol-O-methyl-transferase (along with dopa decarboxylase) is involved in peripheral breakdown of LD. Two inhibitors are available: entacapone and tolcapone (which also inhibits central COMT). Entacapone has a modest effect and is most useful for early wearing-off. It is available either as a single tablet taken with each LD/DDI dose, or as a combination tablet with LD and DDI. The more potent tolcapone is less used because of rare but serious hepatotoxicity.

Amantadine This has a mild, usually short-lived effect on bradykinesia and is rarely used unless patients are unable to tolerate other drugs. It is more commonly employed as a treatment for LD-induced dyskinesias, although again benefit is modest and short-lived. Adverse effects include livedo reticularis, peripheral oedema, delirium and other anticholinergic effects.

Anticholinergic drugs These were the main treatment for PD prior to the introduction of LD. Their role now is limited by lack of efficacy (apart from an effect on tremor sometimes) and adverse effects, including dry mouth, blurred vision, constipation, urinary retention, delirium and hallucinosis, as well as long-term concerns regarding cognitive impairment. Several anticholinergics are available, including trihexyphenidyl (benzhexol) and orphenadrine.

i 25.56 Dopamine agonists*

Ergot-derived	
• Bromocriptine	• Pergolide
• Lisuride	• Cabergoline
Non-ergot-derived	
• Ropinirole	• Rotigotine (transdermal patch)
• Pramipexole	• Apomorphine (subcutaneous)

*Oral unless otherwise stated.

Surgery

Destructive neurosurgery was commonly used before the introduction of LD. In the last 20 years, stereotactic surgery has emerged and most commonly involves deep brain stimulation (DBS), rather than the destructive approach of previous eras. Various targets have been identified, including the thalamus (only effective for tremor), globus pallidus and subthalamic nucleus. DBS is usually reserved for individuals with medically refractory tremor or motor fluctuations, and careful patient selection is vital to success. Intracranial delivery of fetal grafts or specific growth factors remains experimental.

Physiotherapy, occupational therapy and speech therapy

Patients at all stages of PD benefit from physiotherapy, which helps reduce rigidity and corrects abnormal posture. Occupational therapists can provide equipment to help overcome functional limitations, such as rails for stairs and the toilet, and bathing equipment. Speech therapy can help where dysarthria and dysphonia interfere with communication, and advice may also be provided to those with dysphagia. As with many complex neurological disorders, patients with PD should ideally be managed by a multidisciplinary team, including PD specialist nurses.

Other parkinsonian syndromes

Cerebrovascular disease and drug-induced parkinsonism are the most common alternative causes of parkinsonism (see Box 25.54). There are several degenerative conditions that cause parkinsonism, including multiple system atrophy, progressive supranuclear palsy and corticobasal degeneration. They typically have a more rapid progression than PD and tend to be resistant to treatment with LD. They are defined pathologically and identification during life is difficult. There are other conditions that may rarely manifest as parkinsonism, including Huntington's and Wilson's diseases.

Multiple system atrophy

Multiple system atrophy (MSA) is characterised by parkinsonism, autonomic failure and cerebellar symptoms, with either parkinsonism (MSA-P) or cerebellar features (MSA-C) predominating. It is much less common than PD, with a prevalence of about 4/100 000. Although early distinction between PD and MSA-P may be difficult, early falls, postural instability and lack of response to LD are clues. The pathological hallmark is α-synuclein-containing glial cytoplasmic inclusions found in the basal ganglia, cerebellum and motor cortex. Management is symptomatic and the prognosis is less good than for PD, with mean survival from symptom onset of fewer than 10 years and early disability. Cognition is usually unaffected.

Progressive supranuclear palsy

Progressive supranuclear palsy (PSP) presents with symmetrical parkinsonism, cognitive impairment, early falls and bulbar symptoms. The characteristic eye movement disorder, with slowed vertical saccades leading to impairment of up- and down-gaze, may take years to emerge. PSP has different pathological

features, being associated with abnormal accumulation of tau (τ) proteins and degeneration of the substantia nigra, subthalamic nucleus and mid-brain. It is therefore a tauopathy rather than synucleinopathy. The prevalence is about 5/100 000, with average survival similar to that in MSA. There is no treatment, and the parkinsonism usually does not respond to LD.

Corticobasal degeneration

Corticobasal degeneration (CBD) is less common than MSA or PSP, and the clinical manifestations are variable, including parkinsonism, dystonia, myoclonus and 'alien limb' phenomenon, whereby a limb (usually upper) moves about or interferes with the other limb without apparent conscious control. Cortical symptoms, including dementia and especially apraxia, are common and may be the only features in some cases. A number of other diseases may present with a corticobasal syndrome, including other dementias. CBD is a tauopathy with widespread deposition throughout the brain, and has similar survival rates to MSA and PSP.

Wilson's disease

This is an autosomal recessive disorder resulting from mutation in the *ATP7B* gene, causing a defect of copper metabolism (p. 896). It is a treatable cause of various movement disorders, including tremor, dystonia, parkinsonism and ataxia; psychiatric symptoms may also occur. Wilson's disease should always be excluded in patients under the age of 50 presenting with any movement disorder.

Huntington's disease

Huntington's disease (HD) is an autosomal dominant disorder, presenting in adults usually but occasionally in children. It is due to expansion of a trinucleotide CAG repeat in the *Huntingtin* gene on chromosome 4 (p. 43). The disease frequently demonstrates the phenomenon of anticipation, in which there is a younger age at onset as the disease is passed through generations, due to progressive expansion of the repeat. The prevalence is about 4–8/100 000.

Clinical features

HD typically presents with a progressive behavioural disturbance, abnormal movements (usually chorea), and cognitive impairment leading to dementia. Onset under 18 years is rare but patients may then present with parkinsonism rather than chorea (the 'Westphal variant'). There is always a family history, although this may be concealed.

Investigations and management

The diagnosis is confirmed by genetic testing; pre-symptomatic testing for other family members is available but must be preceded by appropriate counselling (p. 59). Brain imaging may show caudate atrophy but is not a reliable test. There are a number of HD mimics.

Management is symptomatic. The chorea may respond to neuroleptics such as risperidone or sulpiride, or tetrabenazine. Depression and anxiety are common and may be helped by medication.

Ataxias

The ataxias are a heterogeneous group of inherited and acquired disorders, presenting either with pure ataxia or in association with other neurological and non-neurological features. The differential

25.57 Causes of acquired ataxia

Structural	
• Brain tumour	• Brain abscess
Toxic	
• Drugs: lithium, phenytoin, amiodarone, toluene, 5-fluorouracil, cytosine arabinoside • Alcohol • Heavy metals/chemicals: mercury, lead, thallium	
Infection/post-infectious	
• HIV • Varicella zoster	• Whipple's disease • Miller Fisher syndrome (p. 1140)
Degenerative	
• Multiple system atrophy • Sporadic Creutzfeldt–Jakob disease	• Idiopathic (or sporadic) late-onset cerebellar ataxia
Inflammatory/immune-mediated	
• Multiple sclerosis • Gluten ataxia (coeliac disease)	• Paraneoplastic ataxia • Hashimoto encephalopathy
Metabolic	
• Vitamin B_1 or E deficiency • Hypothyroidism	• Hypoparathyroidism
Vascular	
• Stroke (ischaemic or haemorrhagic)	• Vascular malformations • Superficial siderosis

is wide (Boxes 25.57 and 25.58), and diagnosis is guided by age of onset, evolution and clinical features. A significant proportion of cases remain idiopathic despite investigation.

The hereditary ataxias are a group of inherited disorders in which degenerative changes occur to varying extents in the cerebellum, brainstem, pyramidal tracts, spinocerebellar tracts and optic and peripheral nerves, and influence the clinical manifestations. Onset ranges from infancy to adulthood, with recessive, sex-linked or dominant inheritance (see Box 25.58). While the genetic abnormality has been identified for some, allowing diagnostic testing, this is not currently the case for many of the hereditary ataxias.

Tremor disorders

25

Tremor (p. 1085) is a feature of many disorders but the most important clinical syndromes are PD, essential tremor, drug-induced tremors (Box 25.59) and functional (psychogenic) tremors.

Essential tremor

This has a prevalence of about 300/100 000 and may display a dominant pattern of inheritance, although no genes have thus far been identified. It may present at any age with a bilateral arm tremor (8–10 Hz), rarely at rest but typical with movement. The head and voice may be involved. The tremor improves in about 50% of patients with small amounts of alcohol. There are no specific tests and essential tremor should be distinguished from other tremor syndromes, including dystonic tremor. Beta-blockers and primidone are sometimes helpful, and DBS of the thalamus is an effective treatment for severe cases.

25.58 Inherited ataxias

Inheritance pattern	Age of onset	Clinical features
Autosomal dominant		
Episodic ataxias	Childhood and early adulthood	Brief episodes of ataxia, sometimes induced by stress or startle. May develop progressive ataxia
Spinocerebellar ataxias (SCAs)	Childhood to middle age	Over 30 subtypes identified thus far. Progressive ataxia, sometimes associated with other features, including retinitis pigmentosa, pyramidal tract abnormalities, peripheral neuropathy and cognitive deficits
Dentato-rubro-pallidoluysian atrophy (DRPLA)	Childhood to middle age	Children present with myoclonic epilepsy and progressive ataxia. Adults have progressive ataxia with psychiatric features, dementia and choreoathetosis
Autosomal recessive		
Friedreich's ataxia	Childhood/adolescence (late onset possible)	Ataxia, nystagmus, dysarthria, spasticity, areflexia, proprioceptive impairment, diabetes mellitus, optic atrophy, cardiac abnormalities. Usually chair-bound
Ataxia telangiectasia	Childhood	Progressive ataxia, athetosis, telangiectasia on conjunctivae, impaired DNA repair, immune deficiency, tendency to malignancies
Abetalipoproteinaemia	Childhood	Steatorrhoea, sensorimotor neuropathy, retinitis pigmentosa, malabsorption of vitamins A, D, E and K
Hereditary ataxia with vitamin E deficiency	<20 years	Similar to Friedreich's ataxia, visual loss or retinitis pigmentosa, chorea
Others	Usually young onset	Numerous, with genes identified only in some
X-linked		
Fragile X tremor ataxia syndrome	>50 years	Tremor, ataxia, parkinsonism, autonomic failure, cognitive impairment and dementia
Adrenoleukodystrophy	Childhood to adult	Impaired adrenal and cognitive function, sometimes spastic paraparesis
Mitochondrial disease	Various	Ataxia features in several mitochondrial diseases, including Kearns–Sayre syndrome, MELAS, MERRF, Leigh's syndrome (p. 49)

(MELAS = mitochondrial myopathy, encephalopathy, lactic acidosis and stroke-like episodes; MERRF = myoclonic epilepsy with ragged red fibres)

25.59 Drug-induced tremor (usually postural)*

- β-agonists (e.g. salbutamol)
- Theophylline
- Sodium valproate
- Thyroxine
- Lithium
- Tricyclic antidepressants
- Recreational drugs (e.g. amphetamines)
- Alcohol
- Caffeine

*Drugs causing parkinsonism and associated tremor are listed in Box 25.54.

Dystonia

Dystonia is characterised by a focal increase in tone affecting muscles in the limbs or trunk. It may be a feature of a number of neurological conditions (PD, Wilson's disease), or occur secondary to brain damage (trauma, stroke) or drugs (tardive syndromes). Dystonia also occurs as a primary disorder. With childhood onset the cause is usually genetic and dystonia is generalised, but adult onset is usually focal; examples include a twisted neck (torticollis), repetitive blinking (blepharospasm) or tremor. Task-specific symptoms (e.g. writer's cramp, musician's dystonia) are often dystonic. Treatment is difficult but botulinum toxin injections or DBS may be useful.

Hemifacial spasm

This usually presents after middle age with intermittent twitching around one eye, spreading ipsilaterally to other facial muscles. The spasms are exacerbated by talking, eating and stress. Hemifacial spasm is usually idiopathic, similar to trigeminal neuralgia; it has been suggested that it may be due to an aberrant arterial loop irritating the 7th nerve just outside the pons. It may, however, be symptomatic and secondary to structural lesions. Drug treatment is not effective but injections of botulinum toxin into affected muscles help, although these usually have to be repeated every 3 months or so. In refractory cases, microvascular decompression may be considered.

Motor neuron disease

Motor neuron disease (MND) is a neurodegenerative condition caused by loss of upper and lower motor neurons in the spinal cord, cranial nerve nuclei and motor cortex. Annual incidence is about 2/100 000, with a prevalence of about 7/100 000. Most cases are sporadic but 10% of cases are familial. Abnormalities in the superoxide dismutase (*SOD1*) gene account for about 20% of such cases, and an expanded repeat sequence in the *C9orf72* gene on chromosome 9 is associated with MND and frontotemporal dementia. The most common form of MND (Fig. 25.33) is amyotrophic lateral sclerosis (ALS), and many use the terms MND and ALS interchangeably. ALS is characterised by a combination of upper and lower motor neuron signs; there are rarer, pure lower (progressive muscular atrophy) or upper (progressive lateral sclerosis) motor neuron variants of MND. The average age of onset is 65, with 10% presenting before 45 years.

Clinical features

Diagnosis can be difficult and is often delayed. MND typically presents focally, either with limb onset (e.g. foot drop or loss of manual dexterity) or with bulbar symptoms (dysarthria, swallowing difficulty); respiratory onset is rare but type II respiratory failure is a common terminal event. Sensory, autonomic and visual symptoms do not occur, although cramp is common (Box 25.60). Examination reveals a combination of lower and upper

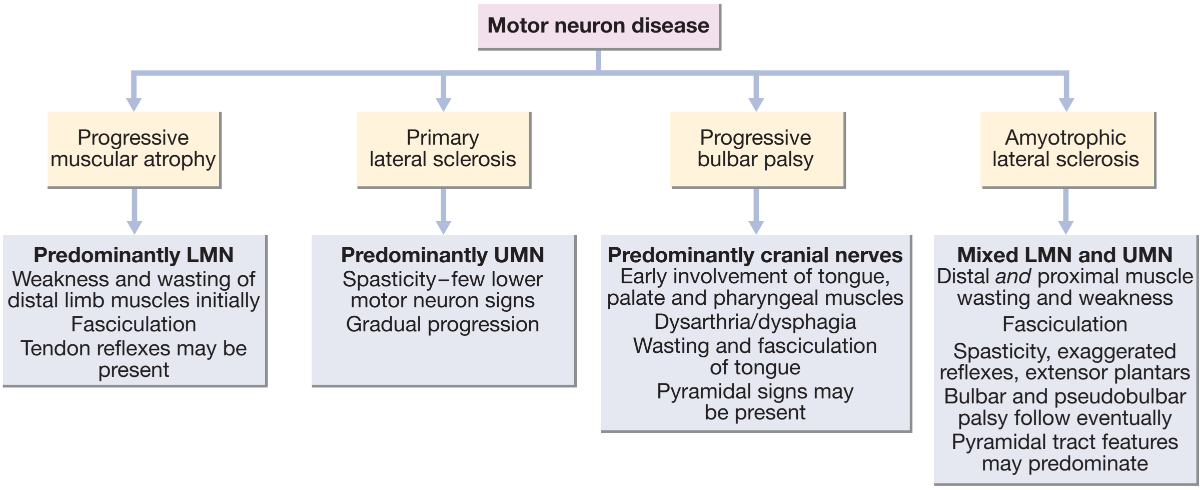

Fig. 25.33 Patterns of involvement in motor neuron disease. (LMN = lower motor neuron; UMN = upper motor neuron)

i 25.60 Clinical features of motor neuron disease

Onset

- Usually after the age of 50 years
- Very uncommon before the age of 30 years
- Affects males more commonly than females

Symptoms

- Limb muscle weakness, cramps, occasionally fasciculation
- Disturbance of speech/swallowing (dysarthria/dysphagia)
- Cognitive and behavioural features common (similar to frontotemporal dementia)

Signs

- Wasting and fasciculation of muscles
- Weakness of muscles of limbs, tongue, face and palate
- Pyramidal tract involvement, causing spasticity, exaggerated tendon reflexes, extensor plantar responses
- External ocular muscles and sphincters usually remain intact
- No objective sensory deficit
- Evidence of cognitive impairment with frontotemporal dominance

Course

- Symptoms often begin focally in one part and spread gradually but relentlessly to become widespread

motor neuron signs (e.g. brisk reflexes in wasted, fasciculating muscles) without sensory involvement (Fig. 25.33). Cognitive impairment is under-recognised in MND: up to 50% will have a mainly executive impairment on formal testing, and around 10% develop a frontotemporal dementia (FTD). About 10% of patients presenting with FTD will develop ALS within a few years of dementia onset. Even with treatment, MND is relentlessly progressive, but median survival is improved with specialist follow-up offering non-invasive ventilation, feeding measures and access to pharmacological treatment.

Investigations

Clinical features are often typical but alternative diagnoses should be excluded. Exclusion of treatable causes, such as immune-mediated multifocal motor neuropathy with conduction block (p. 1140) and cervical myeloradiculopathy, is essential. Blood tests are usually normal, other than a mildly raised creatine kinase. Sensory and motor nerve conduction studies are normal but there may be reduction in amplitude of motor action potentials due to axonal loss. EMG will usually confirm the typical features of widespread denervation and re-innervation. Spinal fluid analysis is not usually necessary. Genetic testing is increasing in importance, with mutations found in *SOD1*, *FUS*, *TARDBP* and *C9orf72* that may help predict risk and phenotype of disease in those with a family history of MND.

Management

Patients should be managed within a multidisciplinary service, including physiotherapists, speech and occupational therapists, dietitians, ventilatory and feeding support, and palliative care teams, with neurological and respiratory input. Riluzole, a glutamate release antagonist, is licensed for ALS but has only a modest effect, prolonging median survival by about 2–3 months.

Non-invasive ventilation significantly prolongs survival and improves or maintains quality of life in people with ALS. Survival and some measures of quality of life are significantly improved in the subgroup of people with better baseline bulbar function but not in those with severe bulbar impairment. Feeding by percutaneous gastrostomy may improve quality of life and prolong survival, even when done at a late stage. Rapid access to palliative care teams is essential for patients as they enter the terminal stages of MND.

Spinal muscular atrophy

This is a group of genetically determined disorders affecting spinal and cranial lower motor neurons, characterised by proximal and distal wasting, fasciculation and weakness of muscles. Involvement is usually symmetrical but occasional localised forms occur. With the exception of the infantile form, progression is slow and the prognosis better than for MND.

Infections of the nervous system

The clinical features of nervous system infections depend on the location of the infection (the meninges or the parenchyma of the brain and spinal cord), the causative organism (virus, bacterium,

- Systemic lupus erythematosus
- Behçet's disease

fungus or parasite), and whether the infection is acute or chronic. The major infections of the nervous system are listed in Box 25.61. The frequency of these varies geographically. Helminthic infections, such as cysticercosis and hydatid disease, and protozoal infections are described in Chapter 11.

Meningitis

Acute infection of the meninges presents with a characteristic combination of pyrexia, headache and meningism. Meningism consists of headache, photophobia and stiffness of the neck, often accompanied by other signs of meningeal irritation, including Kernig's sign (extension at the knee with the hip joint flexed causes spasm in the hamstring muscles) and Brudzinski's sign (passive flexion of the neck causes flexion of the hips and knees). Meningism is not specific to meningitis and can occur in patients with subarachnoid haemorrhage. The severity of clinical features varies with the causative organism, as does the presence of other features such as a rash. Abnormalities in the CSF (see Box 25.6, p. 1078) are important in distinguishing the cause of meningitis. Causes of meningitis are listed in Box 25.62.

Viral meningitis

Viruses are the most common cause of meningitis, usually resulting in a benign and self-limiting illness requiring no specific therapy. It is much less serious than bacterial meningitis unless there is associated encephalitis. A number of viruses can cause meningitis (see Box 25.62), the most common being enteroviruses. Where specific immunisation is not employed, the mumps virus is a common cause.

Clinical features

Viral meningitis occurs mainly in children or young adults, with acute onset of headache and irritability and the rapid development of meningism. The headache is usually the most severe feature. There may be a high pyrexia but focal neurological signs are rare.

Investigations

The diagnosis is made by lumbar puncture. CSF usually contains an excess of lymphocytes. While glucose and protein levels are commonly normal, the latter may be raised. It is important to verify that the patient has not received antibiotics (for whatever cause) prior to the lumbar puncture, as CSF lymphocytosis can also be found in partially treated bacterial meningitis.

Management

There is no specific treatment and the condition is usually benign and self-limiting. The patient should be treated symptomatically in a quiet environment. Recovery usually occurs within days, although a lymphocytic pleocytosis may persist in the CSF. Meningitis may also occur as a complication of a systemic viral infection such as mumps, measles, infectious mononucleosis, herpes zoster and hepatitis. Whatever the virus, complete recovery without specific therapy is the rule.

Bacterial meningitis

Many bacteria can cause meningitis but geographical patterns vary, as does age-related sensitivity (Box 25.63). In the 'meningitis belt' of sub-Saharan Africa, drought and dust storms are often associated with meningococcal outbreaks (Harmattan meningitis). Bacterial meningitis is usually part of a bacteraemic illness, although direct spread from an adjacent focus of infection in the ear, skull fracture or sinus can be causative. Antibiotics have rendered this less common but mortality and morbidity remain

i 25.63 Bacterial causes of meningitis

Age of onset	Common	Less common
Neonate	Gram-negative bacilli (*Escherichia coli*, *Proteus*) Group B streptococci	*Listeria monocytogenes*
Pre-school child	*Haemophilus influenzae* *Neisseria meningitidis* (subtypes B, C, Y, W) *Streptococcus pneumoniae*	*Mycobacterium tuberculosis*
Older child and adult	*N. meningitidis* (subtypes B, C, Y, W) *Strep. pneumoniae*	*L. monocytogenes* *M. tuberculosis* *Staphylococcus aureus* (skull fracture) *H. influenzae*

significant. An important factor in determining prognosis is early diagnosis and the prompt initiation of appropriate therapy. The meningococcus and other common causes of meningitis are normal commensals of the upper respiratory tract. New and potentially pathogenic strains are acquired by the air-borne route but close contact is necessary. Epidemics of meningococcal meningitis occur, particularly in cramped living conditions or where the climate is hot and dry. The organism invades through the nasopharynx, producing sepsis and leading to meningitis.

Pathophysiology

The meningococcus (*Neisseria meningitidis*) is now the most common cause of bacterial meningitis in Western Europe after *Streptococcus pneumoniae*, while in the USA *Haemophilus influenzae* remains common. In India, *H. influenzae* B and *Strep. pneumoniae* are probably the most common causes of bacterial meningitis, especially in children. *Streptococcus suis* is a rare zoonotic cause of meningitis associated with porcine contact. Infection stimulates an immune response, causing the pia–arachnoid membrane to become congested and infiltrated with inflammatory cells. Pus then forms in layers, which may later organise to form adhesions. These may obstruct the free flow of CSF, leading to hydrocephalus, or they may damage the cranial nerves at the base of the brain. Hearing loss is a frequent complication. The CSF pressure rises rapidly, the protein content increases, and there is a cellular reaction that varies in type and severity according to the nature of the inflammation and the causative organism. An obliterative endarteritis of the leptomeningeal arteries passing through the meningeal exudate may produce secondary cerebral infarction. Pneumococcal meningitis is often associated with a very purulent CSF and a high mortality, especially in older adults.

Clinical features

Headache, drowsiness, fever and neck stiffness are the usual presenting features. In severe bacterial meningitis the patient may be comatose, later developing focal neurological signs. Ninety per cent of patients with meningococcal meningitis will have two of the following: fever, neck stiffness, altered consciousness and rash. When accompanied by sepsis, presenting signs may evolve rapidly, with abrupt onset of obtundation due to cerebral oedema. Complications of meningococcal sepsis are listed in Box 25.64. Chronic meningococcaemia is a rare condition in which the patient can be unwell for weeks or even months

i 25.64 Complications of meningococcal sepsis

- Meningitis
- Rash (morbilliform, petechial or purpuric)
- Shock
- Intravascular coagulation
- Renal failure
- Peripheral gangrene
- Arthritis (septic or reactive)
- Pericarditis (septic or reactive)

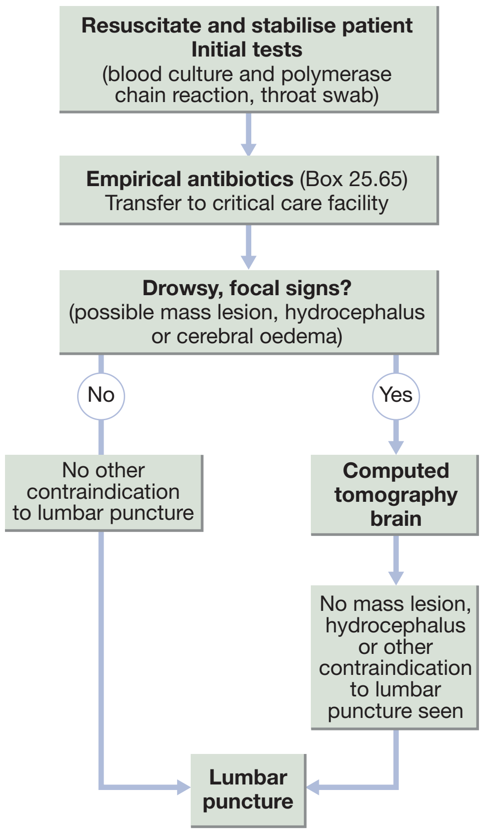

Fig. 25.34 The investigation of meningitis.

with recurrent fever, sweating, joint pains and transient rash. It usually occurs in the middle-aged and elderly, and in those who have previously had a splenectomy. In pneumococcal and *Haemophilus* infections there may be an accompanying otitis media. Pneumococcal meningitis may be associated with pneumonia and occurs especially in older patients and alcoholics, as well as those with hyposplenism. *Listeria monocytogenes* is an increasing cause of meningitis and rhombencephalitis (brainstem encephalitis) in the immunosuppressed, people with diabetes, alcoholics and pregnant women (p. 259). It can also cause meningitis in neonates.

Investigations

Lumbar puncture is mandatory unless there are contraindications (p. 1077). If the patient is drowsy and has focal neurological signs or seizures, is immunosuppressed, has undergone recent neurosurgery or has suffered a head injury, it is wise to obtain a CT to exclude a mass lesion (such as a cerebral abscess) before lumbar puncture because of the risk of coning. This should not, however, delay treatment of presumed meningitis. If lumbar puncture is deferred or omitted, it is essential to take blood cultures and to start empirical treatment (Fig. 25.34). Lumbar

puncture will help differentiate the causative organism: in bacterial meningitis the CSF is cloudy (turbid) due to the presence of many neutrophils (often > 1000×10^6 cells/L), the protein content is significantly elevated and the glucose reduced. Gram film and culture may allow identification of the organism. Blood cultures may be positive. PCR techniques can be used on both blood and CSF to identify bacterial DNA. These methods are useful in detecting meningococcal infection and in typing the organism.

Management

There is an untreated mortality rate of around 80%, so action must be swift. In suspected bacterial meningitis the patient should be given parenteral benzylpenicillin immediately (intravenous is preferable) and prompt hospital admission should be arranged.

25.65 Treatment of pyogenic meningitis of unknown cause

1. Adults aged 18–50 years with or without a typical meningococcal rash
• Cefotaxime 2 g IV 4 times daily *or* • Ceftriaxone 2 g IV twice daily
2. Patients in whom penicillin-resistant pneumococcal infection is suspected, or in areas with a significant incidence of penicillin resistance in the community
As for (1) but add: • Vancomycin 1 g IV twice daily *or* • Rifampicin 600 mg IV twice daily
3. Adults aged > 50 years and those in whom *Listeria monocytogenes* infection is suspected (brainstem signs, immunosuppression, diabetic, alcoholic)
As for (1) but add: • Ampicillin 2 g IV 6 times daily *or* • Co-trimoxazole 5 mg/kg IV daily in two divided doses
4. Patients with a clear history of anaphylaxis to β-lactams
• Chloramphenicol 25 mg/kg IV 4 times daily *plus* • Vancomycin 1 g IV twice daily
5. Adjunctive treatment (see text)
• Dexamethasone 0.15 mg/kg 4 times daily for 2–4 days

The only contraindication is a history of penicillin anaphylaxis. Recommended empirical therapies are outlined in Box 25.65, and the preferred antibiotic when the organism is known after CSF examination is stipulated in Box 25.66. Adjunctive glucocorticoid therapy is useful in reducing hearing loss and neurological sequelae in both children and adults in developed countries where the incidence of penicillin resistance is low, but its role where there are high rates of resistance or in countries where there are high rates of untreated HIV is unclear.

In meningococcal disease, mortality is doubled if the patient presents with features of sepsis rather than meningitis. Individuals likely to require intensive care facilities and expertise include those with cardiac, respiratory or renal involvement, and those with CNS depression prejudicing the airway. Early endotracheal intubation and mechanical ventilation protect the airway and may prevent the development of the acute respiratory distress syndrome (ARDS, p. 198). Adverse prognostic features include hypotensive shock, a rapidly developing rash, a haemorrhagic diathesis, multisystem failure and age over 60 years.

Prevention of meningococcal infection

Close contacts of patients with meningococcal infection (Box 25.67) should be given 2 days of oral rifampicin. In adults, a single dose of ciprofloxacin is an alternative. If not treated with ceftriaxone, the index case should be given similar treatment to clear infection from the nasopharynx before hospital discharge. Vaccines are available for most meningococcal subgroups but not group B, which is one of the most common serogroups isolated in many countries.

Tuberculous meningitis

Tuberculous meningitis is now uncommon in developed countries except in immunocompromised individuals, although it is still seen in those born in endemic areas and in developing countries. It is seen more frequently as a secondary infection in patients with the acquired immunodeficiency syndrome (AIDS).

Pathophysiology

Tuberculous meningitis most commonly occurs shortly after a primary infection in childhood or as part of miliary tuberculosis (p. 588). The usual local source of infection is a caseous focus in

25.66 Chemotherapy of bacterial meningitis when the cause is known

Pathogen	Regimen of choice	Alternative agents
Neisseria meningitidis	Benzylpenicillin 2.4 g IV 6 times daily for 5–7 days	Cefuroxime, ampicillin Chloramphenicol*
Streptococcus pneumoniae (sensitive to β-lactams, MIC < 1 mg/L)	Cefotaxime 2 g IV 4 times daily *or* Ceftriaxone 2 g IV twice daily for 10–14 days	Chloramphenicol*
Strep. pneumoniae (resistant to β-lactams)	As for sensitive strains but add: Vancomycin 1 g IV twice daily *or* Rifampicin 600 mg IV twice daily	Vancomycin plus rifampicin* Moxifloxacin Gatifloxacin
Haemophilus influenzae	Cefotaxime 2 g IV 4 times daily *or* Ceftriaxone 2 g IV twice daily for 10–14 days	Chloramphenicol*
Listeria monocytogenes	Ampicillin 2 g IV 6 times daily *plus* Gentamicin 5 mg/kg IV daily	Ampicillin 2 g IV 4-hourly *plus* Co-trimoxazole 50 mg/kg daily in two divided doses
Streptococcus suis	Cefotaxime 2 g IV 4 times daily *or* Ceftriaxone 2 g IV twice daily for 10–14 days	Chloramphenicol*

*For patients with a history of anaphylaxis to β-lactam antibiotics.
(MIC = minimum inhibitory concentration)

i 25.67 Chemoprophylaxis following meningococcal exposure

Close contacts warranting chemoprophylaxis

- Household contacts (including persons who ate or slept in the same dwelling as the patient during the 7 days prior to disease onset)
- Child-care and nursery-school contacts
- Persons having contact with patient's oral secretions during the 7 days prior to disease onset:
  - Kissing
  - Sharing of toothbrushes
  - Sharing of eating utensils
  - Mouth-to-mouth resuscitation
  - Unprotected contact during endotracheal intubation
- Aircraft contacts for persons seated next to the patient for >8 hrs

Persons at low risk in whom chemoprophylaxis is not recommended

- Casual contact (e.g. at school or work) without direct exposure to patient's oral secretions
- Indirect contact only (contact with a high-risk contact and not a case)
- Health-care worker without direct exposure to patient's oral secretions

i 25.68 Clinical features and staging of tuberculous meningitis

Symptoms

- Headache
- Vomiting
- Low-grade fever
- Lassitude
- Depression
- Delirium
- Behaviour changes

Signs

- Meningism (may be absent)
- Oculomotor palsies
- Papilloedema
- Depression of conscious level
- Focal hemisphere signs

Staging of severity

- Stage I (early): non-specific symptoms and signs without alteration of consciousness
- Stage II (intermediate): altered consciousness without coma or delirium *plus* minor focal neurological signs
- Stage III (advanced): stupor or coma, severe neurological deficits, seizures or abnormal movements

the meninges or brain substance adjacent to the CSF pathway. The brain is covered by a greenish, gelatinous exudate, especially around the base, and numerous scattered tubercles are found on the meninges.

Clinical features

The clinical features and staging criteria are listed in Box 25.68. Onset is much slower than in other bacterial meningitis – over 2–8 weeks. If untreated, tuberculous meningitis is fatal in a few weeks but complete recovery is usual if treatment is started at stage I (Box 25.68). When treatment is initiated later, the rate of death or serious neurological deficit may be as high as 30%.

Investigations

Lumbar puncture should be performed if the diagnosis is suspected. The CSF is under increased pressure. It is usually clear but, when allowed to stand, a fine clot ('spider web') may form. The fluid contains up to 500×10^6 cells/L, predominantly lymphocytes, but can contain neutrophils. There is a rise in protein and a marked fall in glucose. The tubercle bacillus may be detected in a smear of the centrifuged deposit from the CSF but a negative result does not exclude the diagnosis. The CSF should be cultured but, as this result will not be known for up to 6 weeks, treatment must be started without waiting for confirmation. Brain imaging may show hydrocephalus, brisk meningeal enhancement on enhanced CT or MRI, and/or an intracranial tuberculoma.

Management

As soon as the diagnosis is made or strongly suspected, chemotherapy should be started using one of the regimens that include pyrazinamide, described on page 592. The use of glucocorticoids in addition to antituberculous therapy has been controversial. Recent evidence suggests that it improves mortality, especially if given early, but not focal neurological damage. Surgical ventricular drainage may be needed if obstructive hydrocephalus develops. Skilled nursing is essential during the acute phase of the illness, and adequate hydration and nutrition must be maintained.

Other forms of meningitis

Fungal meningitis (especially cryptococcosis; p. 302) usually occurs in patients who are immunosuppressed and is a recognised complication of HIV infection (p. 321). The CSF findings are similar to those of tuberculous meningitis, but the diagnosis can be confirmed by microscopy or specific serological tests.

In some areas, meningitis may be caused by spirochaetes (leptospirosis, Lyme disease and syphilis; pp. 257, 255 and 337), rickettsiae (typhus fever; p. 270) or protozoa (amoebiasis; p. 286).

Meningitis can also be due to non-infective pathologies. This is seen in recurrent aseptic meningitis resulting from systemic lupus erythematosus (SLE), Behçet's disease or sarcoidosis, as well as a condition of previously unknown origin known as Mollaret's syndrome, in which the recurrent meningitis is associated with epithelioid cells in the spinal fluid ('Mollaret' cells). Recent evidence suggests that this condition may be due to herpes simplex virus type 2 and is therefore infective after all. Meningitis can also be caused by direct invasion of the meninges by neoplastic cells ('malignant meningitis'; see Box 25.62).

Parenchymal viral infections

Infection of the substance of the nervous system will produce symptoms of focal dysfunction (deficits and/or seizures) with general signs of infection, depending on the acuteness of the infection and the type of organism.

Viral encephalitis

A range of viruses can cause encephalitis but only a minority of patients report recent systemic viral infection. In Europe, the most serious cause of viral encephalitis is herpes simplex (p. 247), which probably reaches the brain via the olfactory nerves. Varicella zoster is also an important cause. The development of effective therapy for some forms of encephalitis has increased the importance of clinical diagnosis and virological examination of the CSF. In some parts of the world, viruses transmitted by mosquitoes and ticks (arboviruses) are an important cause of encephalitis. The epidemiology of some of these infections is changing. Japanese encephalitis (p. 249) has spread relentlessly across Asia to Australia, and there have been outbreaks of West Nile encephalitis in Romania, Israel and New York. Zika virus has

mutated in the last decades and become a more significant global health problem. HIV may cause encephalitis with a subacute or chronic presentation but occasionally has an acute presentation with seroconversion.

Pathophysiology

The infection provokes an inflammatory response that involves the cortex, white matter, basal ganglia and brainstem. The distribution of lesions varies with the type of virus. For example, in herpes simplex encephalitis, the temporal lobes are usually primarily affected, whereas cytomegalovirus can involve the areas adjacent to the ventricles (ventriculitis). Inclusion bodies may be present in the neurons and glial cells, and there is an infiltration of polymorphonuclear cells in the perivascular space. There is neuronal degeneration and diffuse glial proliferation, often associated with cerebral oedema.

Clinical features

Viral encephalitis presents with acute onset of headache, fever, focal neurological signs (aphasia and/or hemiplegia, visual field defects) and seizures. Disturbance of consciousness ranging from drowsiness to deep coma supervenes early and may advance dramatically. Meningism occurs in many patients. Rabies presents a distinct clinical picture and is described below.

Investigations

Imaging by CT scan may show low-density lesions in the temporal lobes but MRI is more sensitive in detecting early abnormalities. Lumbar puncture should be performed once imaging has excluded a mass lesion. The CSF usually contains excess lymphocytes but polymorphonuclear cells may predominate in the early stages. The CSF may be normal in up to 10% of cases. Some viruses, including the West Nile virus, may cause a sustained neutrophilic CSF. The protein content may be elevated but the glucose is normal. The EEG is usually abnormal in the early stages, especially in herpes simplex encephalitis, with characteristic periodic slow-wave activity in the temporal lobes. Virological investigations of the CSF, including PCR, may reveal the causative organism but treatment initiation should not await this.

Management

Optimum treatment for herpes simplex encephalitis (aciclovir 10 mg/kg IV 3 times daily for 2–3 weeks) has reduced mortality from 70% to around 10%. This should be given early to all patients suspected of having viral encephalitis.

Some survivors will have residual epilepsy or cognitive impairment. For details of post-infectious encephalomyelitis, see page 1110. Antiepileptic treatment may be required (p. 1101) and raised intracranial pressure may indicate the need for dexamethasone.

Brainstem encephalitis

This presents with ataxia, dysarthria, diplopia or other cranial nerve palsies. The CSF is lymphocytic, with a normal glucose. The causative agent is presumed to be viral. However, *Listeria monocytogenes* may cause a similar syndrome with meningitis (and often a polymorphonuclear CSF pleocytosis) and requires specific treatment with ampicillin (500 mg 4 times daily; see Box 25.66).

Rabies

Rabies is caused by a rhabdovirus that infects the central nervous tissue and salivary glands of a wide range of mammals. It is usually conveyed by saliva through bites or licks on abrasions or on intact mucous membranes. Humans are most frequently infected from dogs and bats. In Europe, the maintenance host is the fox. The incubation period varies in humans from a minimum of 9 days to many months but is usually between 4 and 8 weeks. Severe bites, especially if on the head or neck, are associated with shorter incubation periods. Human rabies is a rare disease, even in endemic areas. However, because it is usually fatal, major efforts are directed at limiting its spread and preventing its importation into uninfected countries, such as the UK.

Clinical features

At the onset there may be fever, and paraesthesia at the site of the bite. A prodromal period of 1–10 days, during which the patient becomes increasingly anxious, leads to the characteristic 'hydrophobia'. Although the patient is thirsty, attempts at drinking provoke violent contractions of the diaphragm and other inspiratory muscles. Delusions and hallucinations may develop, accompanied by spitting, biting and mania, with lucid intervals in which the patient is markedly anxious. Cranial nerve lesions develop and terminal hyperpyrexia is common. Death ensues, usually within a week of the onset of symptoms.

Investigations

During life, the diagnosis is usually made on clinical grounds but rapid immunofluorescent techniques can detect antigen in corneal impression smears or skin biopsies.

Management

Established disease

Only a few patients with established rabies have survived. All received some post-exposure prophylaxis (see below) and needed intensive care facilities to control cardiac and respiratory failure. Otherwise, only palliative treatment is possible once symptoms have appeared. The patient should be heavily sedated with diazepam, supplemented by chlorpromazine if needed. Nutrition and fluids should be given intravenously or through a gastrostomy.

Pre-exposure prophylaxis

Pre-exposure prophylaxis is required by those who handle potentially infected animals professionally, work with rabies virus in laboratories or live at special risk in rabies-endemic areas. Protection is afforded by intradermal injections of human diploid cell strain vaccine, or two intramuscular injections given 4 weeks apart, followed by yearly boosters.

Post-exposure prophylaxis

The wounds should be thoroughly cleaned, preferably with a quaternary ammonium detergent or soap; damaged tissues should be excised and the wound left unsutured. Rabies can usually be prevented if treatment is started within a day or two of biting. Delayed treatment may still be of value. For maximum protection, hyperimmune serum and vaccine are required.

The safest antirabies antiserum is human rabies immunoglobulin. The dose is 20 IU/kg body weight; half is infiltrated around the bite and half is given intramuscularly at a different site from the vaccine. Hyperimmune animal serum may be used but hypersensitivity reactions, including anaphylaxis, are common.

The safest vaccine, free of complications, is human diploid cell strain vaccine; 1.0 mL is given intramuscularly on days 0, 3, 7, 14, 30 and 90. In developing countries, where human rabies globulin may not be obtainable, 0.1 mL of vaccine may be given

intradermally into eight sites on day 1, with single boosters on days 7 and 28. Where human products are not available and when risk of rabies is slight (licks on the skin, or minor bites of covered arms or legs), it may be justifiable to delay starting treatment while observing the biting animal or awaiting examination of its brain, rather than use the older vaccine.

Poliomyelitis

Pathophysiology

Disease is caused by one of three polioviruses, which constitute a subgroup of the enteroviruses. Poliomyelitis has become much less common in developed countries following the widespread use of oral vaccines but is still a problem in the developing world, especially parts of Africa. Infection usually occurs through the nasopharynx.

The virus causes a lymphocytic meningitis and infects the grey matter of the spinal cord, brainstem and cortex. There is a particular propensity to damage anterior horn cells, especially in the lumbar segments.

Clinical features

The incubation period is 7–14 days. Figure 25.35 illustrates the various features of the infection. Many patients recover fully after the initial phase of a few days of mild fever and headache. In other individuals, after a week of well-being, there is a recurrence of pyrexia, headache and meningism. Weakness may start later in one muscle group and can progress to widespread paresis. Respiratory failure may supervene if intercostal muscles are paralysed or the medullary motor nuclei are involved. Epidemics vary widely in terms of the incidence of non-paralytic cases and in mortality rate. Death occurs from respiratory paralysis. Muscle weakness is maximal at the end of the first week and gradual recovery may then take place over several months. Muscles showing no signs of recovery after a month will probably not regain useful function. Second attacks are very rare but occasionally patients show late deterioration in muscle bulk and power many years after the initial infection (this is termed the 'post-polio syndrome').

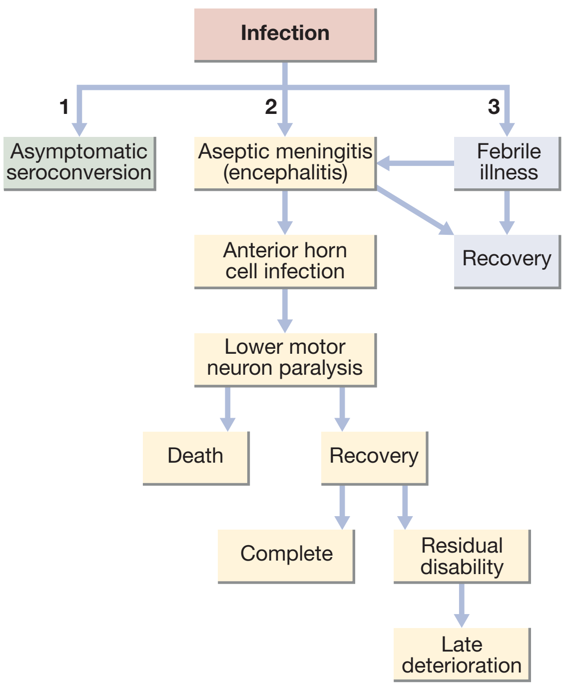

Fig. 25.35 Poliomyelitis. Possible consequences of infection.

Investigations

The CSF shows a lymphocytic pleocytosis, a rise in protein and a normal sugar content. Poliomyelitis virus may be cultured from CSF and stool.

Management

Established disease

In the early stages, bed rest is imperative because exercise appears to worsen the paralysis or precipitate it. At the onset of respiratory difficulties, a tracheostomy and ventilation are required. Subsequent treatment is by physiotherapy and orthopaedic measures.

Prophylaxis

Prevention of poliomyelitis is by immunisation with live (Sabin) vaccine. In developed countries where polio is now very rare, the live vaccine has been replaced by the killed vaccine in childhood immunisation schedules.

Herpes zoster (shingles)

Herpes zoster is the result of reactivation of the varicella zoster virus that has lain dormant in a nerve root ganglion following chickenpox earlier in life. Reactivation may be spontaneous (as usually occurs in the middle-aged or elderly) or due to immunosuppression (as in patients with diabetes, malignant disease or AIDS). Full details are given on page 239.

Subacute sclerosing panencephalitis

This is a rare, chronic, progressive and eventually fatal complication of measles, presumably a result of an inability of the nervous system to eradicate the virus. It occurs in children and adolescents, usually many years after the primary virus infection. There is generalised neurological deterioration and onset is insidious, with intellectual deterioration, apathy and clumsiness, followed by myoclonic jerks, rigidity and dementia.

The CSF may show a mild lymphocytic pleocytosis and the EEG demonstrates characteristic periodic bursts of triphasic waves. Although there is persistent measles-specific IgG in serum and CSF, antiviral therapy is ineffective and death ensues within a few years.

Progressive multifocal leucoencephalopathy

This was originally described as a rare complication of lymphoma, leukaemia or carcinomatosis but has become more frequent as a feature of AIDS (p. 319) or secondary to immunosuppression, e.g. following organ transplantation or use of disease-modifying drugs for MS. It is an infection of oligodendrocytes by human polyomavirus JC, causing widespread demyelination of the white matter of the cerebral hemispheres. Clinical signs include dementia, hemiparesis and aphasia, which progress rapidly, usually leading to death within weeks or months. Areas of low density in the white matter are seen on CT but MRI is more sensitive, showing diffuse high signal in the cerebral white matter on T2-weighted images. The only treatment available is restoration of the immune response (by treating AIDS or reversing immunosuppression).

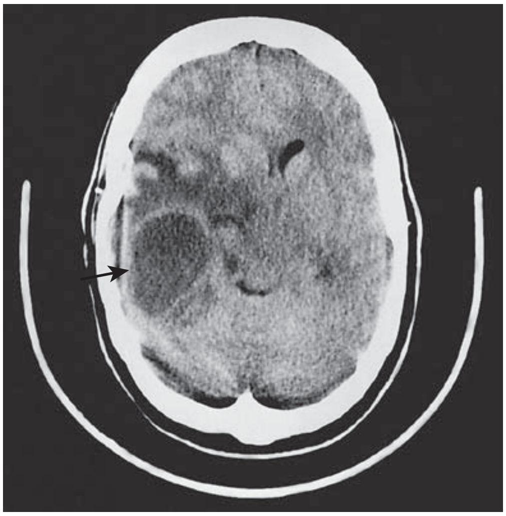
Parenchymal bacterial infections

Cerebral abscess

Bacteria may enter the cerebral substance through penetrating injury, by direct spread from paranasal sinuses or the middle ear, or secondary to sepsis. Untreated congenital heart disease is a recognised risk factor. The site of abscess formation and the likely causative organism are both related to the source of infection (Box 25.69). Initial infection leads to local suppuration followed by loculation of pus within a surrounding wall of gliosis, which in a chronic abscess may form a tough capsule. Haematogenous spread may lead to multiple abscesses.

Clinical features

A cerebral abscess may present acutely with fever, headache, meningism and drowsiness, but more commonly presents over days or weeks as a cerebral mass lesion with little or no evidence of infection. Seizures, raised intracranial pressure and focal hemisphere signs occur alone or in combination. Distinction from a cerebral tumour may be impossible on clinical grounds.



Investigations

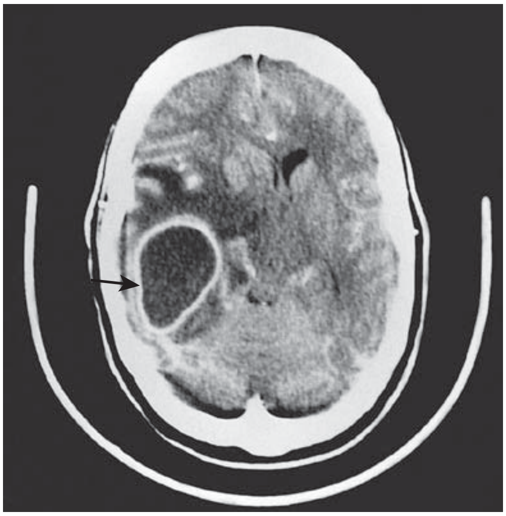
Lumbar puncture is potentially hazardous in the presence of raised intracranial pressure and CT should always precede it. CT reveals single or multiple low-density areas, which show ring enhancement with contrast and surrounding cerebral oedema (Fig. 25.36). There may be an elevated white blood cell count and ESR in patients with active local infection. The possibility of cerebral toxoplasmosis or tuberculous disease secondary to HIV infection (p. 320) should always be considered.

Management and prognosis

Antimicrobial therapy is indicated once the diagnosis is made. The likely source of infection should guide the choice of antibiotic (see Box 25.69). In neurosurgical patients, the addition of vancomycin should be considered. Surgical drainage by burr-hole aspiration or excision may be necessary, especially where the presence of a capsule may lead to a persistent focus of infection. Epilepsy frequently develops and is often resistant to treatment.

Despite advances in therapy, mortality remains 10–20% and may partly relate to delay in diagnosis and treatment.

A



B

Fig. 25.36 Right temporal cerebral abscess (arrows), with surrounding oedema and midline shift to the left. A Unenhanced computed tomography (CT) image. B Contrast-enhanced CT image.

25.69 Aetiology and treatment of bacterial cerebral abscess

Site of abscess	Source of infection	Likely organisms	Recommended treatment
Frontal lobe	Paranasal sinuses Teeth	Streptococci Anaerobes	Cefotaxime 2–3 g IV 4 times daily *plus* Metronidazole 500 mg IV 3 times daily
Temporal lobe	Middle ear	Streptococci Enterobacteriaceae	Ampicillin 2–3 g IV 3 times daily *plus* Metronidazole 500 mg IV 3 times daily *plus either*
Cerebellum	Sphenoid sinus Mastoid/middle ear	*Pseudomonas* spp. Anaerobes	Ceftazidime 2 g IV 3 times daily *or* Gentamicin* 5 mg/kg IV daily
Any site	Penetrating trauma	Staphylococci	Flucloxacillin 2–3 g IV 4 times daily *or* Cefuroxime 1.5 g IV 3 times daily
Multiple	Metastatic and cryptogenic	Streptococci Anaerobes	Benzylpenicillin 1.8–2.4 g IV 4 times daily if endocarditis or cyanotic heart disease Otherwise cefotaxime 2–3 g IV 4 times daily *plus* Metronidazole 500 mg IV 3 times daily

*Monitor gentamicin levels.

Subdural empyema

This is a rare complication of frontal sinusitis, osteomyelitis of the skull vault or middle ear disease. A collection of pus in the subdural space spreads over the surface of the hemisphere, causing underlying cortical oedema or thrombophlebitis. Patients present with severe pain in the face or head and pyrexia, often with a history of preceding paranasal sinus or ear infection. The patient then becomes drowsy, with seizures and focal signs such as a progressive hemiparesis.

The diagnosis rests on a strong clinical suspicion in patients with a local focus of infection. Careful assessment with contrast-enhanced CT or MRI may show a subdural collection with underlying cerebral oedema. Management requires aspiration of pus via a burr hole and appropriate parenteral antibiotics. Any local source of infection must be treated to prevent re-infection.

Spinal epidural abscess

The characteristic clinical features are pain in a root distribution and progressive transverse spinal cord syndrome with paraparesis, sensory impairment and sphincter dysfunction. Features of the primary focus of infection may be less obvious and thus can be overlooked. The resurgence of resistant staphylococcal infection and intravenous drug misuse has contributed to a recent marked rise in incidence.

X-ray changes occur late, if present, so MRI or myelography should precede urgent neurosurgical intervention. Decompressive laminectomy with abscess drainage relieves the pressure on the dura. Organisms may be grown from the pus or blood. Surgery, together with appropriate antibiotics, may prevent complete and irreversible paraplegia.

Lyme disease

Infection with *Borrelia burgdorferi* can cause numerous neurological problems, including polyradiculopathy, meningitis, encephalitis and mononeuritis multiplex (p. 255).

Neurosyphilis

Neurosyphilis may present as an acute or chronic process and may involve the meninges, blood vessels and/or parenchyma of the brain and spinal cord. The decade to 2008 saw a 10-fold increase in the incidence of syphilis, mostly as a result of misguided relaxation of safe sex measures with the advent of effective antiretroviral treatments for AIDS. Paralleled future increases in neurosyphilis are inevitable. The clinical manifestations are diverse and early diagnosis and treatment are essential.

Clinical features

The clinical and pathological features of the three most common presentations are summarised in Box 25.70. Neurological examination reveals signs indicative of the anatomical localisation of lesions. Delusions of grandeur suggest general paresis of the insane, but more commonly there is simply progressive dementia. Small and irregular pupils that react to convergence but not light, as described by Argyll Robertson (see Box 25.22, p. 1092), may accompany any neurosyphilitic syndrome but most commonly tabes dorsalis.

Investigations

Routine screening for syphilis is warranted in many neurological patients. Treponemal antibodies (p. 338) are positive in the serum in most patients, but CSF examination is essential if neurological involvement is suspected. Active disease is suggested by an elevated cell count, usually lymphocytic, and the protein content may be elevated to 0.5–1.0 g/L with an increased gamma globulin fraction. Serological tests in CSF are usually positive but progressive disease can occur with negative CSF serology.

i 25.70 Clinical and pathological features of neurosyphilis

Type and interval from primary infection	Pathology	Clinical features
Meningovascular (5 years)*	Endarteritis obliterans Meningeal exudate Granuloma (gumma)	Stroke Cranial nerve palsies Seizures/mass lesion
General paralysis of the insane (5–15 years)*	Degeneration in cerebral cortex/ cerebral atrophy Thickened meninges	Dementia Tremor Bilateral upper motor signs
Tabes dorsalis (5–20 years)*	Degeneration of sensory neurons Wasting of dorsal columns Optic atrophy	Lightning pains Sensory ataxia Visual failure Abdominal crises Incontinence Trophic changes
Any of the above		Argyll Robertson pupils (p. 1092)

Management

The injection of procaine benzylpenicillin (procaine penicillin) and probenecid for 17 days is essential in the treatment of neurosyphilis of all types (p. 338). Further courses of penicillin must be given if symptoms are not relieved, if the condition continues to advance or if the CSF continues to show signs of active disease. The cell count returns to normal within 3 months of completion of treatment, but the elevated protein takes longer to subside and some serological tests may never revert to normal. Evidence of clinical progression at any time is an indication for renewed treatment.

Diseases caused by bacterial toxins

Tetanus

This disease results from infection with *Clostridium tetani*, a commensal in the gut of humans and domestic animals that is found in soil. Infection enters the body through wounds, which may be trivial. It is rare in the UK, occurring mostly in gardeners and farmers, but a recent increase has been seen in intravenous drug misusers. By contrast, the disease is common in many developing countries, where dust contains spores derived from animal and human excreta. Unhygienic practices soon after birth may lead to infection of the umbilical stump or site of circumcision, causing tetanus neonatorum. Tetanus is still one of the major killers of adults, children and neonates in developing countries, where the mortality rate can be nearly 100% in the newborn and around 40% in others.

In circumstances unfavourable to growth of the organism, spores are formed and these may remain dormant for years in the soil. Spores germinate and bacilli multiply only in the anaerobic conditions that occur in areas of tissue necrosis or if the oxygen tension is lowered by the presence of other organisms, particularly if aerobic. The bacilli remain localised but produce an exotoxin with an affinity for motor nerve endings and motor nerve cells.

The anterior horn cells are affected after the exotoxin has passed into the blood stream and their involvement results in rigidity and convulsions. Symptoms first appear from 2 days to several weeks after injury: the shorter the incubation period, the more severe the attack and the worse the prognosis.

Clinical features

By far the most important early symptom is trismus – spasm of the masseter muscles, which causes difficulty in opening the mouth and in masticating; hence the name 'lockjaw'. Lockjaw in tetanus is painless, unlike the spasm of the masseters due to dental abscess, septic throat or other causes. Conditions that can mimic tetanus include hysteria and phenothiazine overdosage, or overdose in intravenous drug misusers.

In tetanus, the tonic rigidity spreads to involve the muscles of the face, neck and trunk. Contraction of the frontalis and the muscles at the angles of the mouth leads to the so-called 'risus sardonicus'. There is rigidity of the muscles at the neck and trunk of varying degree. The back is usually slightly arched ('opisthotonus') and there is a board-like abdominal wall.

In the more severe cases, violent spasms lasting for a few seconds to 3–4 minutes occur spontaneously, or may be induced by stimuli such as movement or noise. These episodes are painful and exhausting, and suggest a grave outlook, especially if they appear soon after the onset of symptoms. They gradually increase in frequency and severity for about 1 week and the patient may die from exhaustion, asphyxia or aspiration pneumonia. In less severe illness, periods of spasm may not commence until a week or so after the first sign of rigidity, and in very mild infections they may never appear. Autonomic involvement may cause cardiovascular complications, such as hypertension. Rarely, the only manifestation of the disease may be 'local tetanus' – stiffness or spasm of the muscles near the infected wound – and the prognosis is good if treatment is commenced at this stage.

Investigations

The diagnosis is made on clinical grounds. It is rarely possible to isolate the infecting organism from the original locus of entry.

Management

Established disease

Management of established disease should begin as soon as possible, as shown in Box 25.71.

25.71 Treatment of tetanus

Neutralise absorbed toxin
- Give IV injection of 3000 IU of human tetanus antitoxin

Prevent further toxin production
- Débride wound
- Give benzylpenicillin 600 mg IV 4 times daily (metronidazole if patient is allergic to penicillin)

Control spasms
- Nurse in a quiet room
- Avoid unnecessary stimuli
- Give IV diazepam
- If spasms continue, paralyse patient and ventilate

General measures
- Maintain hydration and nutrition
- Treat secondary infections

Prevention

Tetanus can be prevented by immunisation and prompt treatment of contaminated wounds by débridement and antibiotics. In patients with a contaminated wound, the immediate danger of tetanus can be greatly reduced by the injection of 1200 mg of penicillin followed by a 7-day course of oral penicillin. For those allergic to penicillin, erythromycin should be used. When the risk of tetanus is judged to be present, an intramuscular injection of 250 IU of human tetanus antitoxin should be given, along with toxoid, which should be repeated 1 month and 6 months later. For those already immunised, only a booster dose of toxoid is required.

Botulism

Botulism is caused by the neurotoxins of *Clostridium botulinum*, which are extremely potent and cause disease after ingestion of even picogram amounts. Its classical form is an acute onset of bilateral cranial neuropathies associated with symmetric descending weakness.

Anaerobic conditions are necessary for the organism's growth. It may contaminate and thrive in many foodstuffs, where sealing and preserving provide the requisite conditions. Contaminated honey has been implicated in infant botulism, in which the organism colonises the gastrointestinal tract. Wound botulism is a growing problem in injection drug-users.

The toxin causes predominantly bulbar and ocular palsies (difficulty in swallowing, blurred or double vision, ptosis), progressing to limb weakness and respiratory paralysis. Criteria for the clinical diagnosis are shown in Box 25.72.

25.72 US Centers for Disease Control (CDC) definition of botulism

Three main syndromes
- Infantile
- Food-borne
- Wound infection

Clinical features
- Absence of fever
- Symmetrical neurological deficits
- Patient remains responsive
- Normal or slow heart rate and normal blood pressure
- No sensory deficits with the exception of blurred vision

Management includes assisted ventilation and general supportive measures until the toxin eventually dissociates from nerve endings 6–8 weeks following ingestion. A polyvalent antitoxin is available for post-exposure prophylaxis and for the treatment of suspected botulism. It specifically neutralises toxin types A, B and E and is not effective against infantile botulism (in which active growth of the organism allows continued toxin production).

Prion diseases

Prions are unique amongst infectious agents in that they are devoid of any nucleic acid. They appear to be transmitted by acquisition of a normal mammalian protein (prion protein, PrP^{C}) that is in an abnormal conformation (PrP^{SC}, containing an excess of beta-sheet protein); the abnormal protein inhibits the 26S

i 25.73 Prion diseases affecting humans

Disease	Mechanism
Creutzfeldt–Jakob disease	
Sporadic	Unknown: spontaneous PrP^{C} to PrP^{SC} conversion or somatic mutation
Familial	Genetic: mutations in the *PrP* gene
Variant	Dietary ingestion: infection from bovine spongiform encephalopathy
Gerstmann–Sträussler–Scheinker disease	Genetic: mutations in the *PrP* gene
Fatal familial insomnia	Genetic: mutations in the *PrP* gene
Sporadic fatal insomnia	Genetic: spontaneous PrP^{C} to PrP^{SC} conversion or somatic mutation
Kuru	Dietary: ingestion of affected human brain

proteasome, which can degrade misfolded proteins, leading to accumulation of the abnormally configured PrP^{SC} protein instead of normal PrP^{C}. The result is accumulation of protein that forms amyloid in the CNS, causing a transmissible spongiform encephalopathy (TSE) across several species.

Human prion diseases (Box 25.73) are characterised by the histopathological triad of cortical spongiform change, neuronal cell loss and gliosis. Associated with these changes there is deposition of amyloid, made up of an altered form of a normally occurring protein, the prion protein. Prion proteins are not inactivated by cooking or conventional sterilisation, and transmission is thought to occur by consumption of infected CNS tissue or by inoculation (e.g. via depth EEG electrodes, corneal grafts, cadaveric dura mater grafts and pooled cadaveric growth hormone preparations). The same diseases can occur in an inherited form, due to mutations in the *PrP* gene.

The apparent transmission of bovine spongiform encephalopathy (BSE) to humans was thought to be responsible for the emergence of a new variant of CJD (vCJD) in the UK (see below). This outbreak led to nationwide precautionary measures, such as leucodepletion of all blood used for transfusion, and the mandatory use of disposable surgical instruments wherever possible for tonsillectomy, appendicectomy and ophthalmological procedures.

Creutzfeldt–Jakob disease

Creutzfeldt–Jakob disease (CJD) is the best-characterised human TSE. Some 10% of cases arise from a mutation in the gene coding for the prion protein. The sporadic form is the most common, occurring in middle-aged to elderly patients. Clinical features usually involve a rapidly progressive dementia, with myoclonus and a characteristic EEG pattern (repetitive slow-wave complexes), although a number of other features, such as visual disturbance or ataxia, may also be seen. These are particularly common in CJD transmitted by inoculation (e.g. by infected dura mater grafts). Death occurs after a mean of 4–6 months. There is no effective treatment.

Variant Creutzfeldt–Jakob disease

This type of CJD (vCJD) emerged in the late 1990s, affecting a small number of patients in the UK. The causative agent appears to be identical to that causing BSE in cows, and the disease may have been a result of the epidemic of BSE in the UK a decade earlier. Patients affected by vCJD are typically younger than those with sporadic CJD and present with neuropsychiatric changes and sensory symptoms in the limbs, followed by ataxia, dementia and death. Progression is slightly slower than in patients with sporadic CJD (mean time to death is over a year). Characteristic EEG changes are not present, but MRI brain scans show characteristic high-signal changes in the pulvinar thalami in a high proportion of cases (Fig. 25.37). Brain histology is distinct, with very florid plaques containing the prion proteins. Abnormal prion protein has been identified in tonsil specimens from patients with vCJD, leading to the suggestion that the disease could be transmitted by reticulo-endothelial tissue (like TSEs in animals but unlike sporadic CJD in humans). It was the emergence of this form of the disorder that led to the changes in public health and farming policy in the UK; while the incidence of vCJD has declined dramatically, surveillance and research continue.

Fig. 25.37 Magnetic resonance imaging in variant Creutzfeldt–Jakob disease. Arrows indicate bilateral pulvinar hyperintensity.

Intracranial mass lesions and raised intracranial pressure

Many different types of mass lesion may arise within the intracranial cavity (Box 25.74). In developing countries tuberculoma and other infections are frequent causes, but in the West intracranial haemorrhage and brain tumours are more common. The clinical features depend on the site of the mass, its nature and its rate of expansion. Symptoms and signs (see Box 25.75) are produced by a number of mechanisms.

Raised intracranial pressure

Raised intracranial pressure (RICP) may be caused by mass lesions, cerebral oedema, obstruction to CSF circulation leading

25.74 Common causes of raised intracranial pressure

Mass lesions

- Intracranial haemorrhage (traumatic or spontaneous):
  - Extradural haematoma
  - Subdural haematoma
  - Intracerebral haemorrhage
- Cerebral tumour (particularly posterior fossa lesions or high-grade gliomas: see Box 25.76)
- Infective:
  - Cerebral abscess
  - Tuberculoma
  - Cysticercosis (p. 298)
  - Hydatid cyst (p. 299)
- Colloid cyst (in ventricles)

Disturbance of cerebrospinal fluid circulation

- Obstructive (non-communicating) hydrocephalus: obstruction within ventricular system
- Communicating hydrocephalus: site of obstruction outside ventricular system

Obstruction to venous sinuses

- Cerebral venous thrombosis
- Trauma (depressed fractures overlying sinuses)

Diffuse brain oedema or swelling

- Meningo-encephalitis
- Trauma (diffuse head injury, near-drowning)
- Subarachnoid haemorrhage
- Metabolic (e.g. water intoxication)
- Idiopathic intracranial hypertension

25.75 Clinical features of intracranial mass lesions

Presentation	Features
Seizures	Focal onset ± generalised spread
Focal symptoms	Progressive loss of function Weakness Numbness Dysphasia Cranial neuropathy
False localising signs	Unilateral/bilateral 6th nerve palsies Contralateral 3rd nerve (usually pupil first)
Raised intracranial pressure (usually aggressive tumours causing vasogenic oedema or obstructive hydrocephalus)	Headache worse on lying/straining Vomiting Diplopia (6th nerve involvement) Papilloedema Bradycardia, raised blood pressure Impaired conscious level
Stroke/TIA-like symptoms	Acute haemorrhage into tumour Paroxysmal ‘tumour attacks’
Cognitive/behavioural change	Usually frontal mass lesions
Endocrine abnormalities	Pituitary tumours
Incidental finding	Asymptomatic but identified on imaging (meningiomas commonly)

(TIA = transient ischaemic attack)

to hydrocephalus, impaired CSF absorption and cerebral venous obstruction (see Box 25.74).

Clinical features

In adults, intracranial pressure is less than 10–15 mmHg. The features of RICP are listed in Box 25.75. The speed of pressure increase influences presentation. If slow, compensatory mechanisms may occur, including alteration in the volume of fluid in CSF spaces and venous sinuses, minimising symptoms. Rapid pressure increase (as in aggressive tumours) does not permit these compensatory mechanisms to take place, leading to early symptoms, including sudden death. Papilloedema is not always present, either because the pressure rise has been too rapid or because of anatomical anomalies of the meningeal sheath of the optic nerve.

A false localising sign is one in which the pathology is remote from the site of the expected lesion; in RICP, the 6th cranial nerve (unilateral or bilateral) is most commonly affected but the 3rd, 5th and 7th nerves may also be involved. Sixth nerve palsies are thought to be due either to stretching of the long slender nerve or to compression against the petrous temporal bone ridge. Transtentorial herniation of the uncus may compress the ipsilateral 3rd nerve and usually involves the pupillary fibres first, causing a dilated pupil; however, a false localising contralateral 3rd nerve palsy may also occur, perhaps due to extrinsic compression by the tentorial margin. Vomiting, coma, bradycardia and arterial hypertension are later features of RICP.

The rise in intracranial pressure from a mass lesion may cause displacement of the brain. Downward displacement of the medial temporal lobe (uncus) through the tentorium due to a large hemisphere mass may cause ‘temporal coning’ (Fig. 25.38). This may stretch the 3rd and/or 6th cranial nerves or cause pressure on the contralateral cerebral peduncle (giving rise to ipsilateral upper motor neuron signs), and is usually accompanied by progressive coma. Downward movement of the cerebellar tonsils through the foramen magnum may compress the medulla – ‘tonsillar coning’ (Fig. 25.39). This may result in brainstem haemorrhage and/or acute obstruction of the CSF pathways. As coning progresses, coma and death occur unless the condition is rapidly treated.

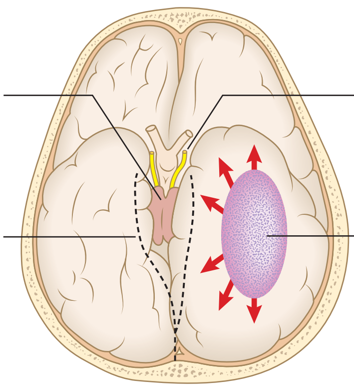


Fig. 25.38 Cerebral tumour displacing medial temporal lobe and causing pressure on the mid-brain and 3rd cranial nerve.

Management

Primary management of RICP should be targeted at relieving the cause (e.g. surgical decompression of mass lesion, glucocorticoids to reduce vasogenic oedema or shunt procedure to relieve hydrocephalus). Supportive treatment includes maintenance of

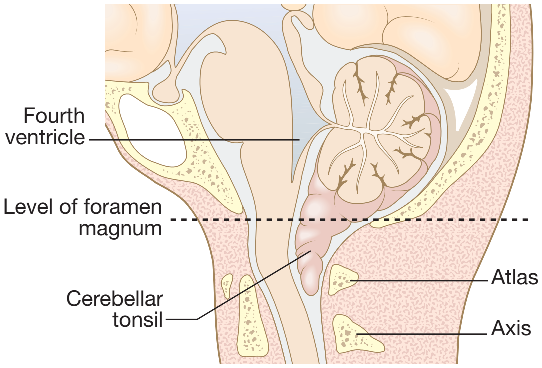

Fig. 25.39 Tonsillar cone. Downward displacement of the cerebellar tonsils below the level of the foramen magnum.

fluid balance, blood pressure control, head elevation, and use of diuretics such as mannitol. Intensive care support may be needed (p. 208).

Brain tumours

Primary brain tumours are a heterogeneous collection of neoplasms arising from the brain tissue or meninges, and vary from benign to highly malignant. Primary malignant brain tumours (Box 25.76) are rare, accounting for 1% of all adult tumours but a higher proportion in children. The most common benign brain tumour is a meningioma. Primary brain tumours do not metastasise due to the absence of lymphatic drainage in the brain. There are rare pathological subtypes, however, such as medulloblastoma, which do have a propensity to metastasise; the reasons for this are not clear. Most cerebral tumours are sporadic but may be associated with genetic syndromes such as neurofibromatosis or tuberous sclerosis. Brain tumours are not classified by the usual TNM system but by the World Health Organisation (WHO) grading I–IV; this is based on histology (e.g. nuclear pleomorphism, presence of mitoses and presence of necrosis), with grade I the most benign and grade IV the most malignant. Gliomas account for 60% of brain tumours, with the aggressive glioblastoma multiforme (WHO grade IV) the most common glioma, followed by meningiomas (20%) and pituitary tumours (10%). Although the lower-grade gliomas (I and II) may be very indolent, with prognosis measured in terms of many years, these may transform to higher-grade disease at any time, with a resultant sharp decline in life expectancy.

Most malignant brain tumours are due to metastases, with intracranial metastases complicating about 20% of extracranial malignancies. The rate is higher with primaries in the bronchus, breast and gastrointestinal tract (Fig. 25.40). Metastases usually occur in the white matter of the cerebral or cerebellar hemispheres but there are diffuse leptomeningeal types.

Clinical features

The presentation is variable and usually influenced by the rate of growth. High-grade disease (WHO grades III and IV) tends to present with a short (weeks) history of mass effect (headache, nausea secondary to RICP), while more indolent tumours can present with slowly progressive focal neurological deficits, depending on their location (see Box 25.75); generalised or focal seizures are common in either. Headache, if present, is usually accompanied by focal deficits or seizures, and isolated stable headache is almost never due to intracranial tumour.

The size of the primary tumour is of far less prognostic significance than its location within the brain. Tumours within the brainstem will result in early neurological deficits, while those in the frontal region may be quite large before symptoms occur.

25.76 Primary brain tumours

Histological type	Common site	Age
Malignant		
Glioma (astrocytoma)	Cerebral hemisphere	Adulthood
	Cerebellum	Childhood/adulthood
	Brainstem	Childhood/young adulthood
Oligodendroglioma	Cerebral hemisphere	Adulthood
Medulloblastoma	Posterior fossa	Childhood
Ependymoma	Posterior fossa	Childhood/adolescence
Cerebral lymphoma	Cerebral hemisphere	Adulthood
Benign		
Meningioma	Cortical dura Parasagittal Sphenoid ridge Suprasellar Olfactory groove	Adulthood (often incidental finding)
Neurofibroma	Acoustic neuroma	Adulthood
Craniopharyngioma	Suprasellar	Childhood/adolescence
Pituitary adenoma	Pituitary fossa	Adulthood
Colloid cyst	Third ventricle	Any age
Pineal tumours	Quadrigeminal cistern	Childhood (teratomas) Young adulthood (germ cell)

Fig. 25.40 Contrast-enhanced computed tomogram of the head showing a large metastasis within the left hemisphere (large arrow). There is surrounding cerebral oedema, and a smaller metastasis (small arrow) within the wall of the right lateral ventricle. The primary lesion was a lung carcinoma.

Fig. 25.41 **Magnetic resonance image showing a meningioma in the frontal lobe (arrow A) with associated oedema (arrow B).**

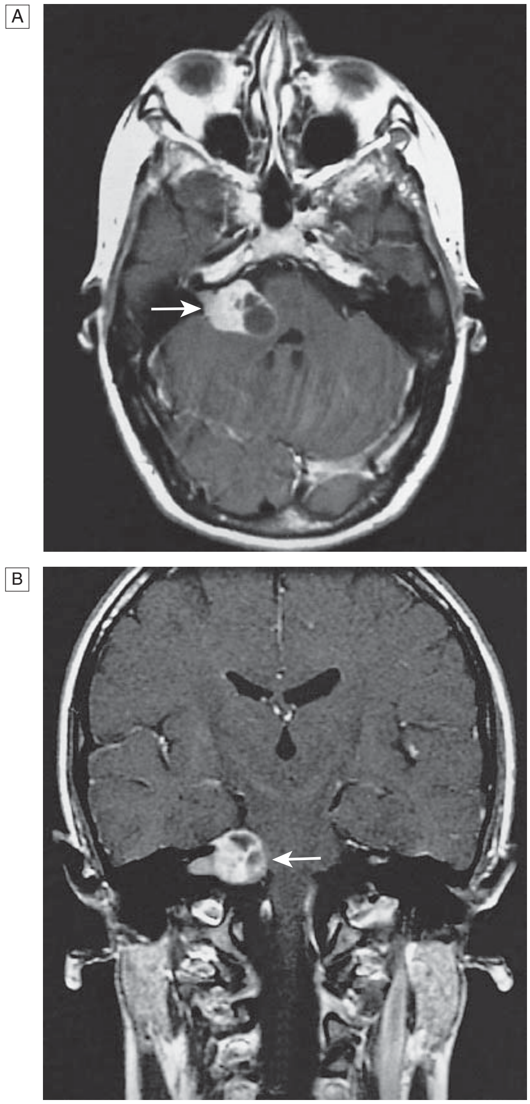

Fig. 25.42 **Magnetic resonance image of an acoustic neuroma (arrows) in the posterior fossa compressing the brainstem.** **A** Axial image. **B** Coronal image.

Investigations

Diagnosis is by neuroimaging (Figs 25.41 and 25.42) and pathological grading following biopsy or resection where possible. The more malignant tumours are more likely to demonstrate contrast enhancement on imaging. If the tumour appears metastatic, further investigation to find the primary is required.

Management

Brain tumours are treated with a combination of surgery, radiotherapy and chemotherapy, depending on the type of tumour and the patient. Advancing age is the most powerful negative prognostic factor in CNS tumours, so best supportive care (including glucocorticoid therapy) may be most appropriate in older patients with metastases or high-grade disease. Treatment may not always be indicated in low-grade gliomas and watchful waiting may be appropriate, although a more aggressive approach is increasingly favoured.

Dexamethasone given orally (or intravenously where RICP is acutely or severely raised) may reduce the vasogenic oedema typically associated with metastases and high-grade gliomas.

Prolactin- or growth hormone-secreting pituitary adenomas (p. 683) may respond well to treatment with dopamine agonists (such as bromocriptine, cabergoline or quinagolide); in this situation, imaging and hormone levels may be all that is required to establish a formal diagnosis, precluding the need for surgery.

Surgical

The mainstay of primary treatment is surgery, either resection (full or partial debulking) or biopsy, depending on the site and likely radiological diagnosis. Clearly, if a tumour occurs in an area of brain that is highly important for normal function (e.g. motor strip), then biopsy may be the only safe surgical intervention but, in general, maximal safe resection is the optimal surgical management. Meningiomas and acoustic neuromas offer the best prospects for complete removal and thus cure. Some meningiomas can recur, however, particularly those of the sphenoid ridge, when partial excision is often all that is possible. Thereafter, post-operative surveillance may be required, as radiotherapy is effective at preventing further growth of residual tumour. Pituitary adenomas may be removed by a trans-sphenoidal route, avoiding the need for a craniotomy. Unfortunately, gliomas, which account for the majority of brain tumours, cannot be completely excised, since infiltration spreads well beyond the apparent radiological boundaries of the intracranial mass. Recurrence is therefore the rule, even if the mass of the tumour is apparently removed completely; partial excision ('debulking') may be useful in alleviating symptoms caused by RICP, but although there is increasing evidence that the degree of surgical excision may have a positive influence on survival, this has not yet been convincingly demonstrated.

Radiotherapy and chemotherapy

In the majority of primary CNS tumours, radiation and chemotherapy are used to control disease and extend survival rather than for cure. Meningioma and pituitary adenoma offer the

best chance of life-long remission. The gliomas are incurable; high-grade, WHO grade IV disease still carries a median survival of just over 1 year. In this situation, patient and family should always be involved in decisions regarding treatment. The diagnosis, and often the symptoms, are devastating, and support from palliative care and social work is crucial at an early stage. In WHO grade III disease, prognosis is a little better (2–4 years), and in rarer, more indolent tumours very prolonged survival is possible.

Advances have been made recently in terms of therapeutic outcome. Standard care for WHO grade IV glioblastoma multiforme is now combination radiotherapy with temozolomide chemotherapy; although this improves median survival of the population from only 12 to 14.5 months, up to 25% of patients survive for more than 2 years (compared to approximately 10% with radiotherapy alone). Ten percept will survive more than 5 years with temozolomide (virtually unheard of with radiotherapy alone). Benefits are more likely in well-debulked patients who are younger and fitter. Implantation of chemotherapy gives a small survival benefit.

Understanding of the molecular biology of brain tumours has allowed the use of biomarkers to guide therapy and prognostic discussions. In patients with methylation of the promoter region of the *MGMT* (methyl guanine methyl transferase) gene (about 30% of the population), 2-year survival is almost 50%. MGMT reduces the cytotoxicity of temozolomide and this mutation also reduces the enzyme's activity, rendering the tumour more sensitive to chemotherapy. In grade II and III gliomas, the presence of the loss of heterozygosity (LOH) 1p19q chromosomal abnormality confers chemosensitivity and thus improves prognosis. The presence of a rare mutation in the *IDH-1* (isocitrate dehydrogenase) gene confers a more favourable prognosis in patients with glioblastoma.

There is a small group of highly malignant grade IV tumours that can be cured with aggressive therapy. Medulloblastomas have a good chance of long-term remission with maximal surgery followed by irradiation of the whole brain and spine; younger patients may also benefit from concomitant and adjuvant chemotherapy. Older patients do not tolerate this, however.

Once tumours relapse, chemotherapy response rates are low and survival is short in high-grade disease. In the more uncommon low-grade tumours, repeated courses of chemotherapy can result in much more prolonged survival.

In metastatic disease, radiotherapy offers a modest improvement in survival but with costs in terms of quality of life; treatment therefore needs careful discussion with the patient. Benefits may be superior in breast cancer but there is little to separate other pathologies. Occasional chemosensitive cancers, such as small-cell lung cancer, may benefit from systemic chemotherapy but intracerebral metastases represent a late stage of disease and have a short prognosis.

Prognosis

The WHO histological grading system is a powerful predictor of prognosis in primary CNS tumours, though it does not yet take account of individual biomarkers. For each tumour type and grade, advancing age and deteriorating functional status are the next most important negative prognostic features. The overall 5-year survival rate of about 14% in adults masks a wide variation that depends on tumour type.

Acoustic neuroma

This is a benign tumour of Schwann cells of the 8th cranial nerve, which may arise in isolation or as part of neurofibromatosis type 2 (see below). When sporadic, acoustic neuroma occurs after the third decade and is more frequent in females. The tumour commonly arises near the nerve's entry point into the medulla or in the internal auditory meatus, usually on the vestibular division. Acoustic neuromas account for 80–90% of tumours at the cerebellopontine angle.

Clinical features

Acoustic neuroma typically presents with unilateral progressive hearing loss, sometimes with tinnitus. Vertigo is an unusual symptom, as slow growth allows compensatory brainstem mechanisms to develop. In some cases, progressive enlargement leads to distortion of the brainstem and/or cerebellar peduncle, causing ataxia and/or cerebellar signs in the limbs. Distortion of the fourth ventricle and cerebral aqueduct may cause hydrocephalus (see below), which may be the presenting feature. Facial weakness is unusual at presentation but facial palsy may follow surgical removal of the tumour. The tumour may be identified incidentally on cranial imaging.

Investigations

MRI is the investigation of choice (see Fig. 25.42).

Management

Surgery is the treatment of choice. If the tumour can be completely removed, the prognosis is excellent, although deafness is a common complication of surgery. Stereotactic radiosurgery (radiotherapy) may be appropriate for some lesions.

Neurofibromatosis

Neurofibromatosis encompasses two clinically and genetically separate conditions, with an autosomal dominant pattern of inheritance. The more common neurofibromatosis type 1 (NF1) is caused by mutations in the *NF1* gene on chromosome 17, half of which are new mutations. NF1 is characterised by neurofibromas (benign peripheral nerve sheath tumours) and skin involvement (Fig. 25.43), and may affect numerous systems (Box 25.77).

Fig. 25.43 **A café au lait spot (arrow A) and subcutaneous nodules (arrows B) on the forearm of a patient with neurofibromatosis type 1.**

25.77 Neurofibromatosis types 1 and 2: clinical features

Neurofibromatosis 1	Neurofibromatosis 2
Skin	
Cutaneous/subcutaneous neurofibromas Angiomas Café au lait patches (>6) Axillary/groin freckling Hypopigmented patches	Much less commonly affected than in NF1 Café au lait patches (usually <6) Cutaneous schwannomas: plaque lesions Subcutaneous schwannomas
Eyes	
Lisch nodules (iris fibromas) Glaucoma Congenital ptosis	Cataracts Retinal hamartoma Optic nerve meningioma
Nervous system	
Plexiform neurofibromas Malignant peripheral nerve sheath tumours Aqueduct stenosis Slight tonsillar descent Cognitive impairment Epilepsy	Vestibular schwannomas Cranial nerve schwannomas (not 1 and 2) Spinal schwannomas Peripheral nerve schwannomas Cranial meningiomas Spinal meningiomas Spinal/brainstem ependymomas Spinal/cranial astrocytoma
Bone	
Scoliosis Osteoporosis Pseudoarthrosis	
Cardiorespiratory systems	
Pulmonary stenosis Hypertension Renal artery stenosis Compression from neurofibroma causing restrictive lung defect	
Gastrointestinal system	
Gastrointestinal stromal tumour (GIST) Duodenal/ampullary neuro-endocrine tumour	

Neurofibromatosis type 2 (NF2) is caused by mutations of the *NF2* gene on chromosome 22, and is characterised by schwannomas (benign peripheral nerve sheath tumours comprising Schwann cells only) with little skin involvement; the clinical manifestations are more restricted to the eye and nervous system (Box 25.77). Malignant change may occur in NF1 neurofibromas but is rare in NF2 schwannomas. The prevalence of NF1 and NF2 is about 20–50 per 100 000 and 1.5 per 100 000, respectively.

Von Hippel–Lindau disease

This rare autosomal dominant disease is caused by mutations of the *VHL* tumour suppressor gene on chromosome 3. It promotes development of tumours affecting the kidney, adrenal gland, CNS, eye, inner ear, epididymis and pancreas, which may undergo malignant change. Benign haemangiomas and haemangioblastomas affect about 80% of patients, and are mostly cerebellar and retinal.

Paraneoplastic neurological disease

Paraneoplastic neurological syndromes often present before the underlying tumour declares itself and cause considerable disability. They are discussed in full on page 1110.

Hydrocephalus

Hydrocephalus is the excessive accumulation of CSF within the brain, and may be caused either by increased CSF production, by reduced CSF absorption, or by obstruction of the circulation (Fig. 25.44). Symptoms range from none to sudden death, depending on the speed at which and degree to which hydrocephalus develops. The causes are listed in Box 25.78. The terms 'communicating' and 'non-communicating' (also known as obstructive) hydrocephalus refer to blockage either outside or within the ventricular system, respectively (Fig. 25.45).

Normal pressure hydrocephalus

Normal pressure hydrocephalus (NPH) is a controversial entity, said to involve intermittent rises in CSF pressure, particularly at night. It is described in old age as being associated with a triad of gait apraxia, dementia and urinary incontinence.

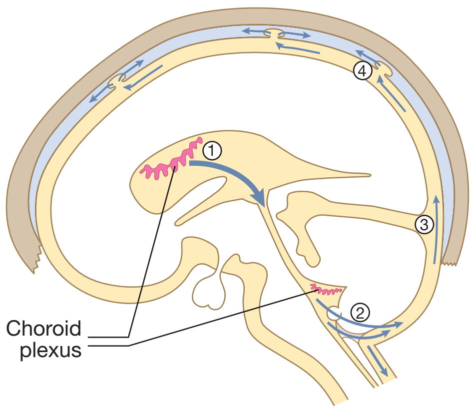

Fig. 25.44 The circulation of cerebrospinal fluid (CSF). (1) CSF is synthesised in the choroid plexus of the ventricles and flows from the lateral and third ventricles through the aqueduct to the fourth ventricle. (2) At the foramina of Luschka and Magendie it exits the brain, flowing over the hemispheres (3) and down around the spinal cord and roots in the subarachnoid space. (4) It is then absorbed into the dural venous sinuses via the arachnoid villi.

25.78 Causes of hydrocephalus

Congenital malformations

- Aqueduct stenosis
- Chiari malformations
- Dandy–Walker syndrome
- Benign intracranial cysts
- Vein of Galen aneurysms
- Congenital central nervous system infections
- Craniofacial anomalies

Acquired causes

- Mass lesions (especially those in the posterior fossa)
- Tumour
- Colloid cyst of third ventricle
- Abscess
- Haematoma
- Absorption blockages due to:
  - Inflammation (e.g. meningitis, sarcoidosis)
  - Intracranial haemorrhage

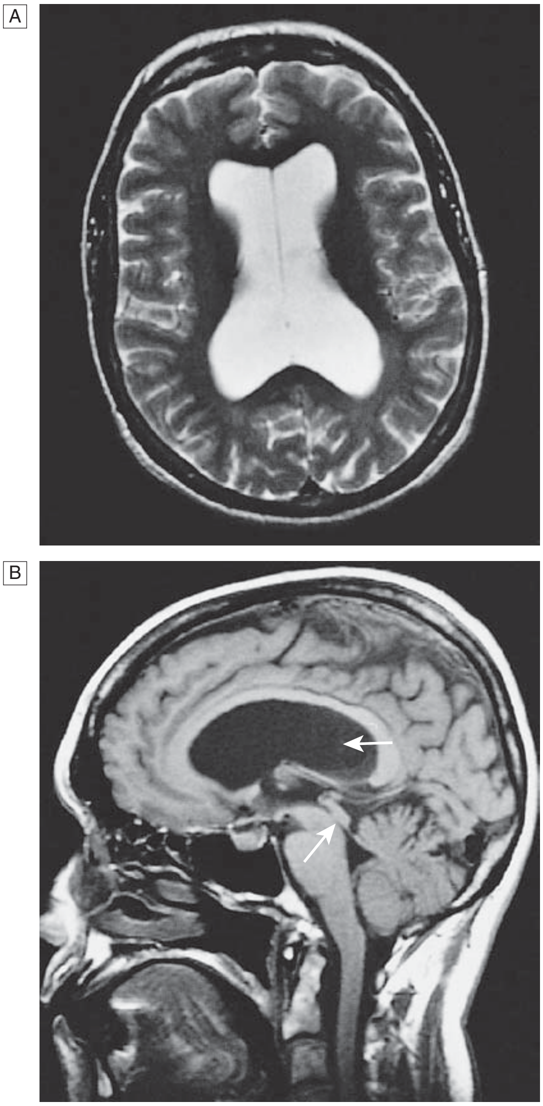

Fig. 25.45 Magnetic resonance image of hydrocephalus due to aqueduct stenosis. **A** Axial T2-weighted image (cerebrospinal fluid appears white): note the dilated lateral ventricles. **B** Sagittal T1-weighted image (cerebrospinal fluid appears black): note the dilated ventricles (top arrow) and narrowed aqueduct (bottom arrow).

Management

Diversion of the CSF by means of a shunt placed between the ventricular system and the peritoneal cavity or right atrium may result in rapid relief of symptoms in obstructive hydrocephalus. The outcome of shunting in NPH is much less predictable and, until a good response can be predicted, the management of individual cases will remain uncertain.

Idiopathic intracranial hypertension

This usually occurs in obese young women. The annual incidence is about 3 per 100 000. RICP occurs in the absence of a structural lesion, hydrocephalus or other identifiable cause. The aetiology is uncertain but there is an association with obesity in females, perhaps inducing a defect of CSF reabsorption by the arachnoid villi. A number of drugs may be associated, including tetracycline, vitamin A and retinoid derivatives.

Clinical features

The usual presentation is with headache, sometimes accompanied by diplopia and visual disturbance (most commonly, transient obscurations of vision associated with changes in posture). Clinical examination reveals papilloedema but little else. False localising cranial nerve palsies (usually of the 6th nerve) may be present. It is important to record visual fields accurately for future monitoring.

Investigations

Brain imaging is required to exclude a structural or other cause (e.g. cerebral venous sinus thrombosis, p. 1162). The ventricles are typically normal in size or small ('slit' ventricles). The diagnosis may be confirmed by lumbar puncture, which shows raised normal CSF constituents at increased pressure (usually >30 cmH_2O CSF).

Management

Management can be difficult and there is no evidence to support any specific treatment. Weight loss in overweight patients may be helpful if it can be achieved. Acetazolamide or topiramate may help to lower intracranial pressure, the latter perhaps aiding weight loss in some patients. Repeated lumbar puncture is an effective treatment for headache but may be technically difficult in obese individuals and is often poorly tolerated. Patients failing to respond, in whom chronic papilloedema threatens vision, may require optic nerve sheath fenestration or a lumbo-peritoneal shunt.

Head injury

Diagnosis of head trauma is usually clear – either from the history or from signs of external trauma to the head. Brain injury is more likely with skull fracture but can occur without. Individual cranial nerves may be damaged in fractures of the facial bones or skull base. Intracranial effects can be substantial and take several forms: extradural haematoma (collection of blood between the skull and dura); subdural haematoma (collection of blood between the dura and the surface of the brain); intracerebral haematoma; or diffuse axonal injury.

Whatever pathology occurs, the resultant RICP may lead to coning (see Figs 25.38 and 25.39). Haematomas are identified by CT and management is by surgical drainage, usually via a burr hole. Penetrating skull fractures lead to increased infection risk. Long-term sequelae include headache, cognitive decline and depression, all contributing to significant social, work, personality and family difficulties.

Subdural haematoma may occur spontaneously, particularly in patients on anticoagulants, in old age, and with alcohol misuse. There may or may not be a history of trauma. Patients present with subacute impairment of brain function, both globally (obtundation and coma) and focally (hemiparesis, seizures). Headache may not be present. The diagnosis should always be considered in those who present with reduced conscious level.

Beyond the immediate consequences of brain injury, there is increasing suspicion of long-term consequences, including dementia, postulated after either single (moderate or severe) injuries or even after multiple mild injuries, such as in boxers. If substantiated, this would encourage more effort to go into prevention of repeated brain injury in sporting contexts.

Disorders of cerebellar function

Cerebellar dysfunction can manifest as incoordination of limb function, gait ataxia (p. 1087), speech or eye movements. Acute dysfunction may be caused by alcohol or prescription drugs (especially the sodium channel-blocking antiepileptic drugs phenytoin and carbamazepine).

Inflammatory changes in the cerebellum may cause symptoms in the aftermath of some infections (especially herpes zoster) or as a paraneoplastic phenomenon. The hereditary spinocerebellar ataxias are described on page 1115; they manifest as progressive ataxias in middle and old age, often with other neurological features that aid specific diagnosis.

Disorders of the spine and spinal cord

The spinal cord and spinal roots may be affected by intrinsic disease or by disorders of the surrounding meninges and bones. The clinical presentation of these conditions depends on the anatomical level at which the cord or roots are affected, as well as the nature of the pathological process involved. It is important to recognise when the spinal cord is at risk of compression (p. 1136) so that urgent action can be taken.

Cervical spondylosis

Cervical spondylosis is the result of osteoarthritis in the cervical spine. It is characterised by degeneration of the intervertebral discs and osteophyte formation. Such 'wear and tear' is extremely common and radiological changes are frequently found in asymptomatic individuals over the age of 50. Spondylosis may be associated with neurological dysfunction. In order of frequency, the C5/6, C6/7 and C4/5 vertebral levels affect C6, C7 and C5 roots, respectively (Fig. 25.46).

Cervical radiculopathy

Acute onset of compression of a nerve root occurs when a disc prolapses laterally. More gradual onset may be due to osteophytic encroachment of the intervertebral foramina.

Clinical features

The patient complains of pain in the neck that may radiate in the distribution of the affected nerve root. The neck is held rigidly and neck movements may exacerbate pain. Paraesthesia and sensory loss may be found in the affected segment and there may be lower motor neuron signs, including weakness, wasting and reflex impairment (Fig. 25.47).

Investigations

Where there is no trauma, imaging should not be carried out for isolated cervical pain. MRI is the investigation of choice in those with radicular symptoms. X-rays offer limited benefit, except in excluding destructive lesions, and electrophysiological studies rarely add to clinical examination with MRI.

Management

Conservative treatment with analgesics and physiotherapy results in resolution of symptoms in the great majority of patients, but a few require surgery in the form of discectomy or radicular decompression.

Cervical myelopathy

Dorsomedial herniation of a disc and the development of transverse bony bars or posterior osteophytes may result in pressure on the spinal cord or the anterior spinal artery, which supplies the anterior two-thirds of the cord (see Fig. 25.46).

Fig. 25.46 Magnetic resonance image showing cervical cord compression (arrow) in cervical spondylosis.

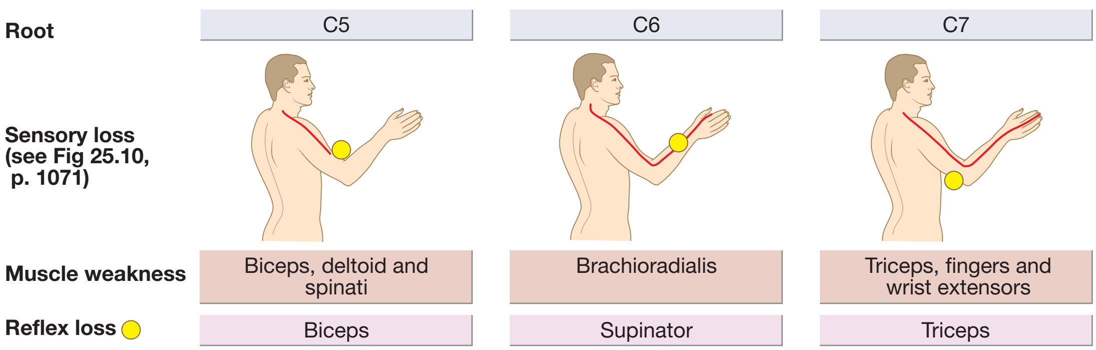

Fig. 25.47 Findings in cervical nerve root compression.

Clinical features

The onset is usually insidious and painless but acute deterioration may occur after trauma, especially hyperextension injury. Upper motor neuron signs develop in the limbs, with spasticity of the legs usually appearing before the arms are involved. Sensory loss in the upper limbs is common, producing tingling, numbness and proprioception loss in the hands, with progressive clumsiness. Sensory manifestations in the legs are much less common. Neurological deficit usually progresses gradually and disturbance of micturition is a very late feature.

Investigations

MRI (see Fig. 25.46) (or rarely myelography) will direct surgical intervention. The former provides information on the state of the spinal cord at the level of compression.

Management

Surgical procedures, including laminectomy and anterior discectomy, may arrest progression of disability but neurological improvement is not the rule. The decision as to whether surgery should be undertaken may be difficult. Manual manipulation of the cervical spine is of no proven benefit and may precipitate acute neurological deterioration.

Prognosis

The prognosis of cervical myelopathy is variable. In many patients, the condition stabilises or even improves without intervention. If progression results in sphincter dysfunction or pyramidal signs, surgical decompression should be considered.

Lumbar spondylosis

This term covers degenerative disc disease and osteoarthritic change in the lumbar spine. Pain in the distribution of the lumbar or sacral roots ('sciatica') is almost always due to disc protrusion but can be a feature of other rare but important disorders, including spinal tumour, malignant disease in the pelvis and tuberculosis of the vertebral bodies.

Lumbar disc herniation

While acute lumbar disc herniation is often precipitated by trauma (usually lifting heavy weights while the spine is flexed), genetic factors may also be important. The nucleus pulposus may bulge or rupture through the annulus fibrosus, giving rise to pressure on nerve endings in the spinal ligaments, changes in the vertebral joints or pressure on nerve roots.

Pathophysiology

The altered mechanics of the lumbar spine result in loss of lumbar lordosis and there may be spasm of the paraspinal musculature. Root pressure is suggested by limitation of flexion of the hip on the affected side if the straight leg is raised (Lasègue's sign). If the third or fourth lumbar root is involved, Lasègue's sign may be negative, but pain in the back may be induced by hyperextension of the hip (femoral nerve stretch test). The roots most frequently affected are S1, L5 and L4; the signs of root pressure at these levels are summarised in Figure 25.48.

Clinical features

The onset may be sudden or gradual. Alternatively, repeated episodes of low back pain may precede sciatica by months or years. Constant aching pain is felt in the lumbar region and may radiate to the buttock, thigh, calf and foot. Pain is exacerbated by coughing or straining but may be relieved by lying flat.

Investigations

MRI is the investigation of choice if available, since soft tissues are well imaged. Plain X-rays of the lumbar spine are of little value in the diagnosis of disc disease, although they may demonstrate conditions affecting the vertebral body. CT can provide helpful images of the disc protrusion and/or narrowing of exit foramina.

Management

Some 90% of patients with sciatica recover following conservative treatment with analgesia and early mobilisation; bed rest does not help recovery. The patient should be instructed in back-strengthening exercises and advised to avoid physical manœuvres likely to strain the lumbar spine. Injections of local anaesthetic or glucocorticoids may be useful adjunctive treatment if symptoms are due to ligamentous injury or joint dysfunction. Surgery may have to be considered if there is no response to conservative treatment or if progressive neurological deficits develop. Central disc prolapse with bilateral symptoms and signs and disturbance of sphincter function requires urgent surgical decompression.

Lumbar canal stenosis

This occurs with a congenitally narrowed lumbar spinal canal, exacerbated by the degenerative changes that commonly occur with age.

Pathophysiology

The symptoms of spinal stenosis are thought to be due to local vascular compromise secondary to the canal stenosis, rendering

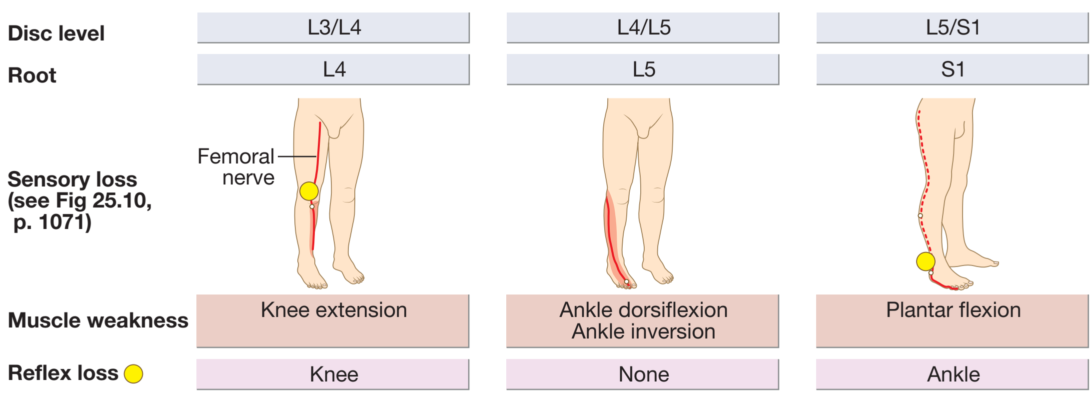

Fig. 25.48 Findings in lumbar nerve root compression.

the nerve roots ischaemic and intolerant of the increased demand that occurs on exercise.

Clinical features

Patients, who are usually elderly, develop exercise-induced weakness and paraesthesia in the legs ('spinal claudication'). These symptoms progress with continued exertion, often to the point that the patient can no longer walk, but are quickly relieved by a short period of rest. Physical examination at rest shows preservation of peripheral pulses with absent ankle reflexes. Weakness or sensory loss may only be apparent if the patient is examined immediately after exercise.

Investigations

The investigation of first choice is MRI, but contraindications (body habitus, metallic implants) may make CT or myelography necessary.

Management

Lumbar laminectomy may provide relief of symptoms and recovery of normal exercise tolerance.

Spinal cord compression

Spinal cord compression is one of the more common neurological emergencies encountered in clinical practice and the usual causes are listed in Box 25.79. A space-occupying lesion within the spinal canal may damage nerve tissue either directly by pressure or indirectly by interference with blood supply. Oedema from venous obstruction impairs neuronal function, and ischaemia from arterial obstruction may lead to necrosis of the spinal cord. The early stages of damage are reversible but severely damaged neurons do not recover; hence the importance of early diagnosis and treatment.

Clinical features

The onset of symptoms of spinal cord compression is usually slow (over weeks) but can be acute as a result of trauma or metastases (see Figs 25.46, 25.49 and 25.50), especially if there is associated arterial occlusion. The symptoms are shown in Box 25.80.

Pain and sensory symptoms occur early, while weakness and sphincter dysfunction are usually late manifestations. The signs vary according to the level of the cord compression and the structures involved. There may be tenderness to percussion over the spine if there is vertebral disease and this may be associated with a local kyphosis. Involvement of the roots at the level of the compression may cause dermatomal sensory impairment and corresponding lower motor signs. Interruption of fibres in the spinal cord causes sensory loss (p. 1083) and upper motor neuron signs below the level of the lesion, and there is often disturbance of sphincter function. The distribution of these signs varies with the level of the lesion (Box 25.81).

The Brown–Séquard syndrome (see Fig. 25.18E, p. 1084) results if damage is confined to one side of the cord; the findings are explained by the anatomy of the sensory tracts (see Fig. 25.11, p. 1072). With compressive lesions, there is usually a band of pain at the level of the lesion in the distribution of the nerve roots subject to compression.

Investigations

Patients with a history of acute or subacute spinal cord syndrome should be investigated urgently, as listed in Box 25.82. The

25.79 Causes of spinal cord compression

Site	Frequency	Causes
Vertebral	80%	Trauma (extradural) Intervertebral disc prolapse Metastatic carcinoma (e.g. breast, prostate, bronchus) Myeloma Tuberculosis
Meninges (intradural, extramedullary)	15%	Tumours (e.g. meningioma, neurofibroma, ependymoma, metastasis, lymphoma, leukaemia) Epidural abscess
Spinal cord (intradural, intramedullary)	5%	Tumours (e.g. glioma, ependymoma, metastasis)

25.80 Symptoms of spinal cord compression

Pain
- Localised over the spine or in a root distribution, which may be aggravated by coughing, sneezing or straining

Sensory
- Paraesthesia, numbness or cold sensations, especially in the lower limbs, which spread proximally, often to a level on the trunk

Motor
- Weakness, heaviness or stiffness of the limbs, most commonly the legs

Sphincters
- Urgency or hesitancy of micturition, leading eventually to urinary retention

25.81 Signs of spinal cord compression

Cervical, above C5
- Upper motor neuron signs and sensory loss in all four limbs
- Diaphragm weakness (phrenic nerve)

Cervical, C5–T1
- Lower motor neuron signs and segmental sensory loss in the arms; upper motor neuron signs in the legs
- Respiratory (intercostal) muscle weakness

Thoracic cord
- Spastic paraplegia with a sensory level on the trunk
- Weakness of legs, sacral loss of sensation and extensor plantar responses

Cauda equina
- Spinal cord ends approximately at the T12/L1 spinal level and spinal lesions below this level can cause lower motor neuron signs only by affecting the cauda equina

25.82 Investigation of acute spinal cord syndrome

- Magnetic resonance imaging of spine or myelography
- Plain X-rays of spine
- Chest X-ray
- Cerebrospinal fluid
- Serum vitamin B_{12}

Fig. 25.49 Axial magnetic resonance image of thoracic spine. A neurofibroma (N) is compressing the spinal cord (SC) and emerging in a 'dumbbell' fashion through the vertebral foramen into the paraspinal space.

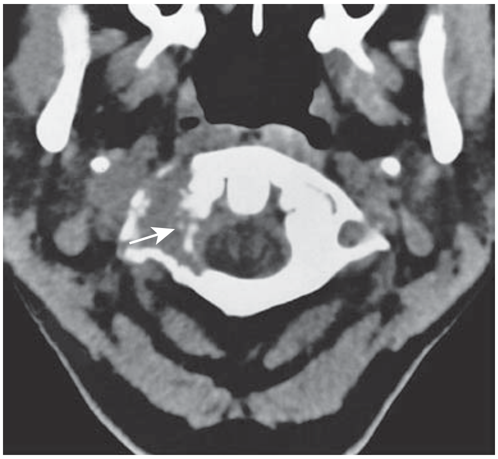

Fig. 25.50 Computed tomographic myelogram of cervical spine at the level of C2 showing bony erosion of vertebra by a metastasis (arrow).

investigation of choice is MRI (Fig. 25.49), as it can define the extent of compression and associated soft-tissue abnormality (Fig. 25.50). Plain X-rays may show bony destruction and soft-tissue abnormalities. Routine investigations, including chest X-ray, may provide evidence of systemic disease. If myelography is performed, CSF should be taken for analysis; in cases of complete spinal block, this shows a normal cell count with a very elevated protein causing yellow discoloration of the fluid (Froin's syndrome). The risk of acute deterioration after myelography in spinal cord compression means that the neurosurgeons should be alerted before it is undertaken. Where a secondary tumour is causing the compression, needle biopsy may be required to establish a tissue diagnosis.

Management

Treatment and prognosis depend on the nature of the underlying lesion. Benign tumours should be surgically excised, and a good functional recovery can be expected unless a marked neurological deficit has developed before diagnosis. Extradural compression due to malignancy is the most common cause of spinal cord compression in developed countries and has a poor prognosis. Useful function can be regained if treatment, such as radiotherapy, is initiated within 24 hours of the onset of severe weakness or sphincter dysfunction; management should involve close cooperation with both oncologists and neurosurgeons.

Spinal cord compression due to tuberculosis is common in some areas of the world and may require surgical treatment. This should be followed by appropriate antituberculous chemotherapy (p. 592) for an extended period. Traumatic lesions of the vertebral column require specialised neurosurgical treatment.

Intrinsic diseases of the spinal cord

There are many disorders that interfere with spinal cord function due to non-compressive involvement of the spinal cord itself. A list of these disorders is given in Box 25.83. The symptoms and signs are generally similar to those that would occur with extrinsic compression (see Boxes 25.80 and 25.81), although a suspended sensory loss (see Fig. 25.18F, p. 1084) can occur only with intrinsic disease such as syringomyelia. Urinary symptoms usually occur earlier in the course of an intrinsic cord disorder than with compressive disorders.

Investigation of intrinsic disease starts with imaging to exclude a compressive lesion. MRI provides most information about structural lesions, such as diastematomyelia, syringomyelia (Fig. 25.51) or intrinsic tumours. Non-specific signal change may be seen in the spinal cord in inflammatory (see Fig. 25.30, p. 1109) or infective conditions and metabolic disorders such as vitamin B_{12} deficiency. Lumbar puncture or blood tests may be required to make a specific diagnosis.

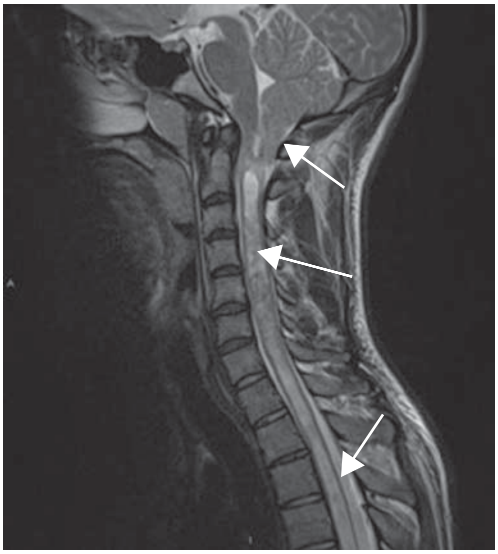

Fig. 25.51 Sagittal magnetic resonance image showing descent of cerebellar tonsils and central syrinx. The MRI shows descent of the cerebellar tonsils (top arrow), with a large central cord syrinx extending down from the cervical cord (middle arrow) to the thoracic cord (bottom arrow).

25.83 Intrinsic diseases of the spinal cord

Type of disorder	Condition	Clinical features
Congenital	Diastematomyelia (spina bifida)	Features variably present at birth and deteriorate thereafter LMN features, deformity and sensory loss of legs Impaired sphincter function Hairy patch or pit over low back Incidence reduced by increased maternal intake of folic acid during pregnancy
	Hereditary spastic paraplegia	Onset usually in adult life Autosomal dominant inheritance usual Slowly progressive UMN features affecting legs > arms Little or no sensory loss
Infective/inflammatory	Transverse myelitis due to viruses (HZV), schistosomiasis, HIV, MS, sarcoidosis	Weakness and sensory loss, often with pain, developing over hours to days UMN features below lesion Impaired sphincter function
	Paraneoplastic	May predate tumour diagnosis
Vascular	Anterior spinal artery infarct due to atherosclerosis, aortic dissection, embolus	Abrupt onset Anterior horn cell loss (LMN) at level of lesion UMN features below it Spinothalamic sensory loss below lesion but dorsal column sensation spared
	Spinal AVM/dural fistula	Onset variable (acute to slowly progressive) Variable LMN, UMN, sensory and sphincter disturbance Symptoms and signs often not well localised to site of AVM
Neoplastic	Glioma, ependymoma	Weakness and sensory loss often with pain, developing over months to years UMN features below lesion in cord; additional LMN features in conus Impaired sphincter function
Metabolic	Vitamin B_{12} deficiency (subacute combined degeneration)	Progressive spastic paraparesis with proprioception loss Absent reflexes due to peripheral neuropathy ± Optic nerve and cerebral involvement (p. 715)
	Copper deficiency	Excess dietary zinc
	Nitrous oxide toxicity	Modifies vitamin B_{12} metabolism
Degenerative	Motor neuron disease	Relentlessly progressive LMN and UMN features, associated bulbar weakness No sensory involvement (p. 1116)
	Syringomyelia	Gradual onset over months or years, pain in cervical segments Anterior horn cell loss (LMN) at level of lesion, UMN features below it Suspended spinothalamic sensory loss at level of lesion, dorsal columns preserved (see Figs 25.18F (p. 1084) and 25.51)

(AVM = arteriovenous malformation; HIV = human immunodeficiency virus; HZV = herpes zoster virus; LMN = lower motor neuron; MS = multiple sclerosis; UMN = upper motor neuron)

Diseases of peripheral nerves

Disorders of the peripheral nervous system are common and may affect the motor, sensory or autonomic components, either in isolation or in combination. The site of pathology may be nerve root (radiculopathy), nerve plexus (plexopathy) or nerve (neuropathy). Neuropathies may present as mononeuropathy (single nerve affected), multiple mononeuropathies ('mononeuritis multiplex') or a symmetrical polyneuropathy (Box 25.84). Cranial nerves 3–12 share the same tissue characteristics as peripheral nerves elsewhere and are subject to the same range of diseases.

Pathophysiology

Damage may occur to the nerve cell body (axon) or the myelin sheath (Schwann cell), leading to axonal or demyelinating neuropathies. The distinction is important, as only demyelinating neuropathies are usually susceptible to treatment. Making the distinction requires neurophysiology (nerve conduction studies and EMG, p. 1076). Neuropathies can occur in association with many systemic diseases, toxins and drugs (Box 25.85).

Clinical features

Motor nerve involvement produces features of a lower motor neuron lesion (p. 1082). Symptoms and signs of sensory nerve involvement depend on the type of sensory nerve involved (p. 1083); small-fibre neuropathies are often painful. Autonomic involvement may cause postural hypotension, disturbance of sweating, cardiac rhythm and gastrointestinal, bladder and sexual functions; isolated autonomic neuropathies are rare and more commonly complicate other neuropathies.

Investigations

The investigations required reflect the wide spectrum of causes (Box 25.86). Neurophysiological tests are key in discriminating between demyelinating and axonal neuropathies, and in identifying entrapment neuropathies. Most neuropathies are of the chronic axonal type.

25.84 Causes of polyneuropathy

Genetic

- Charcot–Marie–Tooth disease (CMT)
- Hereditary neuropathy with liability to pressure palsies (HNPP)
- Hereditary sensory ± autonomic neuropathies (HSN, HSAN)
- Familial amyloid polyneuropathy
- Hereditary neuralgic amyotrophy

Drugs

- Amiodarone
- Antibiotics (dapsone, isoniazid, metronidazole, ethambutol)
- Antiretrovirals
- Chemotherapy (cisplatin, vincristine, thalidomide)
- Phenytoin

Toxins

- Alcohol
- Nitrous oxide (recreational use)
- Rarely: lead, arsenic, mercury, organophosphates, solvents

Vitamin deficiencies

- Thiamin
- Pyridoxine
- Vitamin B_{12}
- Vitamin E

Infections

- HIV
- Leprosy
- Brucellosis

Inflammatory

- Guillain–Barré syndrome
- Chronic inflammatory demyelinating polyradiculoneuropathy
- Vasculitis (polyarteritis nodosa, granulomatosis with polyangiitis (also known as Wegener's granulomatosis), rheumatoid arthritis, systemic lupus erythematosus)
- Paraneoplastic (antibody-mediated)

Systemic medical conditions

- Diabetes
- Renal failure
- Sarcoidosis

Malignant disease

- Infiltration

Others

- Paraproteinaemias
- Amyloidosis
- Critical illness polyneuropathy/myopathy

25.85 Common causes of axonal and demyelinating chronic polyneuropathies

Axonal

- Diabetes mellitus
- Alcohol
- Uraemia
- Cirrhosis
- Amyloid
- Myxoedema
- Acromegaly
- Paraneoplasm
- Drugs and toxins (see Box 25.84)
- Deficiency states (see Box 25.84)
- Hereditary factors
- Infection (see Box 25.84)
- Idiopathic factors

Demyelinating

- Chronic inflammatory demyelinating polyradiculoneuropathy
- Multifocal motor neuropathy
- Paraprotein-associated demyelinating neuropathy
- Charcot–Marie–Tooth disease type I and type X

25.86 Investigation of peripheral neuropathy

Initial tests

- Glucose (fasting)
- Erythrocyte sedimentation rate, C-reactive protein
- Full blood count
- Urea and electrolytes
- Liver function tests
- Serum protein electrophoresis
- Vitamin B_{12}, folate
- ANA, ANCA
- Chest X-ray
- HIV testing

If initial tests are negative

- Nerve conduction studies
- Vitamins E and A
- Genetic testing (see Box 25.84)
- Lyme serology (p. 256)
- Serum angiotensin-converting enzyme
- Serum amyloid

(ANCA = antineutrophil cytoplasmic antibody; ANA = antineutrophil antibody)

Entrapment neuropathy

Focal compression or entrapment is the usual cause of a mononeuropathy. Symptoms and signs of entrapment neuropathy are listed in Box 25.87. Entrapment neuropathies may affect anyone but diabetes, excess alcohol or toxins, or genetic syndromes may be predisposing causes. Unless axonal loss

25.87 Symptoms and signs in common entrapment neuropathies

Nerve	Symptoms	Muscle weakness/ muscle-wasting	Area of sensory loss
Median (at wrist) (carpal tunnel syndrome)	Pain and paraesthesia on palmar aspect of hands and fingers, waking patient from sleep. Pain may extend to arm and shoulder	Abductor pollicis brevis	Lateral palm and thumb, index, middle and lateral half fourth finger
Ulnar (at elbow)	Paraesthesia on medial border of hand, wasting and weakness of hand muscles	All small hand muscles, excluding abductor pollicis brevis	Medial palm and little finger, and medial half fourth finger
Radial	Weakness of extension of wrist and fingers, often precipitated by sleeping in abnormal posture, e.g. arm over back of chair	Wrist and finger extensors, supinator	Dorsum of thumb
Common peroneal	Foot drop, trauma to head of fibula	Dorsiflexion and eversion of foot	Nil or dorsum of foot
Lateral cutaneous nerve of the thigh (meralgia paraesthetica)	Tingling and dysaesthesia on lateral border of thigh	Nil	Lateral border of thigh

25.88 Causes of multifocal mononeuropathy
Axonal (defined on nerve conduction studies)
• Vasculitis (systemic or non-systemic) • Diabetes mellitus • Sarcoidosis • Infection (HIV, hepatitis C, Lyme disease, leprosy, diphtheria)
Focal demyelination with/without conduction block
• Multifocal motor neuropathy • Multiple compression neuropathies (usually in association with underlying disease, such as diabetes or alcoholism) • Multifocal acquired demyelinating sensory and motor neuropathy (MADSAM) • Hereditary neuropathy with a predisposition to pressure palsy (autosomal dominant, peripheral myelin protein 22 gene) • Lymphoma

has occurred, entrapment neuropathies will recover, provided the primary cause is removed, either by avoiding the precipitation of activity or by surgical decompression.

Multifocal neuropathy

Multifocal neuropathy (mononeuritis multiplex) is characterised by lesions of multiple nerve roots, peripheral nerves or cranial nerves (Box 25.88). Vasculitis is a common cause, either as part of a systemic disease or isolated to the nerves, or it may arise on a background of a polyneuropathy (e.g. diabetes). Multifocal motor neuropathy (MMN) with conduction block is a rare pure motor neuropathy, typically affecting the arms; it is associated with anti-GM1 antibodies in about 50% and responds to intravenous immunoglobulin.

Polyneuropathy

A polyneuropathy is typically associated with a 'length-dependent' pattern, occurring in the longest peripheral nerves first and affecting the distal lower limbs before the upper limbs. Sensory symptoms and signs develop in an ascending 'glove and stocking' distribution (p. 1083). In inflammatory demyelinating neuropathies, the pathology may be more patchy, affecting the upper rather than lower limbs.

Guillain–Barré syndrome

Guillain–Barré syndrome (GBS) is a heterogeneous group of immune-mediated conditions with an incidence of 1–2/100 000/year. In Europe and North America, the most common variant is an acute inflammatory demyelinating polyneuropathy (AIDP). Axonal variants, either motor (acute motor axonal neuropathy, AMAN) or sensorimotor (acute motor and sensory axonal neuropathy, AMSAN), are more common in China and Japan, and account for 10% of GBS in Western countries (often associated with *Campylobacter jejuni*). The hallmark is an acute paralysis evolving over days or weeks with loss of tendon reflexes. About two-thirds of those with AIDP have a prior history of infection, and an autoimmune response triggered by the preceding infection causes demyelination. A number of GBS variants have been described, associated with specific anti-ganglioside antibodies; the best recognised is Miller Fisher syndrome, which involves anti-GQ1b antibodies.

Clinical features

Distal paraesthesia and pain precede muscle weakness that ascends rapidly from lower to upper limbs and is more marked proximally than distally. Facial and bulbar weakness commonly develops, and respiratory weakness requiring ventilatory support occurs in 20% of cases. Weakness progresses over a maximum of 4 weeks (usually less). Rapid deterioration to respiratory failure can develop within hours. Examination shows diffuse weakness with loss of reflexes. Miller Fisher syndrome presents with internal and external ophthalmoplegia, ataxia and areflexia.

Investigations

The CSF protein is raised, but may be normal in the first 10 days. There is usually no increase in CSF white cell count ($>10\times10^6$ cells/L suggests an alternative diagnosis). Electrophysiological changes may emerge after a week or so, with conduction block and multifocal motor slowing, sometimes most evident proximally as delayed F waves (p. 1076). Antibodies to the ganglioside GM1 are found in about 25%, usually the motor axonal form. Other causes of an acute neuromuscular paralysis should be excluded (e.g. poliomyelitis, botulism, diphtheria, spinal cord syndromes or myasthenia), via the history and examination rather than investigations.

Management

Active treatment with plasma exchange or intravenous immunoglobulin therapy shortens the duration of ventilation and improves prognosis. In severe GBS, both intravenous immunoglobulin (IVIg) and plasma exchange started within 2 weeks of onset hasten recovery with similar rates of adverse effects but IVIg treatment is significantly more likely to be completed than plasma exchange. Overall, 80% of patients recover completely within 3–6 months, 4% die and the remainder suffer residual neurological disability, which can be severe. Adverse prognostic features include older age, rapid deterioration to ventilation and evidence of axonal loss on EMG. Supportive measures to prevent pressure sores and deep venous thrombosis are essential. Regular monitoring of respiratory function (vital capacity) is needed in the acute phase, as respiratory failure may develop with little warning.

Chronic polyneuropathy

The most common axonal and demyelinating causes of polyneuropathy are shown in Box 25.85. A chronic symmetrical axonal polyneuropathy, evolving over months or years, is the most common form of chronic neuropathy. Diabetes mellitus is the most common cause but in about 25–50% no cause can be found.

Hereditary neuropathy

Charcot–Marie–Tooth disease (CMT) is an umbrella term for the inherited neuropathies. The members of this group of syndromes have different clinical and genetic features. The most common CMT is the autosomal dominantly inherited CMT type 1, usually caused by a mutation in the *PMP-22* gene. Common signs are distal wasting ('inverted champagne bottle' legs), often with pes cavus, and predominantly motor involvement. X-linked and recessively inherited forms of CMT, causing demyelinating or axonal neuropathies, also occur.

Chronic demyelinating polyneuropathy

The acquired chronic demyelinating neuropathies include chronic inflammatory demyelinating peripheral neuropathy (CIDP), multifocal motor neuropathy (see above) and paraprotein-associated demyelinating neuropathy. CIDP typically presents with relapsing or progressive motor and sensory changes, evolving over more than 8 weeks (in distinction to the more acute GBS). It is important to recognise, as it usually responds to glucocorticoids, plasma exchange or intravenous immunoglobulin.

Some 10% of patients with acquired demyelinating polyneuropathy have an abnormal serum paraprotein, sometimes associated with a lymphoproliferative malignancy. They may also demonstrate positive antibodies to myelin-associated glycoprotein (anti-MAG antibodies).

Brachial plexopathy

Trauma usually damages either the upper or the lower parts of the brachial plexus, according to the mechanics of the injury. The clinical features depend on the anatomical site of the damage (Box 25.89). Lower parts of the brachial plexus are vulnerable to infiltration from breast or apical lung tumours (Pancoast tumour, p. 600) or damage by therapeutic irradiation. The lower plexus may also be compressed by a cervical rib or fibrous band between C7 and the first rib at the thoracic outlet.

Neuralgic amyotrophy (also known as brachial neuritis) presents as an acute brachial plexopathy of probable inflammatory origin. Severe shoulder pain precedes the appearance of a patchy upper brachial plexus lesion, with motor and/or sensory involvement. There is no specific treatment and recovery is often incomplete; it may recur in about 25% and there is a rare autosomal dominant hereditary form. The appearance of vesicles should indicate the alternative diagnosis of motor zoster.

25.89 Physical signs in brachial plexus lesions

Site	Affected muscles	Sensory loss
Upper plexus (Erb–Duchenne)	Biceps, deltoid, spinati, rhomboids, brachioradialis (triceps, serratus anterior)	Patch over deltoid
Lower plexus (Déjerine–Klumpke)	All small hand muscles, claw hand (ulnar wrist flexors)	Ulnar border of hand/forearm
Thoracic outlet syndrome	Small hand muscles, ulnar forearm	Ulnar border of hand/forearm/ upper arm

Lumbosacral plexopathy

Lumbosacral plexus lesions may be caused by neoplastic infiltration or compression by retroperitoneal haematomas. A small-vessel vasculopathy can produce a unilateral or bilateral lumbar plexopathy in association with diabetes mellitus ('diabetic amyotrophy') or an idiopathic form in non-diabetic patients. This presents with painful wasting of the quadriceps with weakness of knee extension and an absent knee reflex.

Spinal root lesions

Spinal root lesions (radiculopathy) are described above. Clinical features include muscle weakness and wasting and dermatomal sensory and reflex loss, which reflect the pattern of the roots involved. Pain in the muscles innervated by the affected roots may be prominent.

Diseases of the neuromuscular junction

Myasthenia gravis

This is the most common cause of acutely evolving, fatigable weakness and preferentially affects ocular, facial and bulbar muscles.

Pathophysiology

Myasthenia gravis is an autoimmune disease, most commonly (80% of cases) caused by antibodies to acetylcholine receptors in the post-junctional membrane of the neuromuscular junction. The resultant blockage of neuromuscular transmission and complement-mediated inflammatory response reduces the number of acetylcholine receptors and damages the end plate (Fig. 25.52). Other antibodies can produce a similar clinical picture, most notably autoantibodies to muscle-specific kinase (MuSK), which is involved in the regulation and maintenance of acetylcholine receptors.

About 15% of patients (mainly those with late onset) have a thymoma, most of the remainder displaying thymic follicular hyperplasia. Myasthenic patients are more likely to have associated organ-specific autoimmune diseases. Triggers are not always evident but some drugs (e.g. penicillamine) can precipitate an antibody-mediated myasthenic syndrome that may persist after drug withdrawal. Other drugs, especially aminoglycosides and quinolones, may exacerbate the neuromuscular blockade and should be avoided in patients with myasthenia.

Clinical features

Myasthenia gravis usually presents between the ages of 15 and 50 years and there is a female preponderance in younger patients. In older patients, males are more commonly affected. It tends to run a relapsing and remitting course.

The most evident symptom is fatigable muscle weakness; movement is initially strong but rapidly weakens as muscle use continues. Worsening of symptoms towards the end of the day or following exercise is characteristic. There are no sensory signs or signs of involvement of the CNS, although weakness of the oculomotor muscles may mimic a central eye movement disorder. The first symptoms are usually intermittent ptosis or diplopia but weakness of chewing, swallowing, speaking or limb movement also occurs. Resting of the eyelids (looking downwards) may be followed by increased reflex elevation with up-gaze (so-called Cogan's lid twitch sign). Any limb muscle may be affected, most commonly those of the shoulder girdle; the patient is unable to undertake tasks above shoulder level, such as combing the hair, without frequent rests. Respiratory muscles may be involved and respiratory failure is an avoidable cause of death. Aspiration may occur if the cough is ineffectual. Ventilatory support is required where weakness is severe or of abrupt onset.

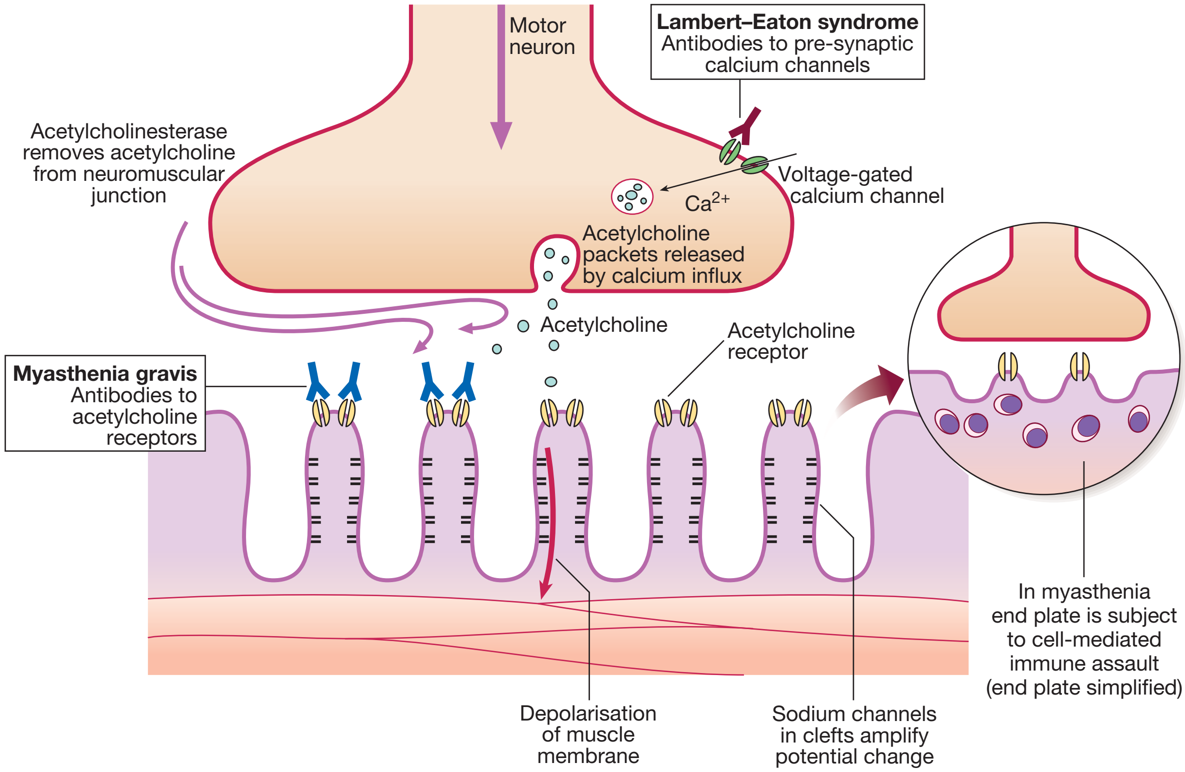

Fig. 25.52 Myasthenia gravis and Lambert–Eaton myasthenic syndrome (LEMS). In myasthenia there are antibodies to the acetylcholine receptors on the post-synaptic membrane, which block conduction across the neuromuscular junction (NMJ). Myasthenic symptoms can be transiently improved by inhibition of acetylcholinesterase (e.g. with Tensilon – edrophonium bromide), which normally removes the acetylcholine. A cell-mediated immune response produces simplification of the post-synaptic membrane, further impairing the 'safety factor' of neuromuscular conduction. In LEMS, antibodies to the pre-synaptic voltage calcium channels impair release of acetylcholine from the motor nerve ending; calcium is required for the acetylcholine-containing vesicle to fuse with the pre-synaptic membrane for release into the NMJ.

Investigations

Intravenous injection of the short-acting anticholinesterase edrophonium bromide (the Tensilon test) is less widely used than before. Improvement in muscle function occurs within 30 seconds and usually persists for 2–3 minutes but the test is not entirely specific or sensitive. Cover with intravenous atropine is necessary to avoid bradycardia. Planning assessment beforehand (e.g. speech or limb movements) allows some objectivity in gauging the effect.

Repetitive stimulation during nerve conduction studies may show a characteristic decremental response (p. 1076) if the muscle has been clinically affected. Anti-MuSK antibodies are more common in acetylcholine receptor antibody-negative patients with prominent bulbar involvement. All patients should have a thoracic CT to exclude thymoma, especially those without anti-acetylcholine receptor antibodies. Screening for associated autoimmune disorders, particularly thyroid disease, is important.

Management

The goals of treatment are to maximise the activity of acetylcholine at remaining receptors in the neuromuscular junctions and to limit or abolish the immunological attack on motor end plates.

The duration of action of acetylcholine is prolonged by inhibiting acetylcholinesterase. The most commonly used anticholinesterase drug is pyridostigmine. Muscarinic side-effects, including diarrhoea and colic, may be controlled by propantheline. Overdosage of anticholinesterase drugs may cause a 'cholinergic crisis' due to depolarisation block of motor end plates, with muscle

i 25.90 Immunological treatment of myasthenia

Acute treatments

Intravenous immunoglobulin
- Lowers production of antibodies and rapidly reduces weakness

Plasma exchange
- Removing antibody from the blood may produce marked improvement; this is usually brief, so is normally reserved for myasthenic crisis or for pre-operative preparation

Long-term treatments

Glucocorticoid treatment
- Improvement is commonly preceded by marked exacerbation of myasthenic symptoms, so treatment should be initiated in hospital
- Usually necessary to continue treatment for months or years, risking adverse effects

Pharmacological immunosuppression treatment
- Azathioprine 2.5 mg/kg daily reduces the necessary dosage of glucocorticoids and may allow their withdrawal. Effect on clinical features may be delayed for months
- Mycophenolate mofetil: less commonly used

Thymectomy
- Should be considered in any antibody-positive patient under 45 years with symptoms not confined to extraocular muscles, unless the disease has been established for more than 7 years
- Likely to be required for thymoma

fasciculation, paralysis, pallor, sweating, excessive salivation and small pupils. This may be distinguished from severe weakness due to exacerbation of myasthenia ('myasthenic crisis') by the clinical features and, if necessary, by the injection of a small dose of edrophonium.

Immunological treatment of myasthenia is outlined in Box 25.90. Thymectomy may improve overall prognosis but awaits clinical trial confirmation. Prognosis is variable and remissions may occur spontaneously. When myasthenia is entirely ocular, prognosis is excellent and disability slight. Young female patients with generalised disease may benefit from thymectomy, while older patients are less likely to have a remission despite treatment. Rapid progression of the disease more than 5 years after onset is uncommon.

Lambert–Eaton myasthenic syndrome

Other rarer conditions can present with muscle weakness due to impaired transmission across the neuromuscular junction. The most common of these is the Lambert–Eaton myasthenic syndrome (LEMS), which can occur as an inflammatory or paraneoplastic phenomenon. Antibodies to pre-synaptic voltage-gated calcium channels (see Fig. 25.52) impair transmitter release. Patients may have autonomic dysfunction (e.g. dry mouth) in addition to muscle weakness but the cardinal clinical sign is absence of tendon reflexes, which return after sustained contraction of the relevant muscle. The condition is associated with underlying malignancy in a high percentage of cases and investigation must be directed towards identifying any neoplasm. Diagnosis is made electrophysiologically on the presence of post-tetanic potentiation of motor response to nerve stimulation at a frequency of 20–50/sec. Treatment is with 3,4-diaminopyridine, or pyridostigmine and immunosuppression.

Diseases of muscle

Muscle disease, either hereditary or acquired, is rare. Most typically, it presents with a proximal symmetrical weakness. Diagnosis is dependent on recognition of clinical clues, such as cardiorespiratory involvement, evolution, family history, exposure to drugs, the presence of contractures, myotonia and other systemic features, and on investigation findings, most importantly EMG and muscle biopsy. Hereditary syndromes include the muscular dystrophies, muscle channelopathies, metabolic myopathies (including mitochondrial diseases) and congenital myopathies.

Muscular dystrophies

These are inherited disorders with progressive muscle destruction and may be associated with cardiac and/or respiratory involvement and sometimes non-myopathic features (Box 25.91). Myotonic dystrophy is the most common, with a prevalence of about 12/100 000.

Clinical features

The pattern of the clinical features is defined by the specific syndromes. Onset is often in childhood, although some patients, especially those with myotonic dystrophy, may present as adults. Wasting and weakness are usually symmetrical, without fasciculation or sensory loss, and tendon reflexes are usually preserved until a late stage. Weakness is usually proximal, except in myotonic dystrophy type 1, when it is distal.

Investigations

The diagnosis can be confirmed by specific molecular genetic testing, supplemented with EMG and muscle biopsy if necessary. Creatine kinase is markedly elevated in the dystrophinopathies

25.91 The muscular dystrophies

Type	Genetics	Age of onset	Muscles affected	Other features
Myotonic dystrophy (DM1)	Autosomal dominant; expanded triplet repeat chromosome 19q	Any	Face (including ptosis), sternomastoids, distal limb, generalised later	Myotonia, cognitive impairment, cardiac conduction abnormalities, lens opacities, frontal balding, hypogonadism
Proximal myotonic myopathy (PROMM; DM2)	Autosomal dominant; quadruplet repeat expansion in *Zn finger protein 9* gene chromosome 3q	8–50 years	Proximal, especially thigh, sometimes muscle hypertrophy	As for DM1 but cognition not affected Muscle pain
Duchenne	X-linked; deletions in *dystrophin* gene Xp21	<5 years	Proximal and limb girdle	Cardiomyopathy and respiratory failure
Becker	X-linked; deletions in *dystrophin* gene Xp21	Childhood/early adulthood	Proximal and limb girdle	Cardiomyopathy common but respiratory failure uncommon
Limb girdle	Many mutations on different chromosomes	Childhood/early adulthood	Limb girdle	Very variable depending on genetic subtype, some involve cardiac and respiratory systems
Facioscapulohumeral (FSH)	Autosomal dominant; tandem repeat deletion chromosome 4q35	7–30 years	Face and upper limb girdle, distal lower limb weakness	Pain in shoulder girdle common, deafness Cardiorespiratory involvement rare
Oculopharyngeal	Autosomal dominant and recessive; triplet repeat expansion in *PABP2* gene chromosome 14q	30–60 years	Ptosis, external ophthalmoplegia, dysphagia, tongue weakness	Mild lower limb weakness
Emery–Dreifuss	X-linked recessive; mutations in *emerin* gene	4–5 years	Humero-peroneal, proximal limb girdle later	Contractures develop early Cardiac involvement leads to sudden death

(Duchenne and Becker) but is normal or moderately elevated in the other dystrophies. Screening for an associated cardiac abnormality (cardiomyopathy or dysrhythmia) is important.

Management

There is no specific therapy for most of these conditions but physiotherapy and occupational therapy help patients cope with their disability. Glucocorticoids can be used in Duchenne muscular dystrophy but side-effects should be anticipated and avoided by dose modification. Ataluren is a compound given by infusion to affected individuals that may 'override' the stop sign in Duchenne, theoretically leading to normalisation of muscle proteins and potentially reducing or arresting functional deteriorations. Treatment of associated cardiac failure or arrhythmia (with pacemaker insertion if necessary) may be required; similarly, management of respiratory complications (including nocturnal hypoventilation) can improve quality of life. Improvements in non-invasive ventilation have led to significant improvements in survival for patients with Duchenne muscular dystrophy. Genetic counselling is important.

Inherited metabolic myopathies

There are a large number of rare inherited disorders that interfere with the biochemical pathways that maintain the energy supply (adenosine triphosphate, ATP) to muscles. These are mostly recessively inherited deficiencies in the enzymes necessary for glycogen or fatty acid (β-oxidation) metabolism (Box 25.92). They typically present with muscle weakness and pain.

Mitochondrial disorders

Mitochondrial diseases are discussed on page 49. Mitochondria are present in all tissues and dysfunction causes widespread effects on vision (optic atrophy, retinitis pigmentosa, cataracts), hearing (sensorineural deafness) and the endocrine, cardiovascular, gastrointestinal and renal systems. Any combination of these should raise the suspicion of a mitochondrial disorder, especially if there is evidence of maternal transmission.

25.92 Inherited disorders of muscle metabolism

Disease	Clinical features	Diagnosis
Carbohydrate (glycogen) metabolism		
Myophosphorylase deficiency (McArdle's disease): autosomal recessive	Exercise-induced myalgia, stiffness, weakness (with 'second wind' phenomenon), myoglobinuria	Creatine kinase (CK) elevated Muscle biopsy Enzyme assay
Acid maltase deficiency (Pompe's disease): autosomal recessive	Infantile form: death within 2 years Childhood: death in twenties or thirties Adult: progressive proximal myopathy with respiratory failure	CK elevated Blood lymphocyte analysis for glycogen granules Muscle biopsy Enzyme assay
Lipid metabolism (β-oxidation)		
Carnitine-palmitoyl transferase (CPT) deficiency	Myalgia *after* exercise, myoglobinuria, weakness	CK normal between attacks Urinary organic acids Enzyme assays Muscle biopsy

25.93 Mitochondrial syndromes

Syndrome	Clinical features
Myoclonic epilepsy with ragged red fibres (MERRF)	Myoclonic epilepsy, cerebellar ataxia, dementia, sensorineural deafness ± peripheral neuropathy, optic atrophy and multiple lipomas
Mitochondrial myopathy, encephalopathy, lactic acidosis and stroke-like episodes (MELAS)	Episodic encephalopathy, stroke-like episodes often preceded by migraine-like headache, nausea and vomiting
Chronic progressive external ophthalmoplegia (CPEO)	Progressive ptosis and external oculomotor palsy, proximal myopathy ± deafness, ataxia and cardiac conduction defects
Kearns–Sayre syndrome	Like CPEO but early age of onset (<20 years), heart block, pigmentary retinopathy
Mitochondrial neurogastrointestinal encephalomyopathy (MNGIE)	Progressive ptosis, external oculomotor palsy, gastrointestinal dysmotility (often pseudo-obstruction), diffuse leucoencephalopathy, thin body habitus, peripheral neuropathy and myopathy
Neuropathy, ataxia and retinitis pigmentosa (NARP)	Weakness, ataxia and progressive loss of vision, along with dementia, seizures and proximal weakness

Mitochondrial dysfunction can be caused by alterations in either mitochondrial DNA or genes encoding for oxidative processes. Genetic abnormalities or mutations in mitochondrial DNA may affect single individuals and single tissues (most commonly muscle). Thus, patients with exercise intolerance, myalgia and sometimes recurrent myoglobinuria may have isolated pathogenic mutations in genes encoding for oxidation pathways.

Inherited disorders of the oxidative pathways of the respiratory chain in mitochondria cause a group of disorders, either restricted to the muscle or associated with non-myopathic features (Box 25.93). Many of these mitochondrial disorders are inherited via the mitochondrial genome, down the maternal line (p. 49). Diagnosis is based on clinical appearances, supported by muscle biopsy appearance (usually with 'ragged red' and/or cytochrome oxidase-negative fibres), and specific mutations either on blood or, more reliably, muscle testing. Mutations may be due either to point mutations or to deletions of mitochondrial DNA.

A disorder called Leber hereditary optic neuropathy (LHON) is characterised by acute or subacute loss of vision, most frequently in males, due to bilateral optic atrophy. Three point mutations account for more than 90% of LHON cases.

Channelopathies

Inherited abnormalities of the sodium, calcium and chloride ion channels in striated muscle produce various syndromes of familial periodic paralysis, myotonia and malignant hyperthermia, which may be recognised by their clinical characteristics and potassium abnormalities (Box 25.94). Genetic testing is available.

Acquired myopathies

These include the inflammatory myopathies, or myopathy associated with a range of metabolic and endocrine disorders or drug and toxin exposure (Fig. 25.53).

25.94 Muscle channelopathies

Channel	Muscle disease	Gene and inheritance	Clinical features
Sodium	Paramyotonia congenita	*SCN4A* (17q35) Autosomal dominant	Cold-evoked myotonia with episodic weakness provoked by exercise and cold
	Potassium-aggravated myotonia	*SCN4A*	Pure myotonia without weakness provoked by potassium
	Hyperkalaemic periodic paralysis	*SCN4A* Autosomal dominant	Brief (mins to hours), frequent episodes of weakness provoked by rest, cold, potassium, fasting, pregnancy, stress Less common than hypokalaemic periodic paralysis
	Hypokalaemic periodic paralysis	*SCN4A* Autosomal dominant (one-third new mutations)	Longer (hours to days) episodic weakness triggered by rest, carbohydrate loading, cold
Chloride	Myotonia congenita:		
	Thomsen's disease	*CLCN1* Autosomal dominant	Myotonia usually mild, little weakness
	Becker's disease	*CLCN1* Autosomal recessive	Myotonia often severe, transient weakness
Calcium	Hypokalaemic periodic paralysis	*CACNA1S* Autosomal dominant	Episodic weakness triggered by carbohydrate meal
	Malignant hyperthermia	*CACNA1S*, *CACNL2A* Autosomal dominant	Hyperpyrexia due to excess muscle activity, precipitated by drugs, usually anaesthetic agents; most common cause of death during general anaesthetic
Potassium	Andersen–Tawil syndrome	*KCNJ2* Autosomal dominant	Similar to hypokalaemic periodic paralysis, associated with cardiac and non-myopathic features (skeletal and facial)
Ryanodine receptor	Malignant hyperthermia	*RYR1* (19q13)	As malignant hyperthermia above
	Central core and multicore disease	*RYR1* Mostly autosomal dominant	Present in infancy with mild progressive weakness

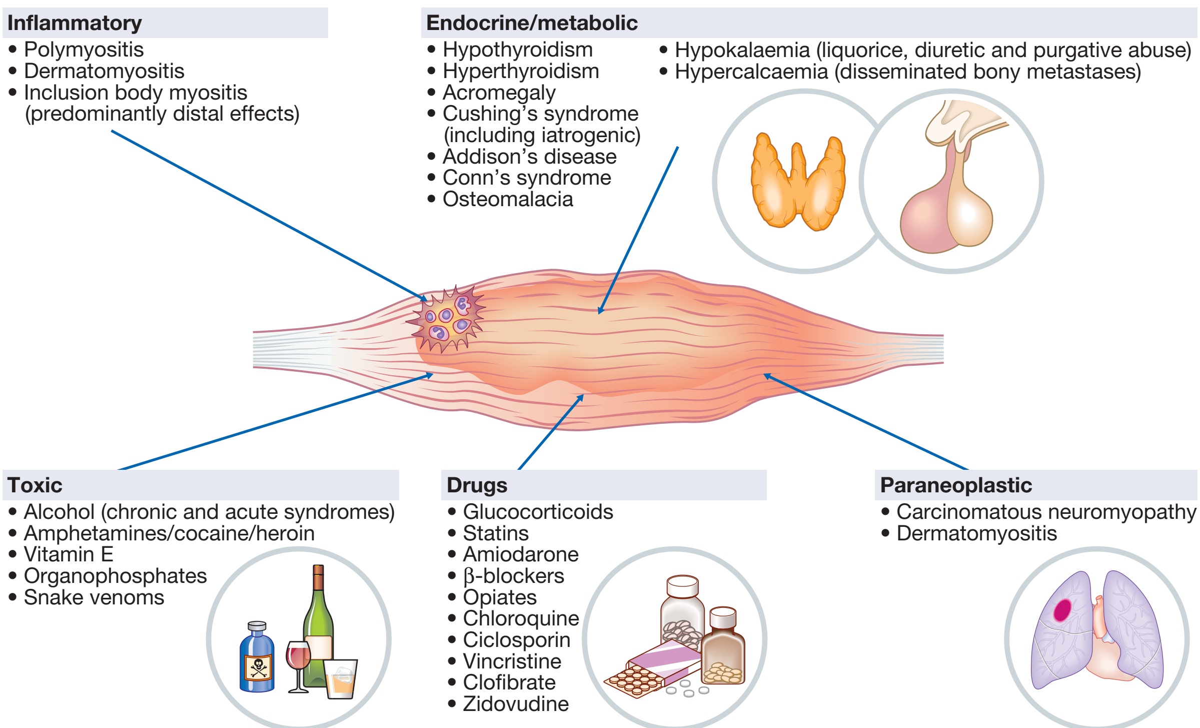

Fig. 25.53 Causes of acquired proximal myopathy.

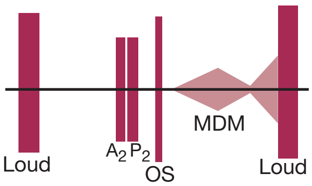
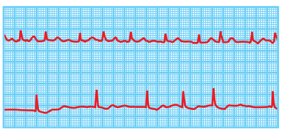
Stroke medicine

Clinical examination in stroke disease



5 Cranial nerve function
Neck stiffness/pain
Visual fields
Nerve palsy, e.g. 3rd, 6th, 7th or 12th

▲ Visual field defect

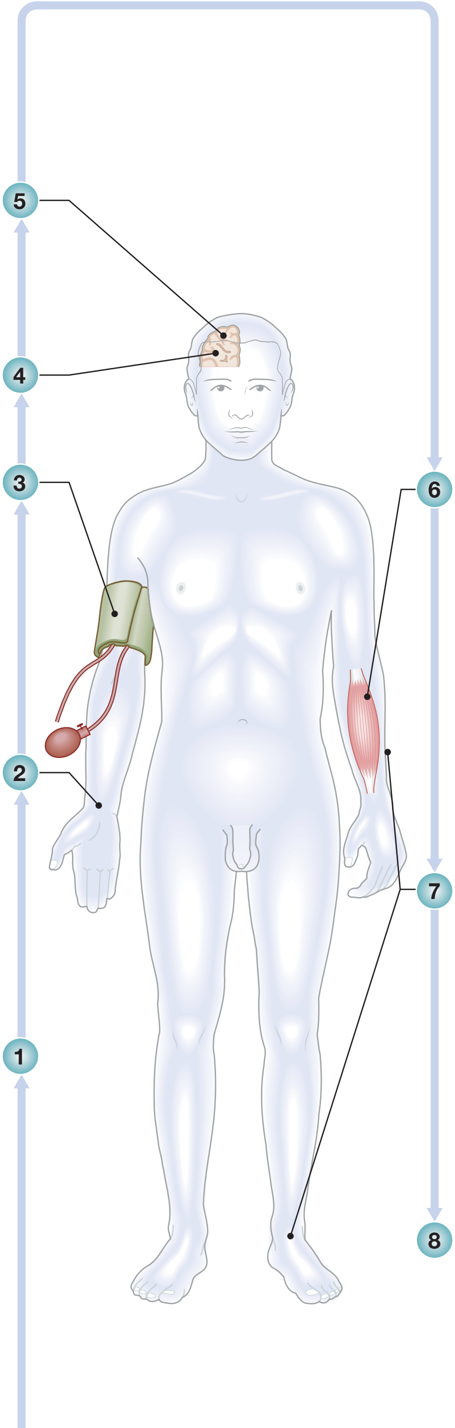


4 Higher cerebral function
Speech and language
Attention and neglect
Abbreviated mental test

3 Blood pressure and cardiac auscultation

▲ Mitral stenosis

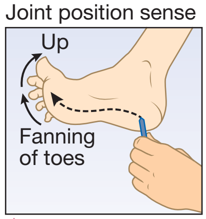
2 Pulse
Rate and rhythm



▲ Atrial fibrillation

1 General appearance
Conscious level
Posture: leaning to one side?
Facial symmetry

▲ Left facial (7th nerve) palsy



6 Motor system
Muscle bulk
Abnormal posture or movements
Tone
Strength, including pronator drift
Co-ordination
Tendon reflexes
Plantar reflexes

▲ Left pronator drift

7 Sensory system
Touch sensation
Cortical sensory function: sensory inattention or neglect
Joint position sense

▲ Extensor plantar reflex

8 Gait
Able to weight-bear?
Ataxic
Hemiparetic gait pattern

▲ Hemiparetic posture

i General examination

Skin
- Xanthelasma
- Rash (arteritis, splinter haemorrhages)
- Colour change (limb ischaemia, deep vein thrombosis)
- Pressure injury

Eyes
- Arcus senilis
- Diabetic retinopathy
- Hypertensive retinopathy
- Retinal emboli

Cardiovascular system
- Heart rhythm (?atrial fibrillation)
- Blood pressure (high or low)
- Carotid bruit
- Jugular venous pulse (raised in heart failure, low in hypovolaemia)
- Murmurs (source of embolism)
- Peripheral pulses and bruits (?generalised arteriopathy)

Respiratory system
- Signs of pulmonary oedema or infection
- Oxygen saturation

Abdomen
- Palpable bladder (urinary retention)

Locomotor system
- Injuries sustained during collapse
- Comorbidities that influence recovery, e.g. osteoarthritis

i Rapid assessment of suspected stroke

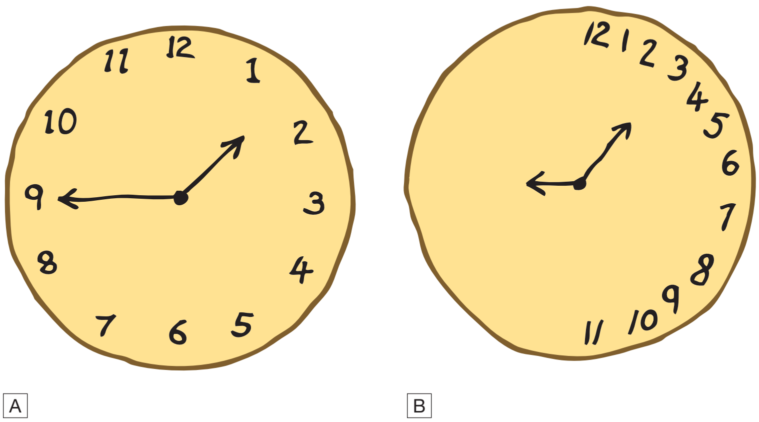
Rosier scale

Can be used by emergency staff to indicate probability of a stroke in acute presentations:

Unilateral facial weakness	+1	Loss of consciousness	–1
Unilateral grip weakness	+1	Seizure	–1
Unilateral arm weakness	+1		
Unilateral leg weakness	+1		
Speech loss	+1		
Visual field defect	+1		

Total (–2 to +6); score of >0 indicates stroke is possible cause

Exclusion of hypoglycaemia
- Bedside blood glucose testing with BMstix



Language deficit
- History and examination may indicate a language deficit
- Check comprehension ('lift your arms, close your eyes') to identify a receptive dysphasia
- Ask patient to name people/objects (e.g. nurse, watch, pen) to identify a nominal dysphasia
- Check articulation (ask patient to repeat phrases after you) for dysarthria

Motor deficit

Subtle pyramidal signs:
- Check for pronator drift: ask patient to hold out arms and maintain their position with eyes closed (see opposite)
- Check for clumsiness of fine finger movements

Sensory and visual inattention
- Establish that sensation/visual field is intact on testing one side at a time
- Retest sensation/visual fields on simultaneous testing of both sides; the affected side will no longer be felt/seen
- Perform clock drawing test (see below)

Truncal ataxia
- Check if patient can sit up or stand without support

Clock drawing test A An image drawn by a doctor. B An image drawn by a patient with left-sided neglect.

26

Cerebrovascular disease is the third most common cause of death in high-income countries after cancers and ischaemic heart disease, and the most common cause of severe physical disability. It includes a range of disorders of the central nervous system (Fig. 26.1). Stroke is the most common clinical manifestation of cerebrovascular disease and results in episodes of brain dysfunction due to focal ischaemia or haemorrhage. Subarachnoid haemorrhage (SAH) and cerebral venous thrombosis (CVT) will be discussed separately, since their pathophysiology, clinical manifestations and management are distinct from those of stroke. Vascular dementia is described on page 1191.

Functional anatomy and physiology

The main arterial supply of the brain comes from the internal carotid arteries, which supply the anterior brain through the anterior and middle cerebral arteries, and the vertebral and basilar arteries (vertebrobasilar system), which provide the posterior circulation to the posterior cerebral arteries. The anterior and middle cerebral arteries supply the frontal and parietal lobes, while the posterior cerebral artery supplies the occipital lobe. The vertebral and basilar arteries perfuse the brainstem, mid-brain and cerebellum (Fig. 26.2). The functions of each of these

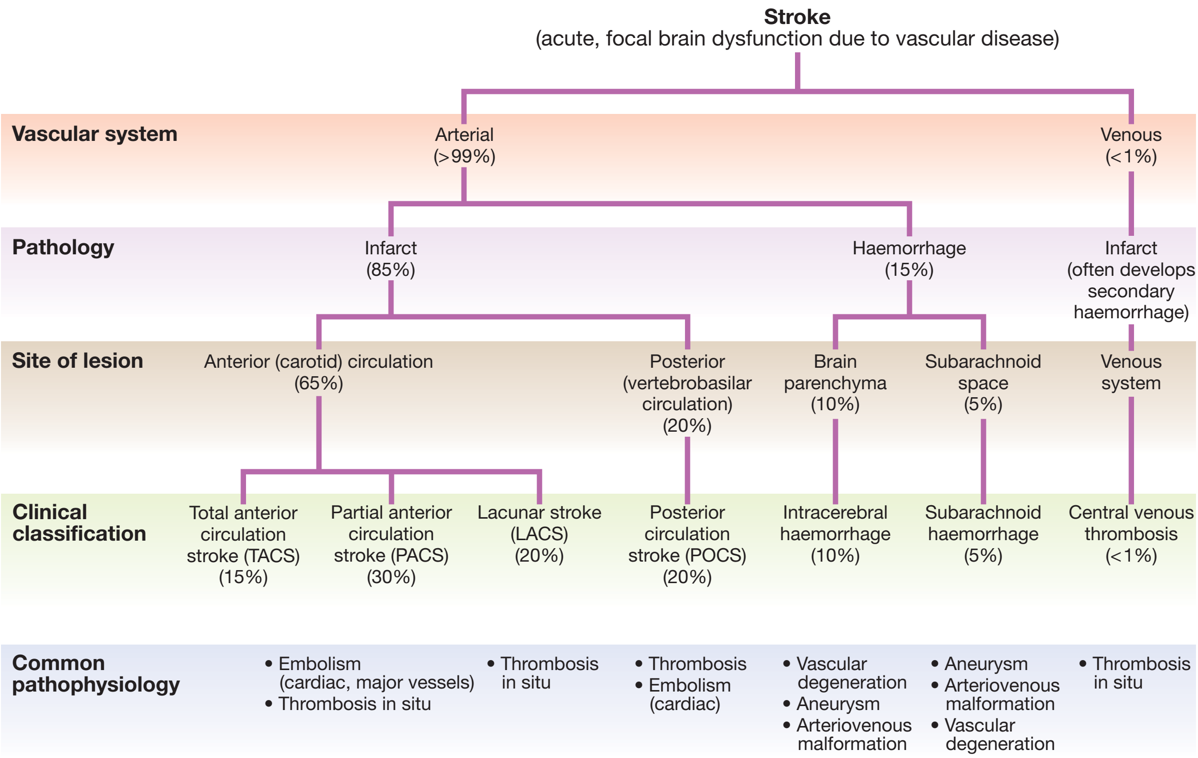


Fig. 26.1 **A classification of stroke disease.**

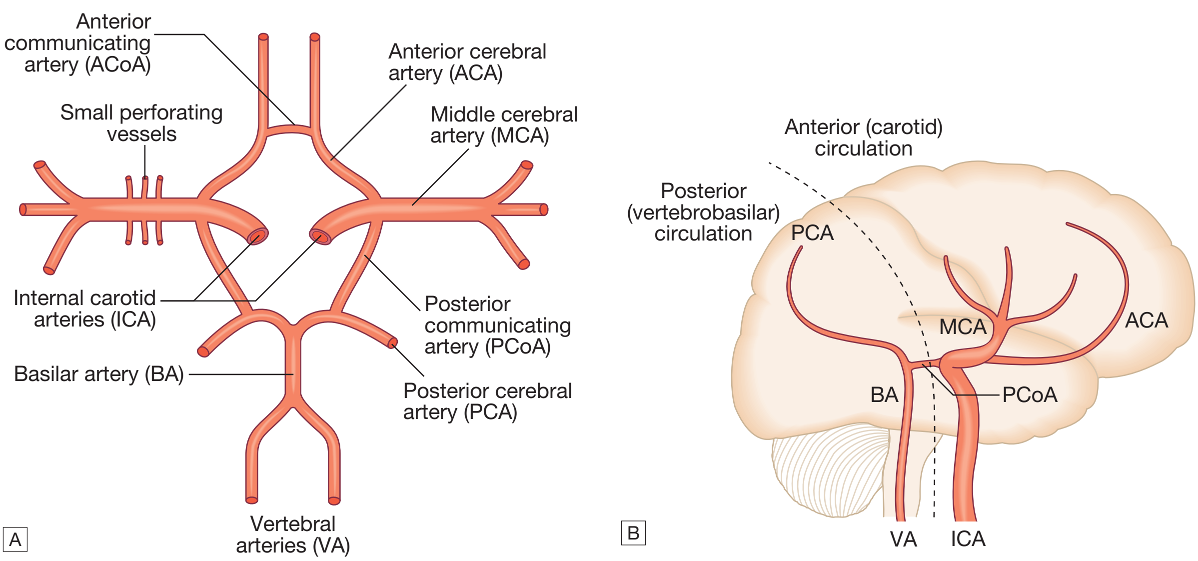

Fig. 26.2 **Arterial circulation of the brain.** A Horizontal view. B Lateral view.

areas of the brain are described on page 1064. Communicating arteries provide connections between the anterior and posterior circulations and between left and right hemispheres, creating protective anastomotic connections that form the circle of Willis. In health, regulatory mechanisms maintain a constant cerebral blood flow across a wide range of arterial blood pressures to meet the high resting metabolic activity of brain tissue; cerebral blood vessels dilate when systemic blood pressure is lowered and constrict when it is raised. This autoregulatory mechanism can be disrupted after stroke. The venous collecting system is formed by a collection of sinuses over the surface of the brain, which drain into the jugular veins (Fig. 26.3).

Investigations

A range of investigations may be required to answer specific questions about brain structure and function and about the function of the vascular system.

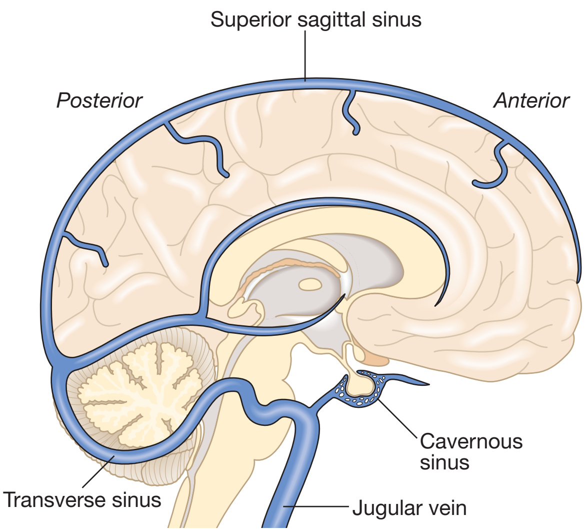

Fig. 26.3 Venous circulation of the brain.

Neuroimaging

Computed tomography (CT) scanning is the mainstay of emergency stroke imaging. It allows the rapid identification of intracerebral bleeding and stroke 'mimics' (i.e. pathologies other than stroke that have similar presentations), such as tumours. Magnetic resonance imaging (MRI) is used when there is diagnostic uncertainty or delayed presentation, and when more information on brain structure and function is required (Fig. 26.4). Contraindications to MRI include cardiac pacemakers and claustrophobia on entering the scanner. CT angiography (CTA) and CT perfusion are now being used to characterise the cerebral circulation and areas of ischaemia better (p. 1072).

Vascular imaging

Various techniques are used to obtain images of extracranial and intracranial blood vessels (Fig. 26.5). The least invasive is ultrasound (Doppler or duplex scanning), which is used to image the carotid and the vertebral arteries in the neck. In skilled hands, reliable information can be provided about the degree of arterial stenosis and the presence of ulcerated plaques. Blood flow in the intracerebral vessels can be examined using transcranial Doppler. While the anatomical resolution is limited, it is improving and many centres no longer require formal angiography before proceeding to carotid endarterectomy (see below). Blood flow can also be detected by specialised sequences in MR angiography (MRA) or CTA but the anatomical resolution is still not as good as that of intra-arterial angiography, which outlines blood vessels by the injection of radio-opaque contrast intravenously or intra-arterially. The X-ray images obtained can be enhanced by the use of computer-assisted digital subtraction or spiral CT. Because of the significant risk of complications, intra-arterial contrast angiography is reserved for use when non-invasive methods have provided a contradictory picture or incomplete information, or when it is necessary to image the intracranial circulation in detail, e.g. to delineate a saccular aneurysm, an arteriovenous malformation or vasculitis.

Blood tests

These identify underlying causes of cerebrovascular disease, e.g. blood glucose (diabetes mellitus), triglycerides and cholesterol (hyperlipidaemia) or full blood count (polycythaemia). Erythrocyte

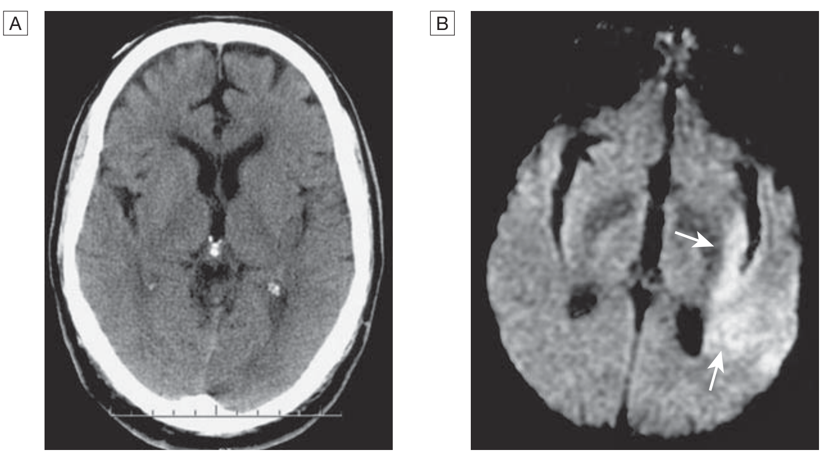

Fig. 26.4 Acute stroke seen on computed tomography (CT) scan with corresponding magnetic resonance imaging (MRI) appearance. A CT may show no evidence of early infarction. D Intra-arterial angiography showing arteriovenous malformation (arrow). *A–D, Courtesy of Dr D. Collie.*

sedimentation rate (ESR) and immunological tests, such as antineutrophil cytoplasmic antibodies (ANCAs, p. 992), may be required when vasculitis is suspected. Genetic testing for rarer inherited conditions, such as CADASIL (cerebral autosomal dominant arteriopathy with subcortical infarcts and leucoencephalopathy), may be indicated.

Lumbar puncture

Lumbar puncture (p. 1077) is reserved for investigation of SAH.

Cardiovascular investigations

Electrocardiography (ECG; p. 448), including ECG monitoring and echocardiography (p. 451), may reveal abnormalities that may cause cardiac embolism in stroke.

Presenting problems

Most vascular lesions develop suddenly within a matter of minutes or hours, and so should be considered in the differential diagnosis of patients with any acute neurological presentation.

Weakness

Unilateral weakness is the classical presentation of stroke and, much more rarely, of CVT. The weakness is sudden, progresses rapidly and follows a hemiplegic pattern (see Fig. 25.17, p. 1082). There is rarely any associated abnormal movement. Reflexes are initially reduced but then become increased with a spastic pattern of increased tone (see Box 25.14, p. 1082). Upper motor neuron weakness of the face (7th cranial nerve) is often present.

Speech disturbance

Dysphasia and dysarthria are the most common presentations of disturbed speech in stroke (p. 1087). Dysphasia indicates damage to the dominant frontal or parietal lobe (see Box 25.2, p. 1066), while dysarthria is a non-localising feature that reflects weakness or incoordination of the face, pharynx, lips, tongue or palate.

Visual deficit

Visual loss can be due to unilateral optic ischaemia (called amaurosis fugax if transient), caused by disturbance of blood flow in the internal carotid artery and ophthalmic artery, leading to monocular blindness. Ischaemia of the occipital cortex or post-chiasmic nerve tracts results in a contralateral hemianopia (p. 1088).

Visuo-spatial dysfunction

Damage to the non-dominant cortex often results in contralateral visuo-spatial dysfunction, e.g. sensory or visual neglect and apraxia (inability to perform complex tasks despite normal motor, sensory and cerebellar function; p. 1086), sometimes misdiagnosed as delirium.

Ataxia

Stroke causing damage to the cerebellum and its connections can present as an acute ataxia (p. 1086) and there may be associated brainstem features such as diplopia (p. 1088) and vertigo (p. 1086). The differential diagnosis includes vestibular disorders (p. 1104).

Headache

Sudden severe headache is the cardinal symptom of SAH but also occurs in intracerebral haemorrhage. Although headache is common in acute ischaemic stroke, it is rarely a dominant feature (p. 1080). Headache also occurs in cerebral venous disease.

Seizure

Seizure is unusual in acute stroke but may be generalised or focal (especially in cerebral venous disease).

Coma

Coma is uncommon, though it may occur with a brainstem event. If present in the first 24 hours, it usually indicates a subarachnoid or intracerebral haemorrhage (see Box 10.26, p. 194).

Stroke

Stroke is a common medical emergency. The incidence rises steeply with age, and in many lower- and middle-income countries it is rising in association with less healthy lifestyles. About 20% of stroke patients die within a month of the event and at least half of those who survive are left with physical disability.

Pathophysiology

Of the 180–300 patients per 100 000 population presenting annually with a stroke, 85% sustain a cerebral infarction due to inadequate blood flow to part of the brain, and most of the remainder have an intracerebral haemorrhage (see Fig. 26.1).

Cerebral infarction

Cerebral infarction is mostly caused by thromboembolic disease secondary to atherosclerosis in the major extracranial arteries (carotid artery and aortic arch). About 20% of infarctions are due to embolism from the heart, and a further 20% are due to thrombosis in situ caused by intrinsic disease of small perforating vessels (lenticulostriate arteries), producing so-called lacunar infarctions. The risk factors for ischaemic stroke reflect the risk factors for the underlying vascular disease (Box 26.1). About 5% are due to rare causes, including vasculitis (p. 1040), endocarditis (p. 527) and cerebral venous disease (see below). Cerebral infarction takes some hours to complete, even though the patient's deficit may be maximal shortly after the vascular occlusion. After the occlusion of a cerebral artery, infarction may be forestalled by the opening of anastomotic channels from other arterial territories that restore perfusion to its territory. Similarly, reduction in perfusion pressure leads to compensatory homeostatic changes to maintain tissue oxygenation (Fig. 26.6). These compensatory changes can sometimes prevent occlusion of even a carotid artery from having any clinically apparent effect.

i 26.1 Risk factors for stroke

Fixed risk factors

- Age
- Gender (male > female except at extremes of age)
- Race (Afro-Caribbean > Asian > European)
- Previous vascular event:
  - Myocardial infarction
  - Stroke
  - Peripheral vascular disease
- Heredity
- Sickle cell disease
- High fibrinogen

Modifiable risk factors

- Blood pressure
- Cigarette smoking
- Hyperlipidaemia
- Diabetes mellitus
- Heart disease:
  - Atrial fibrillation
  - Congestive cardiac failure
  - Infective endocarditis
- Excessive alcohol intake
- Oestrogen-containing drugs:
  - Oral contraceptive pill
  - Hormone replacement therapy
- Polycythaemia

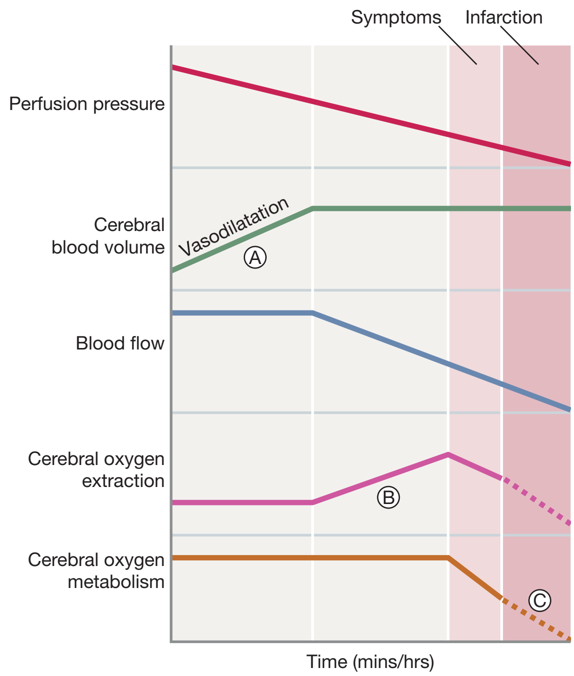

Fig. 26.6 Homeostatic responses to falling perfusion pressure in the brain following arterial occlusion. Vasodilatation initially maintains cerebral blood flow (A), but after maximal vasodilatation further falls in perfusion pressure lead to a decline in blood flow. An increase in tissue oxygen extraction, however, maintains the cerebral metabolic rate for oxygen (B). Still further falls in perfusion, and therefore blood flow, cannot be compensated; cerebral oxygen availability falls and symptoms appear, then infarction (C).

However, if and when these homeostatic mechanisms fail, the process of ischaemia starts, and ultimately leads to infarction unless the vascular supply is restored. As the cerebral blood flow declines, different neuronal functions fail at various thresholds (Fig. 26.7). Once blood flow falls below the threshold for the maintenance of electrical activity, neurological deficit develops. At this level of blood flow, neurons are still viable; if blood flow increases again, function returns and the patient will have had a

transient ischaemic attack (TIA). However, if blood flow falls further, a level is reached at which irreversible cell death starts. Hypoxia leads to an inadequate supply of adenosine triphosphate (ATP), which leads to failure of membrane pumps, thereby allowing influx of sodium and water into cells (cytotoxic oedema) and release

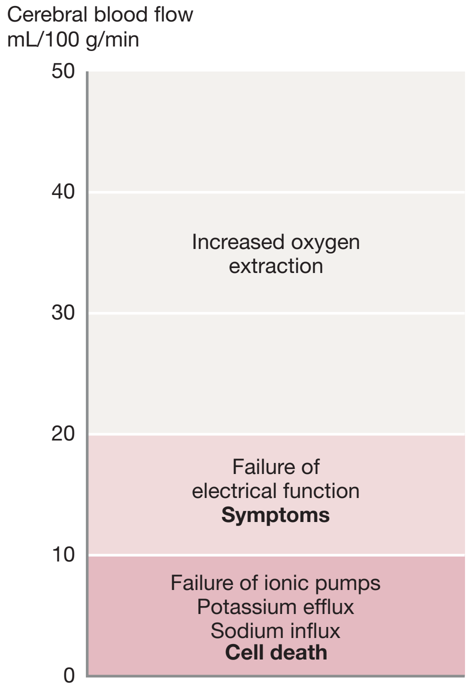

Fig. 26.7 Thresholds of cerebral ischaemia. Symptoms of cerebral ischaemia appear when the blood flow has fallen to less than half of normal and energy supply is insufficient to sustain neuronal electrical function. Full recovery can occur if this level of flow is returned to normal but not if it is sustained. Further blood flow reduction below the next threshold causes failure of cell ionic pumps and starts the ischaemic cascade, leading to cell death.

of the excitatory neurotransmitter glutamate into the extracellular fluid. Glutamate opens membrane channels, allowing influx of calcium and more sodium into the neurons. Calcium activates intracellular enzymes that complete the destructive process. The release of inflammatory mediators by microglia and astrocytes causes death of all cell types in the area of maximum ischaemia. The infarction process is worsened by anaerobic production of lactic acid (Fig. 26.8) and consequent fall in tissue pH. There have been attempts to develop neuroprotective drugs to slow down the processes leading to irreversible cell death but so far these have proved disappointing.

The final outcome of occlusion of a cerebral blood vessel thus depends on the competence of circulatory homeostatic mechanisms, the metabolic demand, and the severity and duration of the reduction in blood flow. Higher brain temperature, e.g. in fever, and higher blood glucose have both been associated with a greater volume of infarction for a given reduction in cerebral blood flow. Subsequent restoration of blood flow may cause haemorrhage into the infarcted area ('haemorrhagic transformation'). This is particularly likely in patients given antithrombotic or thrombolytic drugs, and in patients with larger infarcts.

Radiologically, a cerebral infarct can be seen as a lesion that comprises a mixture of dead brain tissue that is already undergoing autolysis, and tissue that is ischaemic and swollen but recoverable (the 'ischaemic penumbra'). The infarct swells with time and is at its maximal size a couple of days after stroke onset. At this stage, it may be big enough to exert mass effect both clinically and radiologically; sometimes, decompressive craniectomy is required (see below). After a few weeks, the oedema subsides and the infarcted area is replaced by a sharply defined fluid-filled cavity.

Intracerebral haemorrhage

Intracerebral haemorrhage causes about 10% of acute stroke events but is more common in low-income countries. It usually results from rupture of a blood vessel within the brain parenchyma but may also occur in a patient with SAH (see

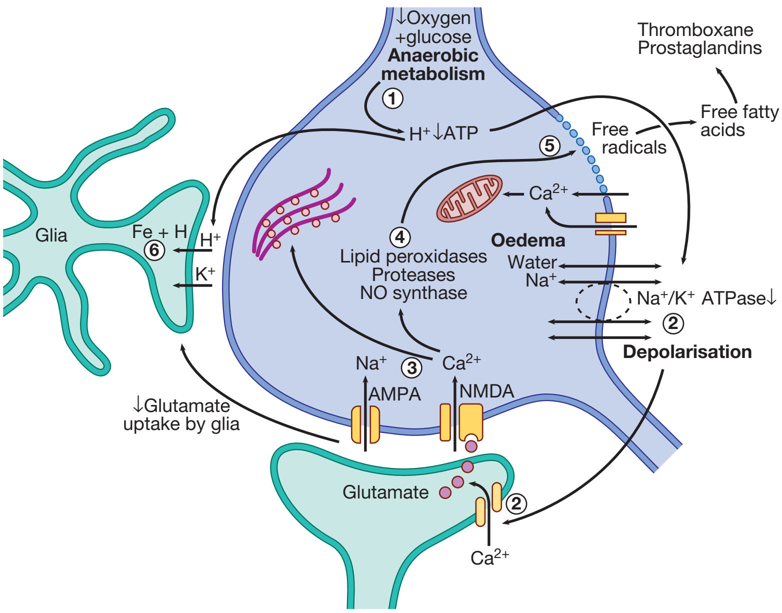

Fig. 26.8 The process of neuronal ischaemia and infarction. (1) Reduction of blood flow reduces supply of oxygen and hence adenosine triphosphate (ATP). H^+ is produced by anaerobic metabolism of available glucose. (2) Energy-dependent membrane ionic pumps fail, leading to cytotoxic oedema and membrane depolarisation, allowing calcium entry and releasing glutamate. (3) Calcium enters cells via glutamate-gated channels and (4) activates destructive intracellular enzymes (5), destroying intracellular organelles and cell membrane, with release of free radicals. Free fatty acid release activates pro-coagulant pathways that exacerbate local ischaemia. (6) Glial cells take up H^+, can no longer take up extracellular glutamate and also suffer cell death, leading to liquefactive necrosis of whole arterial territory. (AMPA = α-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid receptor; NMDA = *N*-methyl-D-aspartate; NO = nitric oxide)

below) if the artery ruptures into the brain substance as well as the subarachnoid space. Haemorrhage frequently occurs into an area of brain infarction and, if the volume of haemorrhage is large, it may be difficult to distinguish from primary intracerebral haemorrhage both clinically and radiologically (Fig. 26.9). The risk factors and underlying causes of intracerebral haemorrhage are listed in Box 26.2. Explosive entry of blood into the brain parenchyma causes immediate cessation of function in that area as neurons are disrupted and white-matter fibre tracts are split apart. The haemorrhage itself may expand over the first minutes or hours, or it may be associated with a rim of cerebral oedema, which, along with the haematoma, acts like a mass lesion to cause progression of the neurological deficit. If big enough, this can cause shift of the intracranial contents, producing transtentorial coning and sometimes rapid death (p. 1127). If the patient survives, the haematoma is gradually absorbed, leaving a haemosiderin-lined slit in the brain parenchyma.

Clinical features

Both acute stroke and transient ischaemic attack (TIA) are characterised by a rapid-onset, focal deficit of brain function and can be considered as a spectrum of symptoms from transient (TIA) to persistent (stroke). The typical presentation occurs over minutes, affects an identifiable area of brain and is 'negative' in character (i.e. abrupt loss of function without positive features such as abnormal movement). Provided there is a clear history of this, the chance of a brain lesion being anything other than vascular is 5% or less (Box 26.3). If symptoms progress over hours or days, other diagnoses must be excluded. Delirium and memory or balance disturbance are more often due to stroke mimics. Transient symptoms, e.g. syncope, amnesia, delirium and dizziness, do not reflect focal cerebral dysfunction but are often mistakenly attributed to TIA (see Fig. 10.3, p. 182, and Box 26.4). Campaigns to raise public awareness of the emergency nature of stroke exploit the fact that weakness of the face or arm, or disturbance of speech is the most common presentation.

The clinical presentation of stroke depends on which arterial territory is involved and the size of the lesion (see Fig. 26.1). These will both have a bearing on management, such as suitability for carotid endarterectomy. The neurological deficit can be identified

26.2 Causes of intracerebral haemorrhage and associated risk factors

Disease	Risk factors
Complex small-vessel disease with disruption of vessel wall	Age Hypertension High cholesterol
Amyloid angiopathy	Familial (rare) Age
Impaired blood clotting	Anticoagulant therapy Blood dyscrasia Thrombolytic therapy
Vascular anomaly	Arteriovenous malformation Cavernous haemangioma
Substance misuse	Alcohol Amphetamines Cocaine

26.3 Differential diagnosis of stroke and transient ischaemic attack

'Structural' stroke mimics

- Primary cerebral tumours
- Metastatic cerebral tumours
- Extradural or subdural haematoma
- Demyelination
- Peripheral nerve lesions (vascular or compressive)
- Cerebral abscess

'Functional' stroke mimics

- Todd's paresis (after epileptic seizure)
- Hypoglycaemia
- Migrainous aura (with or without headache)
- Focal seizures
- Ménière's disease or other vestibular disorder
- Conversion disorder (p. 1202)
- Encephalitis

26.4 Characteristic features of stroke and non-stroke syndromes ('stroke mimics')

Feature	Stroke	Stroke mimics
Symptom onset	Sudden (minutes)	Often slower onset
Symptom progression	Rapidly reaches maximum severity	Often gradual onset
Severity of deficit	Unequivocal	May be variable/uncertain
Pattern of deficit	Hemispheric pattern	May be non-specific with delirium, memory loss, balance disturbance
Loss of consciousness	Uncommon	More common

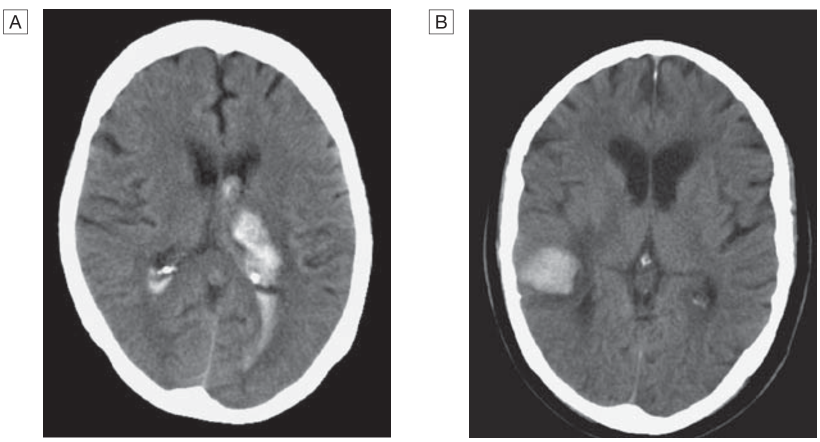

Fig. 26.9 CT scans showing intracerebral haemorrhage. A Basal ganglia haemorrhage with intraventricular extension. B Small cortical haemorrhage. *A and B, Courtesy of Dr A. Farrell and Prof. J. Wardlaw.*

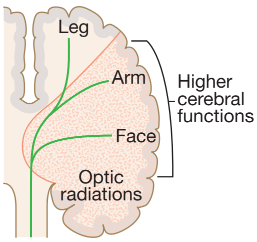
from the patient's history and (if it is persistent) the neurological examination. The presence of a unilateral motor deficit, a higher cerebral function deficit such as aphasia or neglect, or a visual field defect usually places the lesion in the cerebral hemisphere. Ataxia, diplopia, vertigo and/or bilateral weakness usually indicate a lesion in the brainstem or cerebellum. Different combinations of these deficits define several stroke syndromes (Fig. 26.10), which reflect the site and size of the lesion and may provide clues to the underlying pathology.

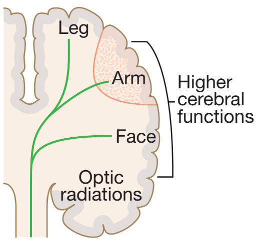
Reduced conscious level usually indicates a large-volume lesion in the cerebral hemisphere but may result from a lesion in the brainstem or complications such as obstructive hydrocephalus, hypoxia or severe systemic infection. The combination of severe headache and vomiting at the onset of the focal deficit is suggestive of intracerebral haemorrhage.

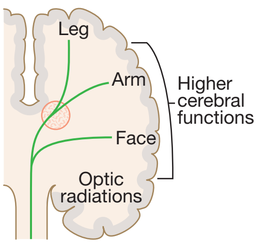
General examination may provide clues to the cause and identify important comorbidities and complications.

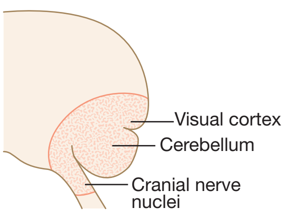
Several terms have been used to classify strokes, often based on the duration and evolution of symptoms:

- *Transient ischaemic attack (TIA)* describes a stroke in which symptoms resolve within 24 hours – an arbitrary cut-off that has little value in practice, apart from perhaps indicating that underlying cerebral haemorrhage or extensive cerebral infarction is extremely unlikely. The term









Clinical syndrome	Common symptoms	Common cause	CT scan features
Total anterior circulation syndrome (TACS) 	Combination of: Hemiparesis Higher cerebral dysfunction (e.g. aphasia) Hemisensory loss Homonymous hemianopia (damage to optic radiations)	Middle cerebral artery occlusion (Embolism from heart or major vessels)	
Partial anterior circulation syndrome (PACS) 	Isolated motor loss (e.g. leg only, arm only, face) Isolated higher cerebral dysfunction (e.g. aphasia, neglect) Mixture of higher cerebral dysfunction and motor loss (e.g. aphasia with right hemiparesis)	Occlusion of a branch of the middle cerebral artery or anterior cerebral artery (Embolism from heart or major vessels)	
Lacunar syndrome (LACS) 	Pure motor stroke – affects two limbs Pure sensory stroke Sensory-motor stroke No higher cerebral dysfunction or hemianopia	Thrombotic occlusion of small perforating arteries (Thrombosis in situ)	
Posterior circulation stroke (POCS) (lateral view) 	Homonymous hemianopia (damage to visual cortex) Cerebellar syndrome Cranial nerve syndromes	Occlusion in vertebral, basilar or posterior cerebral artery territory (Cardiac embolism or thrombosis in situ)	

Fig. 26.10 Clinical and radiological features of the stroke syndromes. The top three diagrams show coronal sections of the brain and the bottom one shows a sagittal section. The anatomical locations of cerebral functions are shown with the nerve tracts in green. A motor (or sensory) deficit (shown by the areas shaded red) can occur with damage to the relevant cortex (PACS), nerve tracts (LACS) or both (TACS). The corresponding CT scans show horizontal slices at the level of the lesion, highlighted by the arrows.

TIA traditionally also includes patients with amaurosis fugax, usually due to a vascular occlusion in the retina.

- *Stroke* describes those events in which symptoms last more than 24 hours. The differential diagnosis of patients with symptoms lasting a few minutes or hours is similar to those with persisting symptoms (see Box 26.3). The term 'minor stroke' is sometimes used to refer to symptoms lasting over 24 hours but not causing significant disability.
- *Progressing stroke (or stroke in evolution)* describes a stroke in which the focal neurological deficit worsens after the patient first presents. Such worsening may be due to increasing volume of infarction, haemorrhagic transformation or increasing cerebral oedema.
- *Completed stroke* describes a stroke in which the focal deficit persists and is not progressing.

When assessing a patient within hours of symptom onset, it is not possible to distinguish stroke from TIA unless symptoms have already resolved. In clinical practice, it is important to distinguish those patients with strokes who have persisting focal neurological symptoms when seen from those whose symptoms have already resolved.

Investigations

Investigation of acute stroke aims to confirm the vascular nature of a lesion, distinguish infarction from haemorrhage and identify the underlying vascular disease and risk factors (Box 26.5).

Risk factor analysis

Initial investigation includes a range of simple blood tests to detect common vascular risk factors and markers of rarer causes, along with an ECG and brain imaging. Where there is uncertainty about the nature of the stroke, further investigations are indicated. This especially applies to younger patients, who are less likely to have atherosclerotic disease (Box 26.6).

26.5 Investigation of a patient with an acute stroke

Diagnostic question	Investigation
Is it a vascular lesion?	CT/MRI
Is it ischaemic or haemorrhagic?	CT/MRI
Is it a subarachnoid haemorrhage?	CT/lumbar puncture
Is there any cardiac source of embolism?	ECG Holter monitoring Echocardiogram
What is the underlying vascular disease?	Duplex ultrasound of carotids MRA CTA Contrast angiography
What are the risk factors?	Full blood count Cholesterol Blood glucose
Is there an unusual cause?	ESR Serum protein electrophoresis Clotting/thrombophilia screen

(CT = computed tomography; CTA = computed tomographic angiography; ECG = electrocardiogram; ESR = erythrocyte sedimentation rate; MRA = magnetic resonance angiography; MRI = magnetic resonance imaging)

Neuroimaging

Brain imaging with either CT or MRI should be performed in all patients with acute stroke. Exceptions are where results would not influence management, such as in the advanced stage of a terminal illness. CT remains the most practical and widely available method of imaging the brain. It will usually exclude non-stroke lesions, including subdural haematomas and brain tumours, and will demonstrate intracerebral haemorrhage within minutes of stroke onset (see Fig. 26.9). However, especially within the first few hours after symptom onset, CT changes in cerebral infarction may be completely absent or only very subtle. Changes often develop over time (see Fig. 26.13) but small cerebral infarcts may never show up on CT scans. For some purposes, a CT scan performed within 24 hours is adequate

26.6 Causes and investigation of acute stroke in young patients

Cause	Investigation
Cerebral infarct	
Cardiac embolism	Echocardiography (including transoesophageal)
Premature atherosclerosis	Serum lipids
Arterial dissection	MRI CTA
Reversible cerebral vasoconstriction syndromes	MRI CTA
Thrombophilia	Protein C, protein S Antithrombin III Factor V Leiden, prothrombin
Homocystinuria (p. 369)	Urinary amino acids Methionine loading test
Antiphospholipid antibody syndrome (p. 977)	Anticardiolipin antibodies/lupus anticoagulant
Systemic lupus erythematosus	ANA
Vasculitis (e.g. primary angiitis of the central nervous system)	ESR CRP ANCA
CADASIL	MRI brain
CARASIL	Genetic analysis Skin biopsy
Mitochondrial cytopathy	Serum lactate White cell mitochondrial DNA Muscle biopsy Mitochondrial molecular genetics
Fabry's disease	Alpha-galactosidase levels
Sickle cell disease	Sickle cell studies
Neurovascular syphilis	Syphilis serology
Primary intracerebral haemorrhage	
AVM	MRI/MRA
Drug misuse	Drug screen (amphetamine, cocaine)
Coagulopathy	PT and APTT Platelet count
Subarachnoid haemorrhage	
Saccular ('berry') aneurysm	MRI/MRA
AVM	MRI/MRA
Vertebral dissection	MRI/MRA

(ANA = antinuclear antibody; ANCA = antineutrophil cytoplasmic antibody; APTT = activated partial thromboplastin time; AVM = arteriovenous malformation; CADASIL/CARASIL = cerebral autosomal dominant/recessive arteriopathy with subcortical infarcts and leucoencephalopathy; CRP = C-reactive protein; CTA = computed tomographic angiography; ESR = erythrocyte sedimentation rate; MRA = magnetic resonance angiography; MRI = magnetic resonance imaging; PT = prothrombin time)

26.7 Indications for immediate CT/MRI in acute stroke

- Patient on anticoagulants or with abnormal coagulation
- Consideration for reperfusion (thrombolysis) or immediate anticoagulation
- Deteriorating conscious level or rapidly progressing deficits
- Suspected cerebellar haematoma, to exclude hydrocephalus

but there are certain circumstances in which an immediate CT scan is essential (Box 26.7). Even in the absence of changes suggesting infarction, abnormal perfusion of brain tissue can be imaged with CT after injection of contrast media (i.e. CT perfusion scanning). This can be useful in guiding immediate treatment of ischaemic stroke.

MRI is not as widely available as CT and scanning times are longer. However, MRI diffusion weighted imaging (DWI) can detect ischaemia earlier than CT, and other MRI sequences can also be used to demonstrate abnormal perfusion (see Fig. 26.4). MRI is more sensitive than CT in detecting strokes affecting the brainstem and cerebellum, and, unlike CT, can reliably distinguish haemorrhagic from ischaemic stroke even several weeks after the onset. CT and MRI may reveal clues as to the nature of the arterial lesion. For example, there may be a small, deep lacunar infarct indicating small-vessel disease, or a more peripheral infarct suggesting an extracranial source of embolism (see Fig. 26.10). In a haemorrhagic lesion, the location might indicate the presence of an underlying vascular malformation, saccular aneurysm or amyloid angiopathy. More recently, CTA is being used to show vessel occlusion suitable for clot retrieval (see later).

Vascular imaging

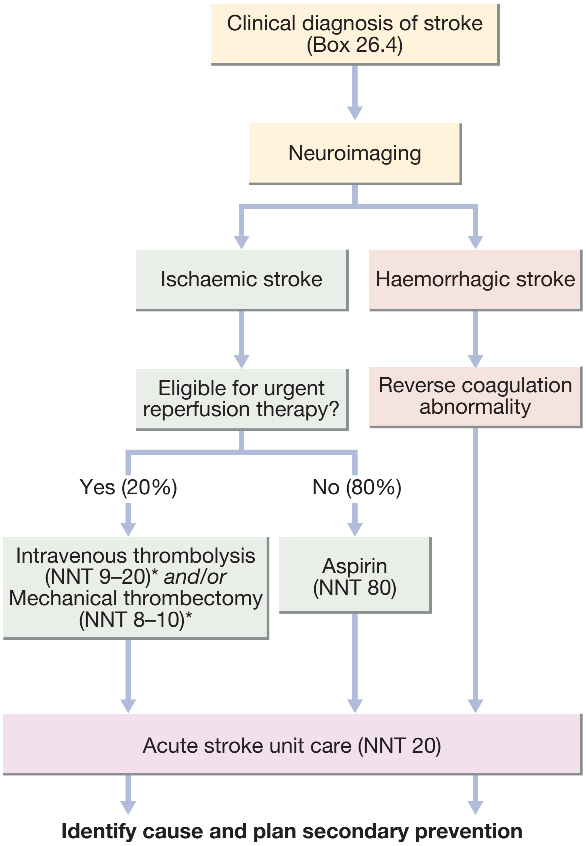
Many ischaemic strokes are caused by atherosclerotic thromboembolic disease of the major extracranial vessels. Detection of extracranial vascular disease can help establish why the patient has had an ischaemic stroke and, in selected patients, may lead on to specific treatments, including carotid endarterectomy to reduce the risk of further stroke (see below). The presence or absence of a carotid bruit is not a reliable indicator of the degree of carotid stenosis. Extracranial arterial disease can be non-invasively identified with duplex ultrasound, MRA or CTA (see Fig. 26.5), or occasionally by intra-arterial contrast radiography as above.

Cardiac investigations

Approximately 20% of ischaemic strokes are due to embolism from the heart. The most common causes are atrial fibrillation, prosthetic heart valves, other valvular abnormalities and recent myocardial infarction. These may be identified by clinical examination and ECG, but a transthoracic or transoesophageal echocardiogram is also required to confirm the presence of a clinically apparent cardiac source or to identify an unsuspected source such as endocarditis, atrial myxoma, intracardiac thrombus or patent foramen ovale. Such findings may lead on to specific cardiac treatment.

Management

Management (Fig. 26.11) is aimed at identifying the cause, minimising the volume of brain that is irreversibly damaged, preventing complications (Fig. 26.12), reducing the patient's disability and handicap through rehabilitation, and reducing the risk of recurrent stroke or other vascular events. With TIA there is no persisting brain damage and disability, so the priority is to reduce the risk of further vascular events.



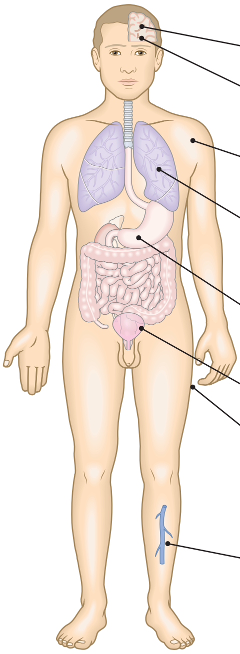


Fig. 26.11 Emergency management of stroke. *Varies with patient selection and delay in treatment. (NNT = number needed to treat to avoid one death or long-term disability)

Supportive care

Rapid admission of patients to a specialised stroke unit facilitates coordinated care from a specialised multidisciplinary team, and has been shown to reduce both mortality and residual disability amongst survivors. For every 1000 patients managed in a stroke unit, an extra 50 will avoid death or long-term disability, compared to those managed in general wards. Consideration of a patient's rehabilitation needs should commence at the same time as acute medical management. Dysphagia is common and can be detected by an early bedside test of swallowing. This allows hydration, feeding and medication to be given safely, if necessary by nasogastric tube or intravenously. In the acute phase, a checklist may be useful (Box 26.8) to ensure that all the factors that might influence outcome have been addressed. In recent years, many services have developed hyperacute stroke units (HASUs) to ensure that patients are given immediate access to these interventions, as well as urgent medical treatments.

The patient's neurological deficits may worsen during the first few hours or days after their onset. This may be due to extension of the area of infarction, haemorrhage transformation of an infarction, or the development of oedema with consequent mass effect. It is important to distinguish these patients from those who

Complications	Prevention	Treatment
Epileptic seizures	Maintain cerebral oxygenation Avoid metabolic disturbance	Anticonvulsants
Depression and anxiety	Maintain positive attitude and provide information	Antidepressants
Painful shoulder	Avoid traction injury Shoulder/arm supports Physiotherapy	Physiotherapy Local glucocorticoid injections
Chest infection	Nurse semi-erect Avoid aspiration (nil by mouth, nasogastric tube, possible gastrostomy)	Antibiotics Physiotherapy
Constipation	Appropriate aperients and diet	Appropriate aperients
Urinary infection	Avoid catheterisation if possible Use penile sheath	Antibiotics
Pressure sores	Frequent turning Monitor pressure areas Avoid urine damage to skin	Nursing care Pressure-relieving mattress
Deep vein thrombosis/ pulmonary embolism	Maintain hydration Early mobilisation Heparin (for high-risk patients only)	Anticoagulation (exclude haemorrhage first)

Fig. 26.12 Complications of acute stroke.

26.8 How to manage a patient with acute stroke

Airway

- Perform bedside screen and keep patient nil by mouth if swallowing unsafe or aspiration occurs

Breathing

- Check respiratory rate and give oxygen if saturation <95%

Circulation

- Check peripheral perfusion, pulse and blood pressure, and treat abnormalities with fluid replacement, anti-arrhythmics and inotropic drugs as appropriate

Hydration

- If signs of dehydration, give fluids parenterally or by nasogastric tube

Nutrition

- Assess nutritional status and provide supplements if needed
- If dysphagia persists for >48 hrs, start feeding via nasogastric tube

Medication

- If dysphagic, consider other routes for essential medications

Blood pressure

- Unless there is heart or renal failure, evidence of hypertensive encephalopathy or aortic dissection, do not lower blood pressure abruptly in first week as it may reduce cerebral perfusion. Blood pressure often returns towards patient's normal level within days

Blood glucose

- Check blood glucose and treat when levels are ≥11.1 mmol/L (200 mg/dL) (by insulin infusion or glucose/potassium/insulin (GKI)
- Monitor closely to avoid hypoglycaemia

Temperature

- If pyrexic, investigate and treat underlying cause
- Control with antipyretics, as raised brain temperature may increase infarct volume

Pressure areas

- Reduce risk of skin breakdown:
    - Treat infection
    - Maintain nutrition
    - Provide pressure-relieving mattress
    - Turn immobile patients regularly

Incontinence

- Check for constipation and urinary retention; treat these appropriately
- Avoid urinary catheterisation unless patient is in acute urinary retention or incontinence is threatening pressure areas

Mobilisation

- Avoid bed rest

are deteriorating as a result of complications such as hypoxia, sepsis, epileptic seizures or metabolic abnormalities that may be reversed more easily. Patients with cerebellar haematomas or infarcts with mass effect may develop obstructive hydrocephalus and some will benefit from insertion of a ventricular drain and/or decompressive surgery (see Fig. 26.11). Some patients with large haematomas or infarction with massive oedema in the cerebral hemispheres may benefit from anti-oedema agents, such as mannitol or artificial ventilation. Surgical decompression to reduce intracranial pressure should be considered in appropriate patients.

Reperfusion (thrombolysis and thrombectomy)

Rapid reperfusion in ischaemic stroke can reduce the extent of brain damage. Intravenous thrombolysis with recombinant tissue

> **26.9 Anticoagulation in old age**
>
> - **Increased risk**: older age and previous stroke increase the risk of stroke in the presence of atrial fibrillation, and bleeding risk with anticoagulation.
> - **Falls risk**: elderly patients are more prone to falls, including head injuries, which increase bleeding risk.
> - **Monitoring of therapy**: fine adjustments to daily dose of warfarin may be more difficult, as may monitoring of therapy.
> - **Impact of comorbidities**: the presence of conditions such as chronic renal impairment, diabetes or heart failure may affect the risk:benefit ratio, and decisions to use anticoagulation must be weighed carefully. Decision aids have been developed to assist (see 'Further information').

plasminogen activator (rt-PA) increases the risk of haemorrhagic transformation of the cerebral infarct with potentially fatal results. The main contraindications are bleeding risk (recent haemorrhage, anticoagulant therapy) and delay to treatment; the earlier treatment is given, the greater the benefit. However, if given within 4.5 hours of symptom onset to carefully selected patients, the haemorrhagic risk is offset by an improved overall outcome. Recently mechanical clot retrieval (thrombectomy) in patients with a large-vessel occlusion can greatly improve the chances of avoiding disability (see Fig. 26.11).

Aspirin

In the absence of contraindications, aspirin (300 mg daily) should be started immediately after an ischaemic stroke unless rt-PA has been given, in which case it should be withheld for at least 24 hours. Aspirin reduces the risk of early recurrence and has a small but clinically worthwhile effect on long-term outcome (see Fig. 26.11); it may be given by rectal suppository or by nasogastric tube in dysphagic patients.

Heparin

Anticoagulation with heparin has been widely used to treat acute ischaemic stroke in the past. While it reduces the risk of early ischaemic recurrence and venous thromboembolism, it increases the risk of both intracranial and extracranial haemorrhage. Furthermore, routine use of heparin does not result in better long-term outcomes, and therefore it should not be used in the routine management of acute stroke. It is unclear whether heparin might provide benefit in selected patients, such as those with recent myocardial infarction, arterial dissection or progressing strokes. Intracranial haemorrhage must be excluded on brain imaging before considering anticoagulation.

Coagulation abnormalities

In those with intracerebral haemorrhage, coagulation abnormalities should be reversed as quickly as possible to reduce the likelihood of the haematoma enlarging. This most commonly arises in those on warfarin therapy. There is no evidence that clotting factors are useful in the absence of a clotting defect.

Management of risk factors

The approaches used are summarised in Figure 26.13. The average risk of a further stroke is 5–10% within the first week of a stroke or TIA, perhaps 15% in the first year and 5% per year thereafter. The risks are not substantially different for intracerebral haemorrhage. The potential gain from good secondary prevention can be expressed as the number needed to treat (NNT) to avoid a recurrent stroke. Patients with ischaemic events should be put on long-term antiplatelet drugs (NNT 100) and statins (NNT 60) to lower cholesterol. For patients in atrial fibrillation, the risk can be reduced substantially (NNT 15) by using oral anticoagulation with warfarin to achieve an international normalised ratio (INR) of 2–3. The newer direct oral anticoagulants (such as dabigatran, rivaroxaban and apixaban) are now widely used, offering improved safety and effectiveness at increased drug cost. The risk of recurrence after both ischaemic and haemorrhagic strokes can be reduced by blood pressure reduction, even for those with relatively normal blood pressures (NNT 50).

Carotid endarterectomy and angioplasty

A small proportion of patients with a carotid territory ischaemic stroke or TIA will have more than 50% stenosis of the carotid artery on the side of the brain lesion. Such patients have a greater than average risk of stroke recurrence. For those without major residual disability, removal of the stenosis has been shown to reduce the overall risk of recurrence (NNT 15), although the operation itself carries about a 5% risk of stroke. Surgery is most effective in patients with more severe stenoses (70–99%) and when it is performed within the first couple of weeks after the TIA or ischaemic stroke. Carotid angioplasty and stenting are technically feasible but have not been shown to be as effective as endarterectomy for the majority of eligible patients. Endarterectomy of asymptomatic carotid stenosis has been shown to reduce the subsequent risk of stroke but the small absolute benefit does not justify its routine use.

Unusual causes

A minority of strokes are caused by arterial dissection of the carotid (carotid dissection) or vertebral artery (vertebral artery dissection). The presenting history often includes minor injury and face or neck pain. After confirmation on angiography (MRA or CTA), treatment is with either antiplatelet drugs or anticoagulation. Reversible vasoconstriction syndromes require good physiological control (particularly blood pressure).

Subarachnoid haemorrhage

Subarachnoid haemorrhage (SAH) is less common than ischaemic stroke or intracerebral haemorrhage (see Fig. 26.1) and affects about 6/100 000 of the population. Women are affected more commonly than men and the condition usually presents before the age of 65. The immediate mortality of aneurysmal SAH is about 30%; survivors have a recurrence (or rebleed) rate of about 40% in the first 4 weeks and 3% annually thereafter.

Some 85% of cases of SAH are caused by saccular or 'berry' aneurysms arising from the bifurcation of cerebral arteries (see Fig. 26.2), particularly in the region of the circle of Willis. The most common sites are in the anterior communicating artery (30%), posterior communicating artery (25%) or middle cerebral artery (20%). There is an increased risk in first-degree relatives of those with saccular aneurysms, and in patients with polycystic kidney disease (p. 405) and congenital connective tissue defects such as Ehlers–Danlos syndrome (p. 970). In about 10% of cases, SAHs are non-aneurysmal haemorrhages (so-called peri-mesencephalic haemorrhages), which have a very characteristic appearance on CT and a benign outcome in terms of mortality and recurrence.

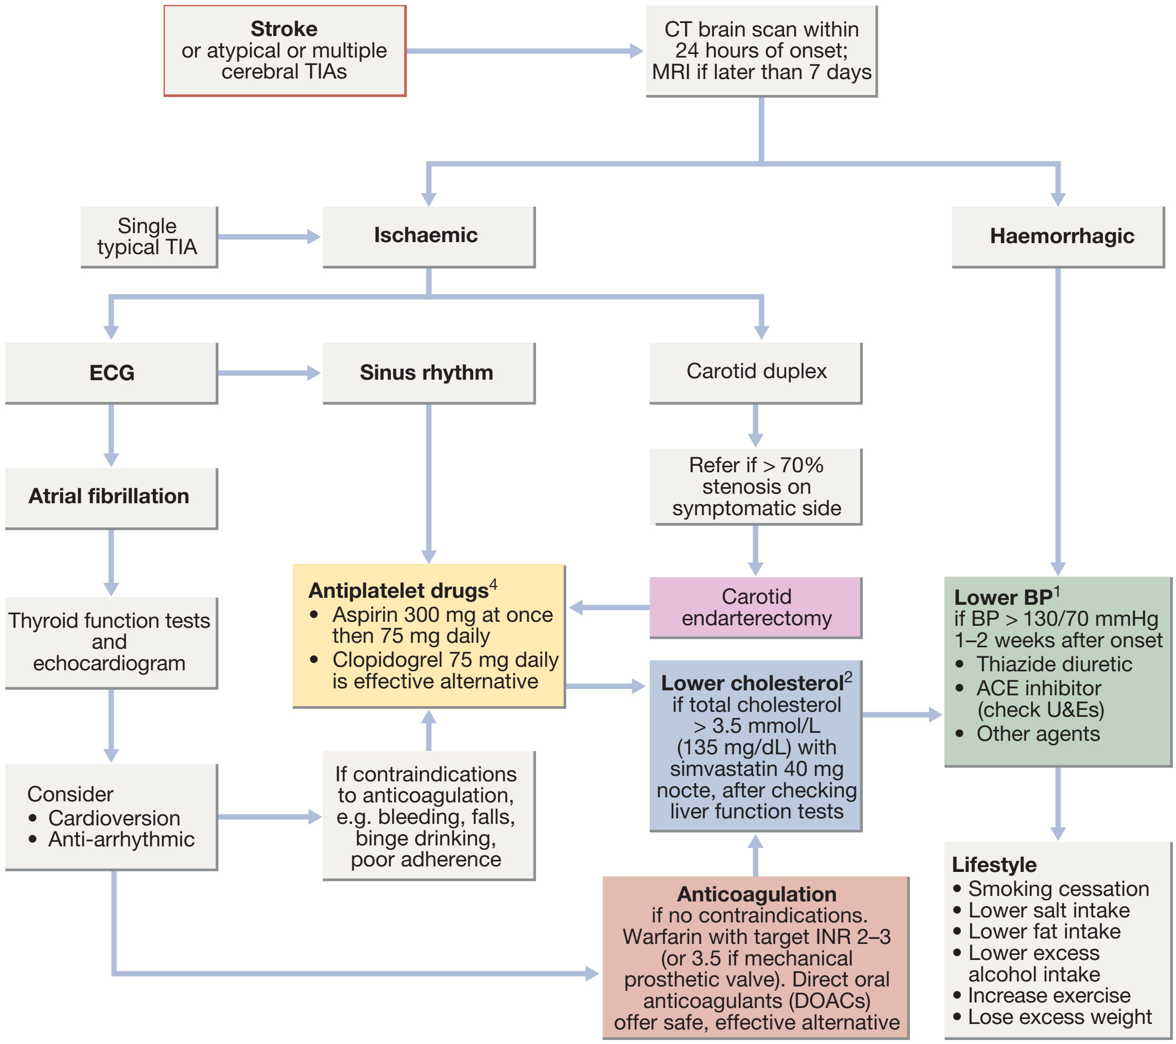

Fig. 26.13 Strategies for secondary prevention of stroke. (1) Lower blood pressure with caution in patients with postural hypotension, renal impairment or bilateral carotid stenosis. (2) Other statins can be used as an alternative to simvastatin in patients on warfarin or digoxin. (3) Warfarin and aspirin have been used in combination in patients with prosthetic heart valves. (4) The combination of aspirin and clopidogrel is indicated only in patients with unstable angina or those with a temporary high risk of recurrence (e.g. carotid stenosis). (ACE = angiotensin-converting enzyme; BP = blood pressure; CT = computed tomography; ECG = electrocardiogram; MRI = magnetic resonance imaging; TIA = transient ischaemic attack; U&Es = urea and electrolytes)

Around 5% of SAHs are due to arteriovenous malformations and vertebral artery dissection.

Clinical features

SAH typically presents with a sudden, severe, 'thunderclap' headache (often occipital), which lasts for hours or even days, often accompanied by vomiting, raised blood pressure and neck stiffness or pain. It commonly occurs on physical exertion, straining and sexual excitement. There may be loss of consciousness at the onset, so SAH should be considered if a patient is found comatose. About 1 patient in 8 with a sudden severe headache has SAH and, in view of this, all who present in this way require investigation to exclude it (Fig. 26.14).

On examination, the patient is usually distressed and irritable, with photophobia. There may be neck stiffness due to subarachnoid blood but this may take some hours to develop. Focal hemisphere signs, such as hemiparesis or aphasia, may be present at onset if there is an associated intracerebral haematoma. A third nerve palsy may be present due to local pressure from an aneurysm of the posterior communicating artery, but this is rare. Fundoscopy may reveal a subhyaloid haemorrhage, which represents blood tracking along the subarachnoid space around the optic nerve.

Investigations

CT brain scanning and lumbar puncture are required. The diagnosis of SAH can be made by CT but a negative result does not completely exclude it, since small amounts of blood in the subarachnoid space cannot be detected by CT (see Fig. 26.14). Lumbar puncture should be performed 12 hours after symptom onset if possible, to allow detection of xanthochromia (p. 1077). If either of these tests is positive, cerebral angiography (see Fig. 26.5) is required to determine the optimal approach to prevent recurrent bleeding.

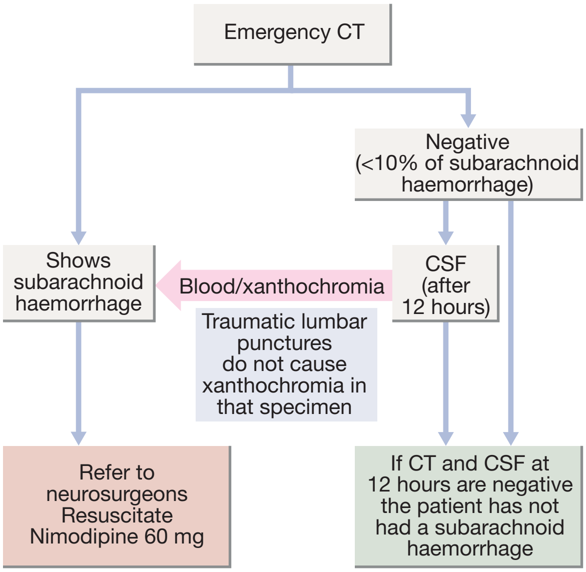

Fig. 26.14 Investigation of subarachnoid haemorrhage. (CSF = cerebrospinal fluid; CT = computed tomography)

Management

Nimodipine (30–60 mg IV for 5–14 days, followed by 360 mg orally for a further 7 days) is usually given to prevent delayed ischaemia in the acute phase. Insertion of platinum coils into an aneurysm (via an endovascular procedure) or surgical clipping of the aneurysm neck reduces the risk of both early and late recurrence. Coiling is associated with fewer perioperative complications and better outcomes than surgery; where feasible, it is now the procedure of first choice. Arteriovenous malformations can be managed either by surgical removal, by ligation of the blood vessels that feed or drain the lesion, or by injection of material to occlude the fistula or draining veins. Treatment may also be needed for complications of SAH, which include obstructive hydrocephalus (that may require drainage via a shunt), delayed cerebral ischaemia due to vasospasm (which may be treated with vasodilators), hyponatraemia (best managed by fluid restriction) and systemic complications associated with immobility, such as chest infection and venous thrombosis.

Cerebral venous disease

Thrombosis of the cerebral veins and venous sinuses (cerebral venous thrombosis) is much less common than arterial thrombosis. However, it has been recognised with increasing frequency in recent years, as access to non-invasive imaging of the venous sinuses using MR venography has increased. The main causes are listed in Box 26.10.

Clinical features

Cerebral venous sinus thrombosis usually presents with symptoms of raised intracranial pressure, seizures and focal neurological symptoms. The clinical features vary according to the sinus involved (Box 26.11 and see Fig. 26.3). Cortical vein thrombosis presents with focal cortical deficits such as aphasia and hemiparesis (depending on the area affected), and epilepsy

i 26.10 Causes of cerebral venous thrombosis

Predisposing systemic causes

- Dehydration
- Pregnancy
- Behçet's disease (p. 1043)
- Thrombophilia (p. 922)
- Hypotension
- Oral contraceptive use

Local causes

- Paranasal sinusitis
- Meningitis, subdural empyema
- Penetrating head and eye wounds
- Facial skin infection
- Otitis media, mastoiditis
- Skull fracture

i 26.11 Clinical features of cerebral venous thrombosis

Cavernous sinus thrombosis

- Proptosis, ptosis, headache, external and internal ophthalmoplegia, papilloedema, reduced sensation in trigeminal first division
- Often bilateral, patient ill and febrile

Superior sagittal sinus thrombosis

- Headache, papilloedema, seizures
- Clinical features may resemble idiopathic intracranial hypertension (p. 1133)
- May involve veins of both hemispheres, causing advancing motor and sensory focal deficits

Transverse sinus thrombosis

- Hemiparesis, seizures, papilloedema
- May spread to jugular foramen and involve cranial nerves 9, 10 and 11

(focal or generalised). The deficit can increase if spreading thrombophlebitis occurs.

Investigations and management

MR venography demonstrates a filling defect in the affected vessel. Anticoagulation, initially with heparin followed by warfarin, is beneficial, even in the presence of venous haemorrhage. In selected patients, endovascular thrombolysis has been advocated. Management of underlying causes and complications, such as persistently raised intracranial pressure, is important.

About 10% of cerebral venous sinus thrombosis, particularly cavernous sinus thrombosis, is associated with infection (most commonly *Staphylococcus aureus*), needing antibiotic treatment. Otherwise, the treatment of choice is anticoagulation.

Medical ophthalmology

The ability to see is an important aspect of everyday life. Although rarely a cause of mortality, visual impairment can have a profoundly negative impact on socioeconomic status.

Globally, although refractive errors and cataract remain the main causes of visual impairment, significant progress has occurred in prevention and treatment. Public health measures have reduced diseases of poor hygiene and unclean water, such as trachoma and onchocerciasis, and greater access to surgery has reduced the burden of untreated cataract and glaucoma. However, conditions associated with longevity, such as age-related macular degeneration, diabetic retinopathy and retinal vein occlusion, for which scientific advances have led to effective but expensive therapies requiring frequent and long-term attendance, are increasing in frequency.

Traditionally, ophthalmology relied on other specialties to undertake extraocular investigation and treatment. Medical ophthalmology bypasses that co-dependence, allowing patients with visual disorders to receive overarching care within ophthalmology. As such, it requires a good grounding in medicine, particularly dermatology, diabetes and endocrinology, infectious diseases, medical genetics, neurology, rheumatology and stroke medicine.

Medical ophthalmology presents a challenge for a medical textbook, as it overlaps with almost all other specialties, but particularly neurology. In this book neuro-ophthalmology is covered in Chapter 25. This chapter concentrates mainly on intraocular inflammation, which was the prime drive to create the specialty, and conditions that require intravitreal injection therapy. It does not therefore represent the totality of the medical ophthalmologist's workload. Ophthalmological conditions that are usually managed within non-ophthalmological specialties are discussed in the corresponding chapters, although for ease of reference the more common ophthalmic features of non-ophthalmological conditions are listed throughout this chapter (haematological disease in Box 27.1, diabetes and endocrine disease in Box 27.2, cardiovascular disease in Box 27.3, respiratory disease in Box 27.4, rheumatological/musculoskeletal disease in Box 27.5, gastrointestinal disease in Box 27.6 and skin disease in Box 27.7).

Functional anatomy and physiology

Visual pathways, innervation of the eye and the control of eye movement are discussed in Chapter 25.

Orbit

The orbit is the fat-filled cavity in which the eye is suspended. It is shaped like a hollow square pyramid, its base the orbital rim. The orbital periosteum ('periorbita') is continuous with the periosteal layer of cranial dura mater. The dura and arachnoid form the optic nerve sheath, its subarachnoid space containing cerebrospinal fluid in continuity with the third ventricle.

Eyelid/orbital septum/conjunctiva

In primary gaze, the eyelids just cover the superior and inferior cornea. The eyelids contain the orbital septum and the tarsal plate.

Within the tarsal plates, modified sebaceous (Meibomian) glands produce an oily surfactant to slow tear evaporation.

The conjunctiva, a mucous membrane, lines the posterior surface of the eyelid, adhering only to the tarsal plates and the scleral/corneal junction. The accessory lacrimal glands provide basal tear production; mucus produced by goblet cells stabilises the tear film by lowering surface tension.

i 27.1 Ophthalmic features of haematological disease

Condition	Ophthalmic findings
Severe anaemia of any cause (retinopathy of anaemia)	Flame haemorrhages Cotton wool spots Roth spots Pre-retinal haemorrhage
Megaloblastic anaemia	Optic neuropathy
Sickle cell anaemia	Conjunctival vasculopathy Peripheral retinal neovascularisation
Thalassaemia	Desferrioxamine-associated pigmentary retinopathy
Leukaemia (leukaemic retinopathy)	Pseudohypopyon Flame haemorrhages Roth spots Retinal oedema Retinal vein occlusion
Lymphoma	
Non-Hodgkin lymphoma	Lacrimal gland infiltration
Central nervous system lymphoma	Posterior uveitis (atypical choroiditis)
Myeloproliferative disorders	
Hyperviscosity	Retinal vein occlusion
Cerebral venous thrombosis	Papilloedema
Paraproteinaemias	
Waldenström's macroglobulinaemia Multiple myeloma	Retinal vein engorgement/ occlusion
Thrombophilia	
Cerebral venous thrombosis	Papilloedema

Lacrimal gland/lacrimal drainage

The lacrimal gland lies within the periorbita of the anterolateral roof of the orbit. Its secretions (tears) wash away surface irritants and convey emotion. Excess tears drain, via canaliculi in the lids, into the lacrimal sac, nasolacrimal duct and inferior nasal meatus.

Extraocular muscles

The extraocular muscles (Fig. 27.1) consist of four recti, two obliques and one levator. The recti originate from a circular condensation of periorbita, the annulus of Zinn, which encircles the superior orbital fissure and the optic canal. They extend forwards to insert into the anterior sclera.

The levator palpebrae superioris originates above the optic canal and inserts into the tarsal plate and overlying skin of the upper eyelid. The superior tarsal muscle (Müller's muscle) originates from the inferior aspect of the levator and also inserts into the tarsal plate.

The superior oblique originates superonasal to the recti, and runs along the roof of the orbit, its tendon passing horizontally through the trochlea at the orbital rim to insert into the anterior sclera.

The inferior oblique originates from the floor of the anterior orbit, just posterior to the lacrimal sac. It turns horizontally, passing beneath the inferior rectus, to insert into the inferior anterior sclera.

Eye

The optic vesicle develops from the diencephalon. The eye is therefore contiguous with the brain. This is reflected in the three-layer structure of the eye:

i 27.2 Ophthalmic features of diabetes and other endocrine disease

Condition	Ophthalmic findings
Diabetes	Proliferative retinopathy Macular oedema Small pupils (autonomic neuropathy) Cataract (including 'snowflake' cataract)
Thyrotoxicosis (any cause)	Eyelid retraction
Graves' disease (TSH receptor antibody-positive)	Exposure keratopathy Conjunctival and periorbital oedema Restrictive ocular motility Proptosis Optic neuropathy
Parathyroid disease	Band keratopathy Corneal calcium deposition
Phaeochromocytoma	Hypertensive retinopathy Cotton wool spots Flame haemorrhages Optic disc oedema with or without macular oedema
Cushing's syndrome	Posterior subcapsular cataract Diabetic retinopathy Central serous retinopathy
Thyroid carcinoma	Horner's syndrome with absent unilateral facial sweating

(TSH = thyroid stimulating hormone)

i 27.3 Ophthalmic features of cardiovascular disease

Condition	Ophthalmic findings
Arteriosclerosis	Arteriovenous nipping Retinal vein occlusion, caused by arteriovenous nipping Retinal artery macroaneurysm Ischaemic optic neuropathy Pupil-sparing third and/or sixth nerve palsy, caused by infarction of the vasa nervosum
Hypertension	Hypertensive retinopathy Cotton wool spots Flame haemorrhages Optic disc oedema, with or without macular oedema
Infective endocarditis	Flame haemorrhages Roth spots Endophthalmitis, caused by haematogenous spread of infection
Drugs	Vortex keratopathy (corneal epithelial deposits), caused by amiodarone (also seen in Fabry's disease, p. 370) Bilateral optic neuropathy, caused by amiodarone
Thromboembolic disorders (including thromboembolus from atrial fibrillation)	Retinal artery occlusion, caused by artery-to-artery embolism Homonymous hemianopia, caused by embolic stroke (p. 1088)

- the sclera/cornea, a fibrous outer layer analogous to the meningeal dura
- the choroid, ciliary body and iris (together known as the uveal tract), a vascular middle layer analogous to the pia-arachnoid
- the retina, an inner layer analogous to white matter.

i 27.4 Ophthalmic features of respiratory disease

Condition	Ophthalmic findings
Chronic obstructive pulmonary disease (p. 573)	Optic disc oedema (type 2 respiratory failure)
Cystic fibrosis (p. 580)	Diabetic retinopathy
Tuberculosis (p. 588)	Anterior uveitis Choroidal granuloma Serpiginous choroiditis Peripheral retinal arteritis Optic neuropathy, visual loss and disturbance of colour vision (adverse effects of ethambutol and isoniazid)
Sarcoidosis (p. 608)	Anterior uveitis (granulomatosis) Mutton fat keratitic precipitates Iris nodules Choroidal granuloma Panuveitis Multifocal choroiditis Retinal periphlebitis Sicca syndrome, caused by lacrimal gland infiltration Exposure keratopathy, caused by corneal exposure secondary to facial nerve palsy Optic neuropathy, caused by optic disc oedema secondary to meningeal infiltration
Lung cancer (p. 928)	Horner's syndrome (p. 1091) Cancer-associated retinopathy

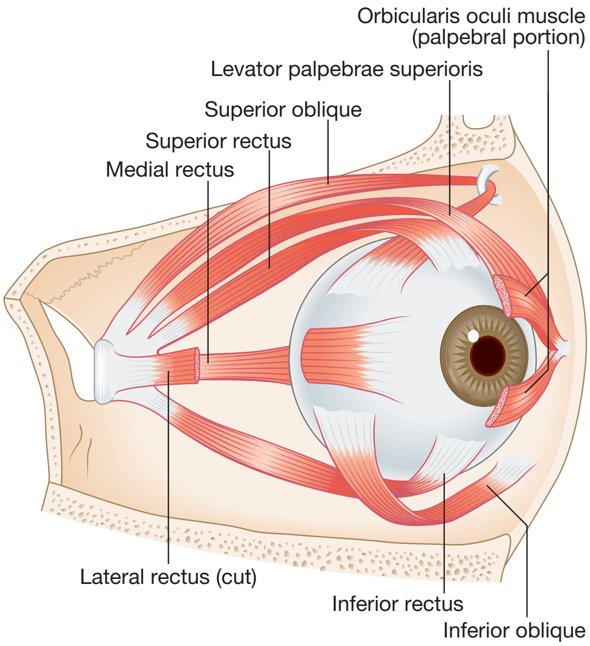

Fig. 27.1 The extraocular musculature (right eye). *Adapted from Batterbury M, Bowling B, Murphy C. Ophthalmology. An illustrated colour text, 3rd edn. Churchill Livingstone, Elsevier Ltd; 2009.*

The major structures of the eye are shown in Figure 27.2.

During embryogenesis, overlying ectoderm sinks into the neuroectoderm of the optic vesicle to form the lens vesicle, thus inducing the optic vesicle to form the two-layered optic cup. The inner and outer layers form the neurosensory retina and the retinal pigment epithelium, respectively. The intervening space is continuous with the third ventricle of the diencephalon,

27.5 Ophthalmic features of rheumatological/musculoskeletal disease

Rheumatoid arthritis

- Keratoconjunctivitis sicca
- Peripheral ulcerative keratitis ('corneal melt')
- Painless episcleritis
- Scleritis and scleromalacia

Seronegative spondyloarthropathies

- Conjunctivitis (chlamydia-associated reactive arthritis)
- Anterior uveitis

Connective tissue diseases

Dermatomyositis
- Periorbital oedema with violaceous eyelid rash

Sjögren's syndrome
- Dry eyes

Treatment effects
- Bull's eye maculopathy (hydroxychloroquine)
- Viral retinitis (immunosuppression)

Systemic vasculitides

Giant cell arteritis
- Central/branch retinal artery occlusion
- Ischaemic optic neuropathy

Behçet's disease
- Occlusive retinal vasculitis (posterior uveitis)
- Anterior uveitis with hypopyon

Granulomatosis with polyangiitis (Wegener's)
- Scleritis with involvement of adjacent cornea (sclerokeratitis)
- Retro-orbital inflammation (see Fig. 25.49)

Polyarteritis nodosa
- Peripheral ulcerative keratitis
- Scleritis
- Retinal arteritis

Others/non-specific
- Necrotising scleritis/sclerokeratitis/peripheral ulcerative keratitis
- Anterior ischaemic optic neuropathy
- Extraocular myositis (painful diplopia)
- Retinal arteritis
- Pupil-sparing 3rd nerve palsy
- 6th nerve palsy
- Proptosis
- Occipital lobe infarction

Diseases of bone

Paget's disease, polyostotic fibrous dysplasia
- Optic neuropathy

Others/non-specific
- Anterior uveitis (adverse effect of bisphosphonates)

the cilia of the third ventricle continuing as cilia on the outer neurosensory retina. Laterally, these cilia form the outer segments of the photoreceptors.

Initially, the hyaloid artery supplies the lens and vitreous. In its final form, the vitreous develops from the retina and the hyaloid artery regresses, leaving only the central retinal artery and its branches.

Mesenchyme forms the tarsal plates of the eyelid, the stroma and the endothelium of the cornea, the sclera and the choroid.

Surface ectoderm, as well as forming the lens, forms the epidermis of the eyelid, the conjunctiva, the epithelium of the cornea and the lacrimal gland.

Sclera/cornea

The sclera lends shape to the eye and provides attachment for the ocular musculature. It makes up five-sixths of the eyeball, the other sixth being formed by transparent cornea.

27.6 Ophthalmic features of gastrointestinal disease

Malabsorption
- Corneal and conjunctival keratinisation
- Rod photoreceptor loss

Chronic pancreatitis
- Diabetic retinopathy

Inflammatory bowel disease
- Episcleritis
- Non-necrotising scleritis
- Anterior uveitis

Large bowel tumours
- Atypical congenital retinal pigment epithelium hypertrophy (familial adenomatous polyposis)

Inherited liver disease
- Kayser–Fleischer corneal rings, sunflower cataracts (Wilson's disease)
- Diabetic retinopathy (haemochromatosis)

27.7 Ophthalmic features of skin disease

Rosacea
- Posterior blepharitis
- Keratitis

Acne vulgaris
- Dry eye (adverse effect of isotretinoin)
- Papilloedema (adverse effect of tetracycline)

Psoriasis
- Anterior uveitis

Eczema
- Atopic keratoconjunctivitis

Urticaria
- Angioedema

Bullous diseases
- Ocular cicatricial pemphigoid
- Stevens–Johnson syndrome

Alopecia areata
- Eyebrow and eyelash loss

Cutaneous melanoma
- Melanoma-associated retinopathy

Skin tumours
- Eyelid tumours (basal cell carcinoma, squamous cell carcinoma, keratoacanthoma, naevus, melanoma)

Skin infections
- Stye (eyelash folliculitis)
- Acute blepharoconjunctivitis (herpes simplex)
- Chronic conjunctivitis (molluscum contagiosum)

The limbus lies at the junction between the cornea and sclera, and contains stem cells and Schlemm's canal. The stem cells allow continuous regeneration of the corneal epithelium. Schlemm's canal, with its overlying trabecular meshwork, drains aqueous fluid from the anterior chamber into the external veins of the episclera and conjunctiva.

The avascular cornea is nourished by diffusion from the anterior chamber, limbal capillaries and oxygen dissolved in the tear film. The cornea, assisted by the lens and the length of the eye, determines the refractive ability of the eye.

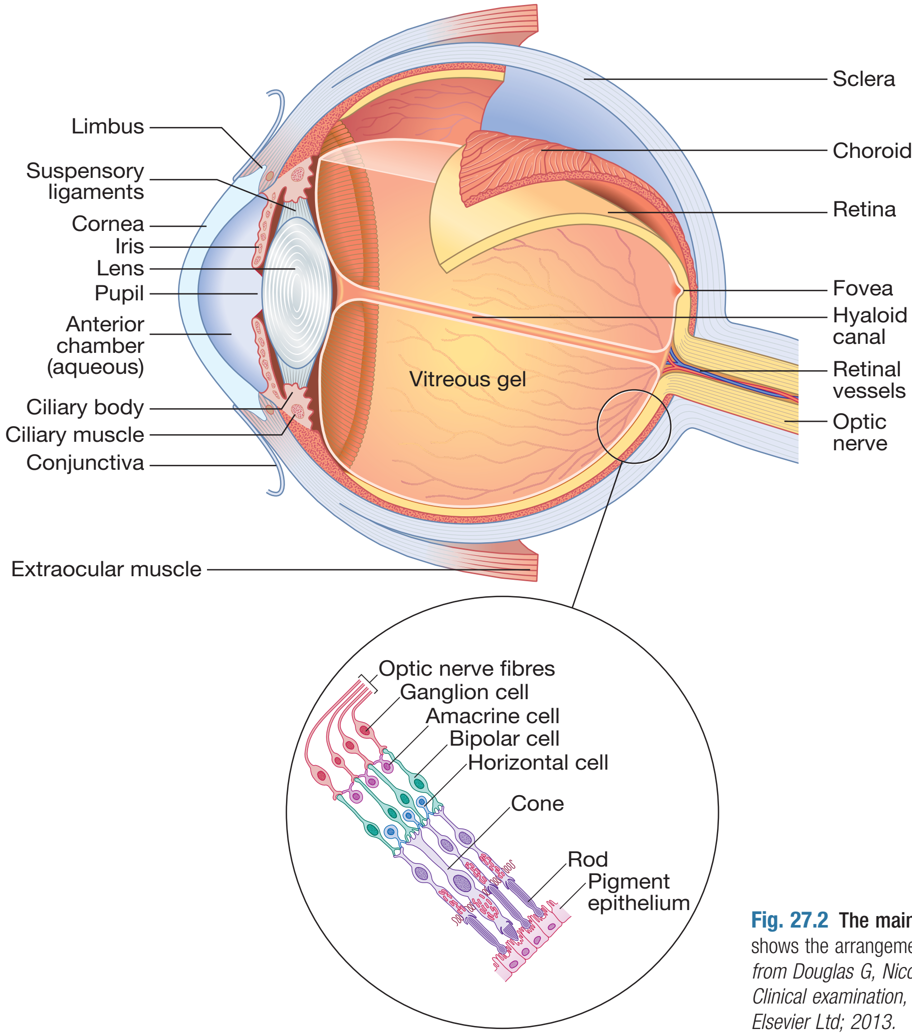

Fig. 27.2 The main structures of the eye. The inset shows the arrangement of the retinal cells. *Inset adapted from Douglas G, Nicol F, Robertson C (eds). Macleod's Clinical examination, 13th edn. Churchill Livingstone, Elsevier Ltd; 2013.*

The sclera is pierced posteriorly by the optic nerve at the lamina cribrosa, a sieve-like conduit. Its outer layer, the episclera, consists of loose connective tissue, separating it from Tenon's capsule, the soft-tissue socket of the eye.

Choroid, ciliary body and iris – the uveal tract

Posteriorly, the choroid acts as a conduit for branches of the ophthalmic artery and veins. The choriocapillaris, a network of wide-bore, fenestrated capillaries, abuts the retinal pigment epithelium.

The ciliary body forms the junction between the choroid and the iris, and lies just inferior to the limbus. Anteriorly, its ciliary processes produce aqueous (fluid) that circulates through the pupil into the anterior chamber. Posteriorly, it constitutes the pars plana and forms the attachments for the suspensory ligaments of the lens. The ciliary muscle encircles the eye within the ciliary body. Contraction of this muscle relaxes the suspensory ligaments of the lens, bringing near objects into focus.

The iris bows gently forwards as it lies against the lens. It is divided into a pupillary zone, containing the circumferential sphincter pupillae muscle, and a ciliary zone, containing the dilator pupillae.

Retina

The retina consists of the neurosensory retina and the retinal pigment epithelium. The two layers are adherent only adjacent to the optic disc and at the edge of the pars plana.

Histologically, the centre of the retina is termed the macula lutea, its yellowish appearance caused by the presence of the xanthophylls (yellow pigments) lutein and zeaxanthin. At the centre of the macula, the neurosensory retina dips to form the fovea.

The single-layered retinal pigment epithelium is highly metabolically active and is essential for the maintenance and survival of the overlying photoreceptors.

The neurosensory retina initiates the visual pathway. Its photoreceptors synapse with radially arranged bipolar neurons, which in turn synapse with circumferentially arranged optic nerve ganglion cells.

'Horizontal' and amacrine cells within the plexiform layers modulate neuronal activity between bipolar cells, photoreceptors and the ganglion cells. At the fovea, a one-to-one relationship between cones, bipolar neurons and ganglion cells leads to the highest acuity. In the peripheral retina, many rods converge on to a bipolar neuron, and many bipolar neurons converge on to a ganglion cell, leading to lower acuity. In effect, the peripheral retina conveys black-and-white sentinel vision, alerting the brain to move the higher-acuity colour vision of the fovea into gaze. Photoreceptors are specialised neurons that cause neurotransmitters to be released in response to light ('phototransduction'). There are three types of photoreceptors: namely, rods, cones and ganglion cells, the latter of which independently respond to blue light, influencing circadian rhythms.

Lens

The lens is a transparent flexible structure suspended between the iris and the vitreous. Its flexibility enables objects over a range of distances to be focused on the retina. It has a capsule, a central nucleus and a peripheral cortex. It continues to grow throughout life, becoming less flexible with age.

Vitreous

The vitreous gel is 99% water and 1% collagen/hyaluronic acid. The outer edge (cortex) of the vitreous condenses to form the anterior and posterior hyaloid membranes. The base of the vitreous strongly adheres to the ora serrata/pars plana and the optic disc rim, where the internal limiting membrane of the retina is thinnest. Lesser degrees of adhesion occur at the parafoveal retina and along the retinal vessels.

Blood supply of the orbit/eye

The main blood supply of the orbit originates from the intracranial internal carotid artery. The ophthalmic artery, the first branch of the internal carotid artery, traverses the subarachnoid space to enter the optic canal within the dural sheath of the optic nerve. On leaving the optic canal, it emerges from the dural sheath to course briefly along, and then over, the optic nerve and reach the medial wall of the orbit.

Several arterial circles are formed. The major arterial circle of the iris is formed within the ciliary body by anterior ciliary arteries anastomosing with the posterior ciliary arteries. The pial branches of the optic nerve and the short ciliary arteries join together, as the circle of Zinn, to supply the intraocular optic nerve.

The infraorbital artery, a branch of the maxillary artery, also contributes to the orbital blood supply, in particular the inferior rectus, the inferior oblique and the lacrimal sac.

The orbit is drained by the superior and inferior ophthalmic veins, which converge to drain through the superior orbital fissure into the cavernous sinus.

Investigation of visual disorders

History is the key to diagnosing visual disorders, with examination and investigations used to confirm or refute the expectations formed by the history.

Perimetry

In the era before modern radiology, manual perimetry was utilised as a non-invasive form of 'neuroimaging'. Nowadays, perimetry is largely automated and its main role lies in the monitoring of glaucoma; it also has a lesser role in assessing neuro-ophthalmic disorders. All methods of perimetry are subjective and rely on patient cooperation and mental agility.

Amsler chart

The Amsler chart (Fig. 27.3) is the simplest method of documenting the visual field, and is easy for both patient and clinician to understand and perform. It can be used for all forms of visual field loss but is best suited to follow up the central scotomata of macular disorders, which are often too subtle for other methods of perimetry.

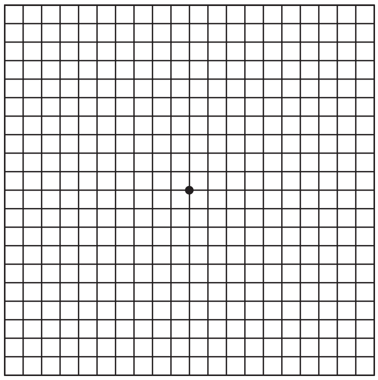

Fig. 27.3 Amsler chart. The Amsler chart is a grid of 0.5 cm squares with a dot in the centre. The subject is asked to fix on the central dot with one eye and any distorted or missing lines are recorded.

Tangent/Goldmann kinetic perimetry

Manual perimetry methods, such as tangent screen and Goldmann kinetic perimetry, appeal to the non-specialist, as they produce easily interpretable contoured maps of the visual field.

The tangent screen is a piece of black cloth attached to a wall, in front of which the operator introduces moving targets into the patient's field of view. It retains an important role in the positive identification of functional peripheral field loss (tunnel vision) versus pathological field loss (funnel vision), although the results are somewhat operator-dependent. Goldmann perimetry is a mechanical improvement on tangent screen perimetry, which utilises targets of varying size and illumination. An automated version is available.

Automated threshold perimetry

Automated visual fields test the threshold of the eye's ability to see at various points within the visual field, forming complex outputs that can be stored digitally. Internal quality assurance mechanisms monitor stability of fixation, false positives due to trigger-happy patients and false negatives due to performance fatigue. Many patients need practice before accurate results are obtained; first-time fields are rarely reliable and often show spurious and misleading findings.

Most automated perimetry assesses only central vision. Few neurological disorders start peripherally, the exception being unilateral loss of peripheral field with disease of the anterior pole of the occipital lobe. However, retinal pathology, such as retinal detachment and retinitis pigmentosa, may be missed if reliance is placed on automated perimetry rather than clinical examination.

Visual field defects on perimetry that affect the whole of the superior or inferior half of the visual field need to be differentiated by confrontation into arcuate visual field defects, which affect central field only, and altitudinal field defects, which affect both central and peripheral vision. Arcuate visual fields defects localise a lesion to the optic nerve head, whereas a lesion anywhere along the optic nerve can cause an altitudinal defect.

Imaging

See Figure 27.4.

Photography

Digital photography is utilised to document surface anatomy. Colour images are ideal for lesions affecting the skin and cornea. For the retina, however, red-free imaging brings additional benefits, particularly for discriminating red haemorrhages or abnormal new vessels from the red background of the retina.

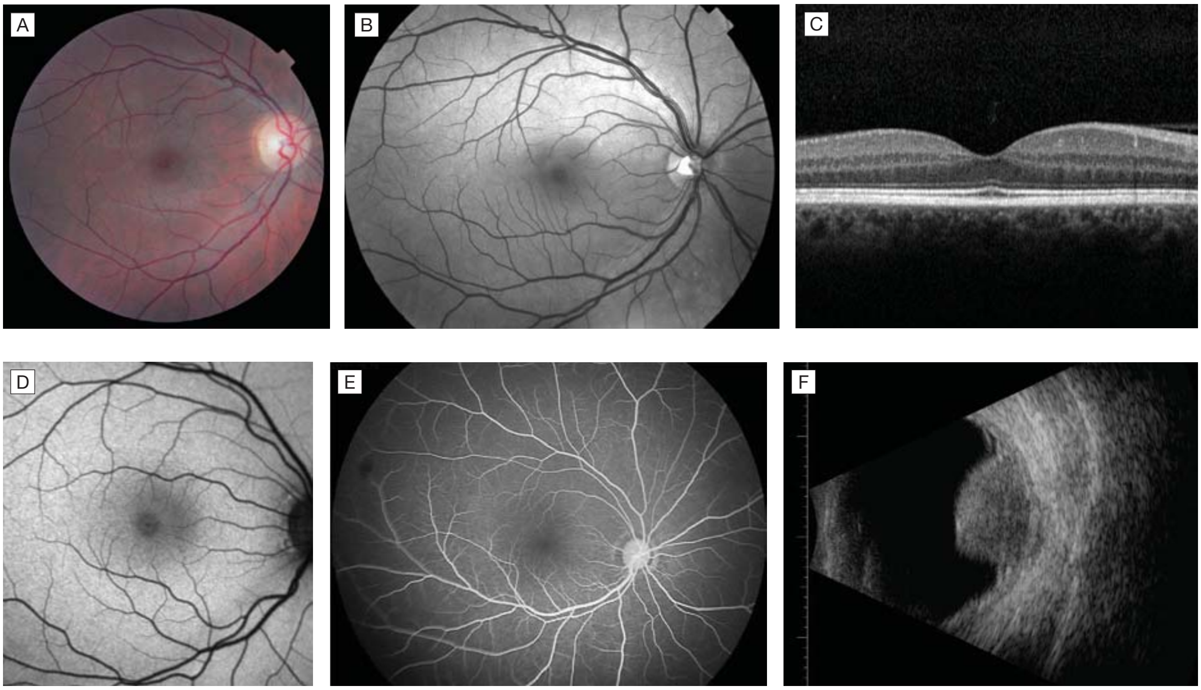

Fig. 27.4 Ocular imaging. A Colour retinal photograph from a healthy subject. B Red-free retinal photograph from a healthy subject. C Optical coherence tomogram of a normal eye, showing the layers of the retina. In this image, the macula shows normal foveal indentation. D Fundus autofluorescence (FAF) of the right eye in a normal subject. Distribution of FAF intensity shows typical background signal with reduced signal at the optic disc (absence of autofluorescent material) and retinal vessels (absorption). Intensity is markedly decreased over the fovea due to the absorption of the blue light by yellow macular pigment. E Fundal fluorescein angiogram of a normal adult retina. F Ocular ultrasound image showing typical biconvex appearance of a choroidal melanoma. *A, B, C and F, Courtesy of Aberdeen Royal Infirmary. D, From Schmitz-Valckenberg S, Fleckenstein M, Hendrik PN, et al. Fundus autofluorescence and progression of age-related macular degeneration. Survey Ophthalmol 2009; 54(1):96–117. E, From Witmer MT, Szilárd K. Wide-field imaging of the retina. Survey Ophthalmol 2013; 58(2):143–154.*

Optical coherence tomography

Optical coherence tomography is the optical equivalent of ultrasound, using light rather than sound waves to create its images. It is invaluable, not least for assessing the integrity of the layers of the retina and detecting macular oedema of any cause.

Autofluorescence

The retinal pigment epithelium contains autofluorescent lipofuscin, which can be excited by blue- and green-coloured light and captured by digital imaging.

Increased autofluorescence occurs when there is abnormal accumulation of lipofuscin, as seen with certain inherited retinal dystrophies; excess retinal pigment epithelium metabolic activity, such as at the edge of evolving atrophic macular degeneration; or drug deposition, such as with hydoxychloroquine.

Fundus angiography

Fluorescein angiography is an invasive technique with risks including local extravasation of dye at the site of intravenous injection and anaphylaxis. Currently, its role is limited to the diagnosis of retinal vasculitis, retinal and choroidal neovascularisation, and capillary occlusion. Non-invasive angiography is now possible using optical coherence tomography, but its applicability is limited by small field of view and inability to demonstrate flow or leakage.

Indocyanine angiography directly images the choroidal circulation and is particularly useful in guiding laser treatment for the choroidal polyps of polypoidal choroidal vasculopathy.

Ocular ultrasound

The main role of ultrasound is where the retina is obscured: for instance, by cataract or vitreous haemorrhage. It also has an important role in diagnosing choroidal melanoma, based on its distinctive internal reflectivity.

Visual electrophysiology

Electrophysiology is used to localise disorders to the photoreceptors (electroretinogram), the retinal ganglion cells (pattern electroretinogram) or the optic pathways (visual evoked potential). The site of photoreceptor involvement can be further localised to specific regions of the retina (multifocal electroretinogram) or the macula itself (pattern electroretinogram).

Electrophysiology requires cooperation, correction of refractive errors and the ability to fixate. Voluntary suppression of the electrical responses is possible by simply not focusing on the target. Despite this, it remains the investigation of choice for visual symptoms unexplained by clinical examination.

27

Presenting problems in ophthalmic disease

Presenting problems that are ophthalmological manifestations of predominantly neurological disease (e.g. ptosis, diplopia, oscillopsia, nystagmus and pupillary abnormalities) are discussed in Chapter 25.

Watery/dry eye

The most common cause of a watery eye is a dry eye triggering reflex lacrimation. Patients with dry eye may complain of a foreign body or gritty sensation in the eye or intermittent visual blurring, triggered by reduced blinking, as occurs when reading or when concentrating on a distant object, such as the television.

Pruritus

Common causes of itch are an acute allergic response to either airborne allergens or direct contact. A significant proportion of people are allergic to topical chloramphenicol, a first-line treatment for many minor ocular ailments.

Pain/headache

The key consideration in deciding whether or not ocular pain and/or headache originates from the eye is whether there is a ciliary flush (red eye) or no ciliary flush (white eye).

Red eye

The presence of a ciliary flush in the region of the limbus is a key finding in intraocular causes of pain. The presence of watering or watery discharge is not a discriminatory feature, and over-reliance on this symptom often results in anterior uveitis being misdiagnosed as viral conjunctivitis.

White eye

In the absence of a ciliary flush, ocular or periorbital pain is most commonly caused by migraine.

Pain on eye movement is a cardinal feature of optic neuritis and scleritis. In optic neuritis the eye is white, whereas in scleritis, except for posterior scleritis, it is red.

Posterior scleritis, in which the visible sclera is white, should be diagnosed only in the setting of positive signs such as disc swelling and exudative retinal detachment, or with confirmation by ocular ultrasound. A more common cause of severe ocular/periocular pain, with associated photophobia and lacrimation, is cluster headache (p. 1096), which is often misdiagnosed as scleritis. Just like scleritis, cluster headache responds to oral glucocorticoids, adding to the diagnostic confusion.

Intermittent, subacute angle closure glaucoma can cause headache, but usually accompanying corneal oedema causes haloes (a form of glare with rainbow colours), elicited by looking at lights or blurring of vision.

Giant cell arteritis is an uncommon, but usually striking, cause of headache, predominantly seen in the elderly. Rarely, it presents with sudden painless visual loss in the absence of raised inflammatory markers. Diagnosis can be made by demonstrating choroidal shutdown on fluorescein angiography.

Photophobia/glare

Excessive sensitivity to light, rather than fear of light, usually indicates ciliary muscle spasm due to inflammation in the iris. Common causes are corneal abrasion, acute anterior uveitis and contact lens-related keratitis.

Occasionally, photophobia can be a symptom of congenital retinal dystrophies, especially cone photoreceptor deficiency. Photophobia may also be a feature of meningitis, usually with accompanying neck stiffness and headache (meningism, p. 1118).

Glare is a common early feature of cataract, particularly triggered by oncoming car headlights when driving at night. It is a relatively common indication for surgery. It may also be an issue where there is insufficient melanin in the retinal pigment epithelium, e.g. in atrophic age-related macular degeneration, in ocular albinism or following extensive pan-retinal laser therapy. If surgery is not an option, or while surgery is awaited, the symptom of glare may be reduced by wearing a broad-brimmed hat.

Photopsia

A flickering light sensation is indicative of photoreceptor activity, either through traction, as in the setting of posterior vitreous detachment, or inflammation, as in the setting of autoimmune or paraneoplastic retinopathy. Rarely, photopsia is a symptom of occipital lobe epilepsy, in which case there is usually an accompanying homonymous hemianopia.

Blurred vision

Blurred vision describes the situation in which patients are able to see what they are looking at, but what they are looking at is out of focus. The most common cause of intermittent blurred vision is dry eye; the most common cause of permanent blurred vision is cataract. If blurred vision is worse in the morning and eases as the day progresses, this suggests macular oedema.

Loss of vision

In visual loss, patients are no longer able to see all or part of what they are looking at. Some symptoms associated with visual loss require urgent ophthalmological assessment (Box 27.8).

27.8 Red flag symptoms in visual loss*

Symptom	Possible causes
Sudden onset	Retinal artery occlusion Ischaemic optic neuropathy
Headache	Giant cell arteritis if age >55 years
Eye pain	Angle closure glaucoma Keratitis Scleritis Anterior uveitis
Pain on eye movement	Optic neuritis Scleritis
Distortion	Choroidal neovascular membrane: Age-related macular degeneration Pathological myopia Posterior uveitis Idiopathic Macular hole Epiretinal membrane
Worse in the morning	Macular oedema: Diabetic macular oedema Retinal vein occlusion Uveitis

*The presence of any of these symptoms in a patient with visual loss requires emergency referral to an ophthalmologist.

The most common cause of transient visual loss is the aura of migraine, usually a positive phenomenon with the object of regard seemingly hidden by something in the way, rather than a negative phenomenon in which part or all of what is being looked at is missing. With positive visual phenomena the obstruction is often white or coloured, expanding across the visual field, or in a constant position but shimmering.

Negative visual phenomena are a cardinal feature of ocular, usually retinal, ischaemia, with complete absence of vision (blackness) occupying part or all the visual field. Transient ocular ischaemia is usually embolic in nature but is occasionally seen in giant cell arteritis, where it suggests critical optic nerve ischaemia. Permanent monocular negative visual phenomena usually indicate previous optic nerve or retinal infarction. Tiny negative visual phenomena may also be seen in capillary disorders such as diabetic retinopathy, where patchy macular capillary occlusion may, for instance, cause letters to be missing from words on reading.

Distortion of vision

Distortion is a cardinal symptom of disruption of foveal photoreceptor alignment. The most common cause is choroidal neovascularisation. Less commonly, it can be caused by epiretinal membrane formation, where posterior hyaloid surface scarring causes foveal traction.

Usually with distortion, objects are not only misshapen but also smaller (micropsia), due to the photoreceptors being pulled apart. Macropsia, where objects look bigger than normal, is uncommon. It is sometimes seen in the 'Alice in Wonderland' syndrome, a paediatric variant of migraine where there is altered visual perception of body images.

Eyelid retraction

Eyelid retraction is usually caused by inflammatory thyroid eye disease or thyrotoxicosis (see pp. 631 and 645, and Fig. 18.8).

The first muscle to be affected in thyroid eye disease is the inferior rectus. The enlarged muscle tethers the eye and restricts upgaze. Compensatory increased innervation to the superior rectus and the levator palpebrae superioris, as well as direct inflammation, leads to eyelid retraction.

In thyrotoxicosis, increased sympathetic nervous activity leads to bilateral eyelid retraction. This, however, resolves with beta-blockade and treatment of thyrotoxicosis.

Rarely, bilateral eyelid retraction is a sign of dorsal midbrain pathology (Collier's sign), where it is accompanied by a supranuclear upgaze palsy and convergence-retraction nystagmus.

Optic disc swelling

Optic disc swelling can be a developmental variant of normal (pseudopapilloedema) or caused by optic nerve pathology, or reflect more widespread nerve fibre oedema as with retinal vein occlusion. Neurological causes of optic disc swelling are discussed in on page 1090.

Proptosis

Proptosis, particularly if bilateral and symmetrical, is often first recognised when it is quite advanced. Accompanying eyelid retraction is a typical feature of thyroid eye disease. By far the most common cause is thyroid eye disease, when proptosis is termed exophthalmos.

Proptosis is a sign of retro-orbital expansion and may be intraconal or extraconal. When expansion is within the cone of extraocular muscles, then movement forwards will be in line with the visual axis. When outside, the eye is additionally displaced to the side.

The primary clinical concern is whether vision is at risk due to optic nerve compression or corneal exposure. In addition, there may be double vision. In thyroid eye disease, diplopia may be absent if the disease is symmetrical. Instead, restricted ocular movements make patients move their head en bloc when looking at objects deviating from the primary position of gaze. To the patient, however, the overarching concern is often the change in appearance.

Specialist ophthalmological conditions

Ocular inflammation

Inflammation can affect any part of the eye. In structures in direct contact with the environment, particularly the cornea and the conjunctiva, inflammation is most likely to be caused by infection. In other structures, such as the uveal tract and sclera, inflammation is more likely to be caused by autoimmune conditions, although it may also be a manifestation of infection or malignancy. Although the latter conditions may present with indicative ocular signs, their presence is often appreciated only retrospectively, after failure to respond to immunosuppression.

Most non-infective forms of ocular inflammation are idiopathic; all are more common in the presence of other autoimmune conditions. Some may be directly associated but asynchronous in disease activity, such as the anterior uveitis of ankylosing spondylitis (p. 1028). Others are direct manifestations of an overarching, underlying, inflammatory condition such as the keratoscleritis of granulomatosis with polyangiitis (formerly known as Wegener's granulomatosis).

Sjögren's syndrome

Sjögren's syndrome is the archetypal autoimmune disease and its secondary form is associated with a large number of other autoimmune conditions (see Box 24.64, p. 1039). The cardinal features are inflammation of the lacrimal gland, its conjunctival accessory glands and the parotid gland, leading to hyposecretion of tears and saliva. Involvement of the lacrimal gland alone causes keratoconjunctivitis sicca, a syndrome of dry eyes and corneal and conjunctival irritation. Keratoconjunctivitis sicca, however, can also be caused by reduced function of the lacrimal glands and/or lacrimal ducts from other causes.

Treatment of the ophthalmological manifestations of Sjögren's syndrome is symptomatic, and consists of supplementing tear production with artificial tears (e.g. hypromellose) and reducing tear loss by humidification and avoidance of dry environments. If these measures are insufficient, tear drainage may be reduced with surgical options such as punctal plugs and punctal occlusion.

Peripheral ulcerative keratitis

Peripheral ulcerative keratitis ('corneal melting') is an autoimmune disorder affecting the corneal limbus, where it may be

accompanied by adjacent scleritis. It may be directly associated with inflammatory disorders in which immune complexes are formed, particularly rheumatoid arthritis, systemic lupus erythematosus and granulomatosis with polyangiitis. Pain and redness are helpful indicators but may not always be present. Systemic immunosuppression is always required but topical glucocorticoids should be used cautiously due to the risk of aggravating keratolysis (corneal thinning). Secondary infection should be prevented with topical antibiotics and attention should be paid to corneal hydration, through the use of artificial tears and lubricants.

More common causes of peripheral corneal ulceration are blepharitis and acne rosacea, causing ocular irritation rather than frank pain. Hypersensitivity to staphylococcal exotoxin leads to stromal infiltrate adjacent to, but sparing, the limbus (marginal keratitis). Resolution of this self-limiting condition can be assisted by the use of topical chloramphenicol, with or without topical glucocorticoids. Prevention is through management of the underlying condition, usually with ocular lid hygiene for simple blepharitis and metronidazole gel for rosacea.

Scleritis

Scleritis is usually accompanied by severe pain, worse on eye movement and often waking the patient through the night. Diagnosis of anterior scleritis is usually straightforward, with the eye showing diffuse or nodular erythema (although it may have to be searched for under the eyelids). Posterior uveitis is often accompanied by reduced vision and oedema of the retina, choroid and extraocular muscles.

White patches of necrosis (pallor) within the erythema are an ominous sign, indicative of systemic vasculitis. Non-necrotising scleritis is commonly idiopathic but may be associated with other autoimmune conditions, particularly rheumatoid arthritis and inflammatory bowel disease. It is also common with herpes zoster ophthalmicus, intraocular involvement being indicated by the involvement of the lateral external nose (Hutchison's sign).

Necrotising scleritis requires aggressive immunosuppression; non-necrotising scleritis can occasionally be managed by topical glucocorticoids or non-steroidal anti-inflammatory drugs (NSAIDs) but usually requires oral glucocorticoids.

Some patients with recurrent episodes of scleritis, or in whom inflammation is gradual and prolonged, may develop scleral thinning (scleromalacia), revealing the underlying blue choroid.

Episcleritis

Episcleritis is a benign self-limiting condition of uncertain aetiology, occasionally associated with other inflammatory disorders. Sectoral redness of the episclera is usual, although nodules can form. Often confused with scleritis, although usually less symptomatic, the diagnostic topical application of phenylephrine turns the inflamed episclera white but has no effect on the redness of scleritis. Treatment is with cold artificial tears, although occasionally topical NSAIDs or topical glucocorticoids are required.

Uveitis

Uveitis is an overarching term for inflammation anywhere in the uveal tract, retina or vitreous. It may be classified according to speed of onset, location, specific features, or aetiology (Box 27.9). Syphilis can cause all forms of uveitis. Active tuberculosis may present with an occlusive vasculitis or serpiginous (snake-like) choroiditis emanating from the optic disc. Latent tuberculosis is a particular concern because treatment of the uveitis with biologics may induce active systemic infection. Furthermore, the most commonly used biologic for uveitis – anti-tumour necrosis factor therapy (e.g. adalimumab, infliximab) – may trigger demyelination.

27.9 Aetiology of uveitis

Idiopathic
- Anterior uveitis often associated with the HLA-B27 haplotype, even in the absence of other manifestations

Primary ophthalmic conditions
- Trauma, including penetrating injury and ophthalmic surgery
- Fuchs' heterochromic cyclitis
- Posner–Schlossman syndrome

Rheumatological
- HLA-B27-associated (seronegative) spondyloarthropathies: ankylosing spondylitis, psoriatic arthritis, reactive arthritis
- Juvenile idiopathic arthritis

Systemic vasculitides
- Behçet's disease
- Polyarteritis nodosa
- Granulomatosis with polyangiitis (Wegener's)

Systemic infections (only the more common causes are listed)
- Brucellosis
- Herpes virus infections (cytomegalovirus, herpes simplex virus, varicella zoster virus)
- Leptospirosis
- Lyme borreliosis
- Syphilis
- Toxoplasmosis
- Tuberculosis
- Whipple's disease

Gastrointestinal conditions
- Inflammatory bowel disease (Crohn's disease, ulcerative colitis)

Malignancy
- Primary central nervous system lymphoma (rare)

Systemic conditions of unknown cause
- Multiple sclerosis
- Sarcoidosis

The most common form of uveitis is anterior uveitis, which is usually idiopathic but may be associated with other autoimmune conditions, particularly HLA-B27-related spondyloarthropathies (p. 1027); it is rarely caused directly by infection. Acutely, dilating drops are used to prevent the inflamed iris from sticking to the lens (posterior synechiae) and obstructing the outflow of aqueous fluid, while a tapering dose of topical glucocorticoids, usually over 4–6 weeks, mitigates the local signs and symptoms of the self-resolving inflammation. Inadequate treatment can lead to pupil block glaucoma and cataract. Posterior complications can also develop, predominantly macular oedema, the main cause of visual impairment in all forms of uveitis.

With intermediate uveitis, inflammation occurs at the pars plana, with most symptoms, predominantly floaters, being a result of inflammation of the vitreous base. Unlike anterior uveitis, pure intermediate uveitis is not associated with iris inflammation; instead, white blood cells are seen predominantly in the anterior vitreous, with a lesser amount overspilling into the anterior chamber. Treatment is challenging. Topical therapy is ineffective, as it does not penetrate beyond the anterior chamber, but symptoms of floaters are not often sufficient to justify systemic immunosuppression. In some cases, vitritis (vitreous inflammation), or more commonly macular oedema, may cause visual impairment. Occasionally, retinal neovascular proliferation may occur, either as an inflammatory response or as a direct result

of capillary occlusion. Intermediate uveitis may be associated with demyelination, sarcoidosis and inflammatory bowel disease.

Posterior uveitis tends to present with visual impairment secondary to macular oedema, vitritis or choroiditis. More chronic forms also exist and these tend to present with photopsia, visual field defects or distortion inducing choroidal neovascular membranes.

Infectious conditions

Conjunctivitis

Conjunctivitis is predominantly caused by bacteria or viruses, and is usually self-limiting in 7–10 days. Bacterial conjunctivitis is associated with a purulent discharge and viral conjunctivitis with a watery discharge, the latter often being confused with the photophobia and reflex lacrimation of anterior uveitis. Underlying chlamydial infection should always be considered if there is a persistent thick, mucopurulent discharge (p. 340).

Allergic conjunctivitis is also common, either as a component of hay fever (allergic rhinitis, p. 622) or as an allergy to chloramphenicol, which is commonly used to treat conjunctivitis.

Rarely, conjunctivitis may be associated with inflammatory systemic mucus membrane disorders, such as ocular mucus membrane (cicatricial) pemphigoid or Stevens–Johnson syndrome (pp. 1254 and 1264). The secondary effects of loss of conjunctival function can be devastating to the cornea. Other causes of conjunctival scarring include trachoma (p. 273), chemical burns and orbital radiotherapy.

Infectious keratitis/corneal ulceration

Inflammation of the cornea should always raise concern about underlying infection (Box 27.10). Central ulceration is always more serious than peripheral, through involvement of the visual axis. Cultures from corneal scraping or biopsy may be required, although much infectious keratitis is treated empirically on the basis of site, morphology and response to treatment.

In the West, the most common cause of infectious keratitis is herpes simplex virus type 1 (occasionally type 2) (Fig. 27.5). All layers of the cornea may be involved: the epithelium in the form of dendritic ulceration; the stroma in the form of white infiltrate and occasionally necrosis; and the endothelium in the form of localised oedema and keratitic precipitates. Loss of corneal sensation is common following herpes simplex keratitis, and occasionally neurotrophic keratopathy may result. Epithelial disease is self-limiting but treatment with topical or oral antivirals reduces the risk of stromal involvement and scarring. Stromal and endothelial disease requires additional topical glucocorticoids, but only once any epithelial defect has healed. Herpes simplex keratitis is analogous to herpes labialis; recurrences are therefore common and, if frequent, may warrant long-term oral antivirals. Corneal grafting may be required but the risk of recurrence remains.

Bacteria also cause infectious keratitis, especially following corneal trauma or contact lens misuse. Other risk factors for microbial keratitis include topical glucocorticoids and pre-existing ocular surface disease. Bacterial keratitis has many causes, some of which do not respond to chloramphenicol, so topical quinolones are used as first-line agents. Rarely, the free-living amoeba *Acanthamoeba castellanii* may be a cause of contact lens-associated keratitis, presenting subacutely and leading to corneal nerve infiltration, keratitis and accompanying scleritis.

Fungal keratitis is the most common cause of infectious keratitis in developing countries, particularly if there has been corneal trauma and contact with soil or plant matter. It is usually caused by *Fusarium*. Fungal keratitis has no particular distinguishing features and delayed diagnosis is common. If it is suspected, cultures should be undertaken and antifungal treatment, which is hampered by poor corneal penetration of antifungals, started promptly. Corneal transplantation is often required.

Endophthalmitis

Endophthalmitis is infection of the anterior and posterior chambers of the eye. It may be exogenous (e.g. from penetrating trauma or following surgery) or, less commonly, endogenous, caused by haematogenous spread of microorganisms within the blood, which gain entry to the eye via the choroid and ciliary body. The causes of endogenous endophthalmitis are therefore the causes of bacteraemia and fungaemia (p. 225). Gram-positive

i 27.10 Common causes of infectious keratitis

Organism	Features/comments	Treatment
Viruses		
Herpes simplex	Characteristic 'dendritic' ulcer is the most common form, often recurrent	Topical/systemic aciclovir (with topical glucocorticoid for stromal keratitis once the epithelium is healed)
Varicella zoster	Herpes zoster ophthalmicus	Systemic aciclovir
Bacteria		
Pseudomonas aeruginosa *Staphylococcus aureus* Coagulase-negative staphylococci *Propionibacterium* spp.	Coagulase-negative staphylococci and *Propionibacterium* spp. are members of the skin flora, and must not be dismissed as contaminants	Topical fluoroquinolone with Gram-positive and Gram-negative cover (e.g. ofloxacin) Subsequent treatment depends on sensitivity testing results
Fungi		
Fusarium sp. *Aspergillus* sp. *Candida* sp.	*Fusarium* and *Aspergillus* keratitis are often associated with soil and/or corneal trauma; may also be contact lens-related *Candida* causes post-keratoplasty keratitis	Options include topical natamycin (if available), amphotericin B, voriconazole and other azoles (e.g. econazole), and systemic fluconazole or voriconazole
Parasites		
Acanthamoeba castellanii (free-living amoeba)	Associated with poor contact lens hygiene	Topical polyhexamethylene biguanide
Onchocerca volvulus (nematode)	See page 292	

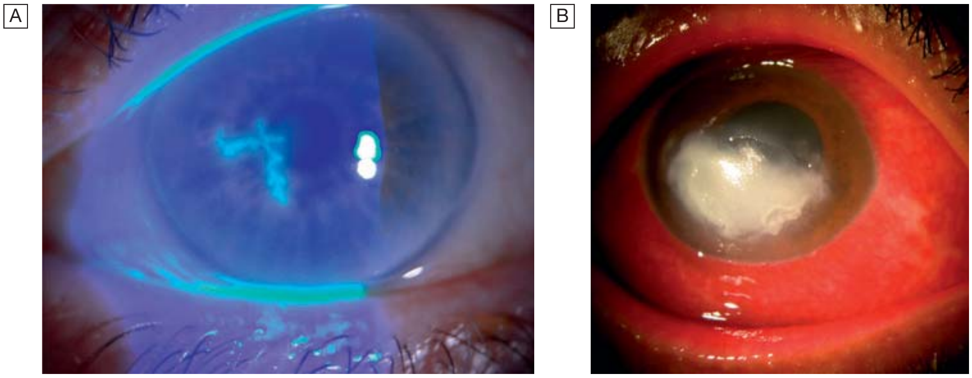

Fig. 27.5 Infective keratitis. A Herpes simplex dendritic ulcer stained with fluorescein. B *Fusarium* keratitis. An irregularly edged lesion suggests a fungal cause but is not pathognomonic. *A, Courtesy of McPherson Optometry, Aberdeen. B, From Macsai MS, Fontes BM. Rapid diagnosis in ophthalmology: anterior segment. Elsevier Inc.; 2008. (Courtesy of the External Eye Disease and Cornea Section, Federal University of São Paulo, Brazil.)*

Fig. 27.6 Focal chorioretinitis in clinically suspected endogenous *Candida* endophthalmitis. This patient was an intravenous drug user and improved with empirical oral fluconazole. *From Ryan SJ (ed). Retina, 5th edn. Saunders, Elsevier Inc.; 2013. (Case courtesy of Jeffrey K. Moore, MD.)*

bacteria are most common, followed by Gram-negative bacteria and then fungi.

Clinical presentation is with visual blurring and/or visual loss, which are usually unilateral. Ocular findings range from a few deposits in the retina/choroid (chorioretinitis) to panendophthalmitis, in which there is a severe inflammatory reaction in both the anterior and posterior chambers. A specific appearance of the retina is described for *Candida* endophthalmitis, which characteristically causes creamy-white retinal or chorioretinal lesions (Fig. 27.6). It is vitally important to sample the vitreous, as this may provide the only opportunity to determine the most appropriate therapy.

Treatment is with systemic and/or intravitreal antibiotics or antifungal agents, depending on the cause and severity. Vitrectomy may also be required.

Cataract

Cataract is permanent opacity of the lens (Fig. 27.7). Globally, untreated cataract is the most common cause of visual impairment, although in countries where surgery is available, age-related macular degeneration is a more common cause.

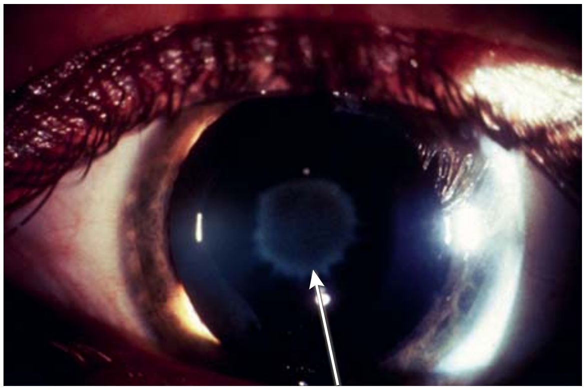

Fig. 27.7 Sunflower cataract and Kayser–Fleischer ring (arrow) in Wilson's disease. *From Kaiser PK, Friedman NJ (eds). Massachusetts Eye and Ear Infirmary Illustrated manual of ophthalmology, 4th edn. Saunders, Elsevier Inc.; 2014.*

The normal lens thickens and opacifies with age, and cataract can be detected in more than half the population over the age 65 (senile cataract). Many ocular and systemic diseases can predispose to cataract formation, the most common being uveitis and diabetes mellitus. Wilson's disease (hepatolenticular degeneration, p. 896) causes a characteristic 'sunflower' cataract. Excessive exposure to ultraviolet light, ionising radiation and glucocorticoid therapy are also predisposing factors.

The characteristic symptoms of cataract are progressive loss of vision and glare. If these become serious enough to require treatment, surgical intervention will be required, usually in the form of ultrasonic phacoemulsification with intraocular lens (IOL) implant.

Other common ophthalmological findings in old age are shown in Box 27.11.

Diabetic eye disease

Diabetic retinopathy

Diabetic retinopathy is one of the most common causes of visual impairment in people of working age in developed countries. The prevalence of diabetic retinopathy increases with the duration of diabetes. Almost all individuals with type 1 diabetes, and most of those with type 2 diabetes, will have some degree of

27.11 Common ophthalmological findings in old age

- **Small pupils that dilate poorly with mydriatics**: common neurodegenerative finding, particularly with diabetes.
- **Spurious findings on automated perimetry**: decreasing manual dexterity and cognitive function often render automated perimetry findings unreliable.
- **Lens opacities**: cataract is ubiquitous but requires treatment only if symptomatic.
- **Drusen**: common from mid-life onwards. Larger (soft) drusen are more likely to herald age-related macular degeneration than smaller (hard) drusen.
- **Glaucoma**: angle closure glaucoma is more common as the increasing size of the lens shallows the anterior chamber. Once it is identified, both eyes are always treated to prevent development/recurrence. Chronic open angle glaucoma is more common in those with a family history or ocular hypertension (isolated raised intraocular pressure).
- **Impaired upgaze**: common. It is differentiated from progressive supranuclear palsy (p. 1114) by the doll's head manœuvre, the full range of vertical movement being retained in progressive supranuclear palsy PSP.
- **Ptosis**: mechanical ptosis is common due to degenerative disinsertion of the levator palpebrae superioris aponeurosis. A high skin crease and preserved ability to elevate help differentiate it from other causes (p. 1090).
- **Late-onset presentation of congenital conditions**: adult pseudovitelliform macular 'degeneration' is an autosomal dominant retinal dystrophy, which causes mild visual impairment. Oculopharyngeal muscular dystrophy is an autosomal dominant condition characterised by later-onset chronic progressive external ophthalmoparesis and swallowing difficulties.

retinopathy after 20 years. Fortunately, most patients develop only mild forms of retinopathy.

Pathogenesis

The underlying pathogenesis of diabetic retinopathy is local vascular endothelial growth factor production initiated by hyperglycaemia-induced capillary occlusion. This occlusion stimulates increased production of retinal vascular endothelial growth factor, which not only increases capillary permeability, leading to retinal oedema, but also stimulates angiogenesis, leading to new vessel formation.

Clinical features

The initial clinical feature of diabetic retinopathy, capillary occlusion, is visible only on retinal angiography. Capillaries adjacent to the occluded capillary form discrete swellings (microaneurysms), which leak fluid and blood, causing oedema and retinal haemorrhages (Fig. 27.8).

Clinically, microaneurysms appear as isolated red dots, the capillaries being too small to visualise. At the edge of any leaking fluid, lipids precipitate out to form exudate, like the tidemark of the sea.

In turn, capillaries with microaneurysms also occlude, their microaneurysms turning white before disappearing entirely from clinical view. As more and more capillaries occlude, larger patches of retinal ischaemia form, leading to sufficient vascular endothelial growth factor production to induce the growth of new vessels at the border of diseased and undiseased retina.

Within patches of retinal ischaemia, diseased remnants of partially perfused capillaries form intraretinal microvascular abnormalities (IRMAs) and retinal veins develop multiple diffuse swellings (venous beading). These signs are best seen on fluorescein angiography.

27.12 Medical ophthalmology in adolescence

Inherited conditions

- **Stargardt's disease**: autosomal recessive macular dystrophy that commonly presents in adolescence/early adulthood, causing significant bilateral impairment of central vision.

Developmental anomalies

- **Pathological myopia**: due to elongated ocular axial length rather than refractive index of cornea and lens. Increased risk of retinal detachment and choroidal neovascular membrane formation.
- **Optic disc drusen**: come to prominence during adolescence and usually first detected during routine examination. Often mistaken for papilloedema, particularly in the setting of coincidental daily headache.
- **Amblyopia**: occasionally detected after the age of 7 years, particularly in the absence of pre-school screening, when it is unlikely to respond to patching of the other eye.
- **Keratoconus**: presents with increasing astigmatism (distortion of vision due to abnormal corneal topography). Hard contact lenses are the mainstay of therapy. Further progression may be prevented through 'cross-linking' surgery.

Deterioration of existing conditions

- **Diabetic retinopathy**: in type 1 diabetes, retinopathy usually first presents at least 5 years after diagnosis, which often coincides with adolescence. Puberty may accelerate progression. Greatest risk is disengagement with diabetes care, including retinal screening, significantly increasing later presentation with advanced symptomatic retinopathy.
- **Adult manifestations of retinopathy of prematurity**: clinical features depend on the type of treatment used in the neonatal period and include retinal detachment, angle closure glaucoma, severe myopia and cataract.

Sexual activity

- **Chlamydia conjunctivitis**: onset of sexual activity may lead to this ocular condition, which is associated with reactive arthritis (p. 1031). Untreated coexistent genital tract infection may cause infertility.

Transition to adult services

- Neurofibromatosis type 1: see page 1131.
- Optic nerve astrocytoma/glioma: often develops in late childhood or early adolescence.

Sports medicine

- **Contact sports**: eye protection is important for all, especially if there is only one functional eye, e.g. with amblyopia.

27.13 Visual disorders and pregnancy

- **Ocular inflammation**: pregnancy appears to have a protective effect on many inflammatory disorders, although not systemic lupus erythematosus. Most patients can taper treatment during pregnancy. Mycophenolate mofetil is teratogenic. Glucocorticoids and tacrolimus appear safe. The use of biologics during pregnancy should be based on a balance of risks, and professional guidelines should be consulted.
- **Diabetic retinopathy**: may be accelerated during pregnancy because the placenta is a potent source of angiogenic growth factors. Retinal screening each trimester is recommended.
- **HELLP/pre-eclampsia/eclampsia** (p. 1284): retinal features of accelerated hypertension (p. 514) may be seen, including optic disc oedema, flame haemorrhages and cotton wool spots. Occasionally, exudative retinal detachments occur. Vasogenic oedema (posterior reversible encephalopathy syndrome), affecting the posterior occipital and parietal lobes, may cause cortical visual impairment. All features tend to resolve with delivery or control of blood pressure.

27

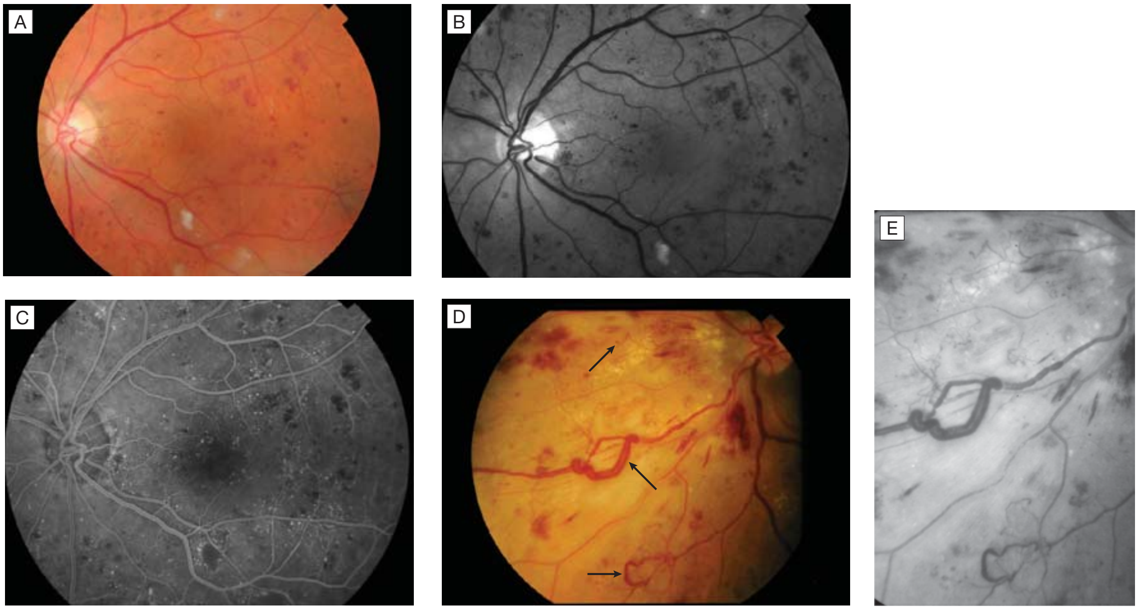

Fig. 27.8 Diabetic retinopathy. **A** Colour photograph of severe background diabetic retinopathy: multiple blot haemorrhages indicative of capillary occlusion; dot haemorrhages indistinguishable from microaneurysms or microaneurysmal bleeds; and cotton wool spots indicative of arteriolar occlusion. **B** Red-free image shows the presence of extensive haemorrhages more clearly; the more haemorrhages, the greater the degree of likely capillary occlusion. **C** Fluorescein angiogram now reveals extensive entrapment of fluorescein within multiple microaneurysms. **D** Colour photograph showing three cardinal consequences of capillary occlusion: intra-retinal microvascular anomalies occurring within an area of capillary occlusion (top arrow); venous reduplication (rare finding), with venous beading, extending from the reduplication towards the optic disc, occurring where capillaries are occluded either side of the vein (middle arrow); and new vessel formation occurring at the border between the diseased and health retina (bottom arrow). **E** Red-free image shows these features, particularly intra-retinal microvascular anomalies, more clearly. Note the relative pallor compared to the right-hand side of the image, which is indicative of widespread capillary occlusion. Absolute pallor never occurs, as it is 'masked' by the highly vascularised choroid lying underneath.
A–E, Courtesy of Aberdeen Royal Infirmary.

New vessels and their glial tissue (like a cabbage leaf) grow from retinal veins, through the overlying internal limiting membrane into the vitreous, triggering local inflammation and contracting scars. The vitreous is strongly adherent to the pars plana. It pulls back on the new vessel, triggering further bleeding, growth, inflammation and scarring. If the scarring is sufficient, then tractional retinal detachment and complete blindness may occur.

Other retinal lesions, not unique to capillary occlusion, are also seen in diabetic retinopathy. These include flame haemorrhages and cotton wool spots (soft exudates). Flame haemorrhages are horizontal streaky haemorrhages in the retinal nerve-fibre layer. They are also seen in any severe anaemia, e.g. bacterial endocarditis and leukaemia. Cotton wool spots are also situated in the nerve-fibre layer and are usually most numerous nasal to the optic disc, where the nerve fibres crowd together. They are also seen in accelerated hypertension, after severe hypoglycaemia and occasionally in giant cell arteritis. A cotton wool spot combined with an enclosing flame haemorrhage is termed a Roth spot. Roth spots have traditionally been associated with endocarditis, although they may be seen with any cause of a flame haemorrhage.

Management of proliferative diabetic retinopathy

If untreated, proliferative retinopathy eventually causes severe visual impairment through recurrent vitreous haemorrhage and retinal detachment. Pan-retinal laser photocoagulation therapy is extremely effective at preserving vision, if applied before complications set in.

Historically, laser therapy was used empirically to ablate the retina extensively outside the macula. However, this caused secondary optic atrophy and night blindness (nyctalopia), which interfered with the ability to drive. Modern application of laser is lighter, more tailored to the sites of underlying capillary ischaemia and relatively free of side-effects, only occasionally resulting in loss of the ability to drive. In the UK there is a requirement to inform the driver licensing authority if retinopathy is (or has been) present in both eyes, irrespective of treatment history.

Intravitreal injections of anti-vascular endothelial growth factor (e.g. ranibizumab, aflibercept, bevacizumab) also cause temporary regression of proliferative retinopathy, whereas, after pan-retinal laser therapy, background and proliferative types of retinopathy regress permanently. If both eyes have been treated with laser, patients can be safely discharged to a retinal screening programme.

Management of diabetic macular oedema

Traditionally, oedema seen on slit-lamp biomicroscopy was categorised according to three patterns of leakage elucidated from fluorescein angiogram studies:

- focal leakage from microaneurysms
- diffuse leakage from diseased capillaries
- ischaemia (no leakage) from thrombosis of the perifoveal capillaries.

Laser was applied, either directly on leaking microaneurysms or empirically by placing a grid of burns on the affected macula, to reduce leakage. The main aim was to treat oedema before the fovea was affected, as laser therapy for oedema affecting the fovea was never particularly effective.

However, retinal screening programmes have demonstrated that extrafoveal macular oedema often resolves spontaneously, and the introduction of intravitreal injection therapy, which rescues vision in 50% of those treated regardless of the mechanism of oedema, has led to a paradigm shift in management. Now, rather than laser treatment of asymptomatic oedema that does not involve the centre of the fovea, the emphasis has shifted to treating those who are symptomatic from centre-involving foveal oedema (confirmed on optical coherence tomography) with anti-vascular endothelial growth factor injections. Although this method of treatment is more effective, monthly injections may be required indefinitely.

Prevention

There is a clear relationship between glycaemic control and the incidence of diabetic retinopathy. A combination of good glycaemic and blood pressure control also slows the progression of retinopathy.

When blood glucose is rapidly lowered in patients with type 1 diabetes, however, there can be a transient deterioration of retinopathy, predominantly in the form of cotton wool spot formation, but occasionally triggering new vessel formation. The trigger is believed to be increased systemic insulin growth factor release, which is most likely to occur with sudden correction of eating disorders or reinstitution of insulin therapy in those who miss out injections, often to induce weight loss. This often occurs during hospitalisation for other reasons.

Although, ideally, any improvement in glycaemic control should be gradual, in many circumstances this is hard to achieve, particularly if the patient suddenly decides to comply with treatment, leading to dramatic improvement in glycaemic control.

Screening

Systematic screening for asymptomatic proliferative retinopathy has been shown to be cost-effective. It has led to the introduction of population-based screening programmes in the UK and other countries, where health care is funded centrally. There is little evidence that screening asymptomatic patients for macular oedema is cost-effective, although a by-product of screening is that suspected macular oedema has become the most common reason for referral from retinal screening to ophthalmology.

Although hand-held ophthalmoscopy has been shown to have poor sensitivity compared to examination by slit-lamp biomicroscopy or retinal photography, any form of screening is better than none where resources are scarce. Currently, optical coherence tomography is being added to the screening pathway to reduce false-negative referrals for macular oedema.

Historically, annual screening has been advocated. However, evidence now indicates that patients with repeated normal screens, particularly those with type 2 diabetes, can be safely screened every 2 years.

In pregnancy, the placenta is a source of angiogenic growth factors. For this reason, although the risk of developing significant retinopathy during pregnancy remains low, pregnant women should be screened every trimester until the placenta is delivered.

Other causes of visual loss in people with diabetes

Around 50% of visual loss in people with type 2 diabetes results from causes other than diabetic retinopathy. These include cataract, age-related macular degeneration, retinal vein occlusion, retinal arterial occlusion, non-arteritic ischaemic optic neuropathy and glaucoma. Some of these conditions are to be expected in this group, as they relate to cardiovascular risk factors (e.g. hypertension, hyperlipidaemia and smoking), all of which are prevalent in people with type 2 diabetes.

In diabetes, metabolic changes in the lens (which are not yet fully elaborated) cause premature and/or accelerated cataract formation. A rare type of 'snowflake' cataract occurs in young patients with poorly controlled diabetes. This does not usually affect vision but tends to make fundal examination difficult. The indications for cataract surgery in diabetes are similar to those in the non-diabetic population, but an additional indication in diabetes is when adequate assessment of the fundus and/or retinal laser therapy becomes impossible.

Retinal vascular occlusion

Retinal vein occlusion (thrombosis)

Retinal vein occlusion is an important vascular cause of visual impairment, visual loss resulting from macular oedema or occasionally from neovascularisation, both of which are managed in a similar way to diabetic macular oedema or proliferative diabetic retinopathy.

Although pathogenesis of retinal vein occlusion is not fully understood, the most common mechanism is believed to be compression of a vein by an adjacent arteriosclerotic artery. Retinal vessels are unusual in that, where the arteries and veins cross over each other, they share a common outer layer (tunica adventitia). This means that arteriosclerotic thickening of an artery leads directly to compression of the adjacent vein (arteriovenous nipping).

A less common cause of retinal vein occlusion is inflammation of the retinal vein (periphlebitis), also called retinal vasculitis (unlike systemic vasculitis, the arterial system is not involved). Periphlebitis should be suspected in younger patients and in patients with no obvious risk factors for arteriosclerosis. Diagnosis is made by fluorescein angiography and treatment is with systemic immunosuppression, with or without adjunctive intravitreal therapy.

Retinal vein occlusion is associated with systemic hypertension and may rarely result from hyperviscosity due to a myeloproliferative disorder, multiple myeloma, Waldenström's macroglobulinaemia or leukaemia. Glaucoma is associated with retinal vein occlusion but whether this is a direct cause or merely a comorbidity in the elderly is not known.

Clinical presentation is with unilateral painless loss of central vision (central retinal vein thrombosis) or an area of peripheral vision (branch retinal vein thrombosis). Fundoscopic features include flame haemorrhages, cotton wool spots, macular oedema and a swollen optic disc (Fig. 27.9).

Fig. 27.9 Central retinal vein occlusion (thrombosis), showing flame haemorrhages, cotton wool spots, macular oedema and a swollen optic disc. *Courtesy of Aberdeen Royal Infirmary.*

27

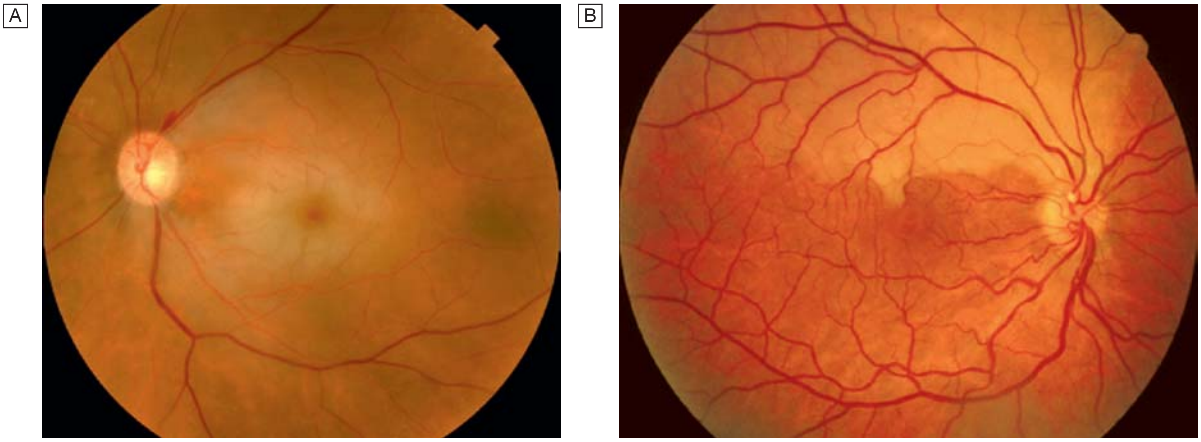

Fig. 27.10 Retinal artery occlusion. A Colour fundus photograph of central retinal artery occlusion, showing a classic cherry-red spot and a superior optic disc haemorrhage. B Superior branch retinal artery occlusion due an embolus at the disc branch retinal artery occlusion, showing a pale segment of retina. *A, From Duker JS, Waheed NK, Goldman DR. Handbook of retinal OCT. Saunders, Elsevier Inc.; 2014. B, From Bowling B. Kanski's Clinical ophthalmology, 8th edn. Elsevier Ltd; 2016.*

The management of retinal vein occlusion is twofold: management of the underlying aetiology and management of the consequences of retinal vein occlusion. Where an underlying risk factor for arteriosclerosis is clearly present (p. 484), then secondary prevention measures should be commenced. However, the role of secondary prevention of arteriosclerosis in isolated retinal vein occlusion, although common practice by some, remains controversial.

Retinal artery occlusion

Retinal artery occlusion is usually an embolic phenomenon. Common predisposing factors are therefore (predominantly carotid) atherosclerosis valvular heart disease, arrhythmias and infective endocarditis. The next most common cause is vasculitis, mainly giant cell arteritis (p. 1042).

Retinal artery occlusion presents with painless unilateral visual loss, the extent and location of which depend on whether there is a central occlusion or a branch occlusion (peripheral occlusions may be asymptomatic). Transient occlusion of the internal carotid or ophthalmic artery causes transient visual loss, or amaurosis fugax (p. 1152). The typical fundoscopic finding in a central occlusion is a transiently pale retina with a 'cherry-red' spot at the macula, the appearance developing over an hour or so after the occlusion (Fig. 27.10). In branch occlusions there is no cherry-red spot and the retinal pallor is regional.

Age-related macular degeneration

Age-related macular degeneration is the most common cause of visual impairment in the Western world. There are two basic forms: atrophic (dry) and neovascular (wet). The underlying mechanism is dysfunction of the retinal pigment epithelium, leading to overlying photoreceptor death. Choroidal neovascularisation, growing under and into the overlying retina, may occur, distorting the anatomy of the photoreceptors and ending in scar formation. Both forms are preceded by deposits under the retinal pigment epithelium ('drusen'), often followed by the development of focal areas of macular hypo- and hyperpigmentation, where diseased retinal pigment epithelial cells have precipitated their pigment (age-related maculopathy).

The atrophic form presents with gradual onset of central visual blurring, accompanied, to a lesser degree, by visual distortion. Large (geographic), central patches of atrophy are seen with areas of adjacent hyperpigmentation. In the neovascular form, sudden onset of central distortion, progressing within weeks, is the predominant symptom. Apart from age the main risk factor appears to be smoking.

The advent of anti-vascular endothelial growth factor injectors has led to effective therapy for the neovascular form, in many but not all. Unfortunately, treatment is expensive and requires considerable financial and staff resources to treat in timely fashion; delayed treatment can lead to irreversible visual loss. For whichever type, whether treatable or not, visual rehabilitation, through the use of appropriate magnifiers, alteration in lighting and specialised adaptation of everyday living objects, remains important adjunctive therapy.

Medical psychiatry

Psychiatric disorders have traditionally been considered as 'mental' rather than as 'physical' illnesses. This is because they manifest with disordered functioning in the areas of emotion, perception, thinking and memory, and formerly had no clearly biological basis. However, as biochemical and structural abnormalities of the brain are identified in an increasing number of psychiatric disorders, and psychological and behavioural factors are identified in many medical illnesses, the distinction between mental and physical illness has become questionable.

The World Health Organisation (WHO) periodically publishes its International Classification of Disease (ICD), which provides definitions for every recognised clinical condition. The current edition (ICD-10) comprises 22 chapters. The diagnoses listed in Chapter V, 'Mental and behavioural disorders' (Box 28.1), are used by psychiatrists around the world in everyday clinical practice and it is these conditions that provide the focus for this chapter.

Psychiatric disorders are among the most common of all human illnesses. The WHO's Global Burden of Disease study found 'Mental, neurological and substance misuse disorders' to be the leading cause of 'Years lost to disability' (YLDs), accounting for 28.5% of global YLDs. As with most clinical conditions, the prevalence of mental disorders varies with the setting. In the general population, depression, anxiety disorders and adjustment disorders are most common (>10%) and psychosis is rare (<2%); in acute medical wards of general hospitals, organic disorders such as delirium are very common, with prevalence highest among sick, elderly patients; in specialist general psychiatric services, psychoses are the most common disorders (Box 28.2).

Clinical examination

As in other areas of medicine, the psychiatric assessment comprises a structured clinical history and examination followed by appropriate investigations. However, psychiatric assessment differs from a standard medical assessment in the following ways:

- There is greater emphasis on the history and relatively less reliance on investigations.
- A large part of the clinical examination component is conducted as the history is being taken rather than as a discrete set of procedures afterwards.

28.1 World Health Organisation classification of psychiatric disorders

Chapter V (F00–F99) Mental and behavioural disorders	Examples
F00–F09 Organic mental disorders	Dementias Delirium Other mental disorders due to brain damage or disease
F10–F19 Disorders due to psychoactive substances: alcohol, opioids, cannabinoids etc.	Intoxication Harmful use Dependence Withdrawal
F20–F29 Schizophrenia and delusional disorders	Schizophrenia
F30–F39 Mood [affective] disorders	Depression Bipolar affective disorder
F40–F48 Neurotic, stress-related and somatoform disorders	Phobias Generalised anxiety disorder Obsessive–compulsive disorder Post-traumatic stress disorder Adjustment disorders Somatoform disorders
F50–F59 Behavioural syndromes associated with physiological disturbances	Eating disorders: anorexia and bulimia nervosa Sexual dysfunction
F60–F69 Disorders of adult personality and behaviour	Specific personality disorders Trichotillomania Gender identity disorders
F70–F79 Mental retardation	Mild, moderate, severe or profound
F80–F89 Disorders of psychological development	Autism Asperger's syndrome
F90–F98 Behavioural and emotional disorders of childhood	Hyperkinetic disorders Tic disorders

28.2 Prevalence of psychiatric disorders by medical setting

	Medical/surgical			
	General practice	**Outpatients**	**Inpatients**	**General psychiatric services**
Delirium	–	–	+++	–
Alcohol/substance abuse	++	++	+++	+++
Schizophrenia	–	–	–	+++
Bipolar affective disorder	–	–	–	+++
Depression	++	++	+++	+++
Anxiety disorders	++	++	++	+++
Adjustment disorders	++	++	+++	+
Somatoform disorders	+	+++	++	–
Personality disorders	+	+	+	+++

– 'rare' (<2%); + 'uncommon' (2–5%); ++ 'common' (5–10%); +++ 'very common' (>10%)

- It commonly includes the interviewing of an informant, usually a relative or friend who knows the patient, especially when the illness affects the patient's ability to give an accurate history.

A full psychiatric history (Box 28.3) incorporating a detailed mental state examination may take an hour or more because of its complexity. A brief mental state examination, usually taking no more than a few minutes (see below), should be part of the assessment of *all* patients, not merely those deemed to have psychiatric illnesses.

The psychiatric interview

The aims of the interview are to:

- establish a therapeutic relationship with the patient
- elicit the symptoms, history and background information (Box 28.3)
- examine the mental state
- provide information, reassurance and advice.

28.3 How to structure a psychiatric interview

Presenting problem

Reason for referral
- Why the patient has been referred and by whom

Presenting complaints
- The patient should be asked to describe the main problems for which help is requested and what they want the doctor to do

History of present illness
- The patient should be asked to describe the course of the illness from when symptoms were first noticed
- The interviewer asks direct questions to determine the nature, duration and severity of symptoms, and any associated factors

Background

Family history
- Description of parents and siblings, and a record of any mental illness in relatives

Personal history
- Birth and early developmental history, major events in childhood, education, occupational history, relationship(s), marriage, children, current social circumstances

Previous medical and psychiatric history
- Previous health, accidents and operations
- Use of alcohol, tobacco and other drugs
- Direct questions may be needed concerning previous psychiatric history since this may not be volunteered: 'Have you ever been treated for depression or nerves?' or 'Have you ever suffered a nervous breakdown?'

Previous personality
- The patterns of behaviour and thinking that characterise a person, including their relationships with other people and reactions to stress (useful information may be obtained from an informant who has known the patient well for many years)

The mental state examination

The mental state examination (MSE) is a systematic examination of the patient's thinking, emotion and behaviour. As with the clinical examination in other areas of medicine, the aim is to elicit objective clinical signs. While many aspects of the patient's mental state may be observed as the history is being taken, specific enquiries about important features should always be made.

General appearance and behaviour

Any abnormalities of alertness or motor behaviour, such as restlessness or retardation, should be noted. The level of consciousness should be determined, especially in the assessment of possible delirium.

Speech

Speed and fluency should be observed, including slow (retarded) speech and word-finding difficulty. 'Pressure of speech' describes rapid speech that is difficult to interrupt.

Mood

This can be judged by facial expression, posture and movements. Patients should also be asked if they feel sad or depressed and if they lack ability to experience pleasure (anhedonia). Are they anxious, worried or tense? Is mood elevated with excess energy and a reduced need for sleep, as in (hypo)mania?

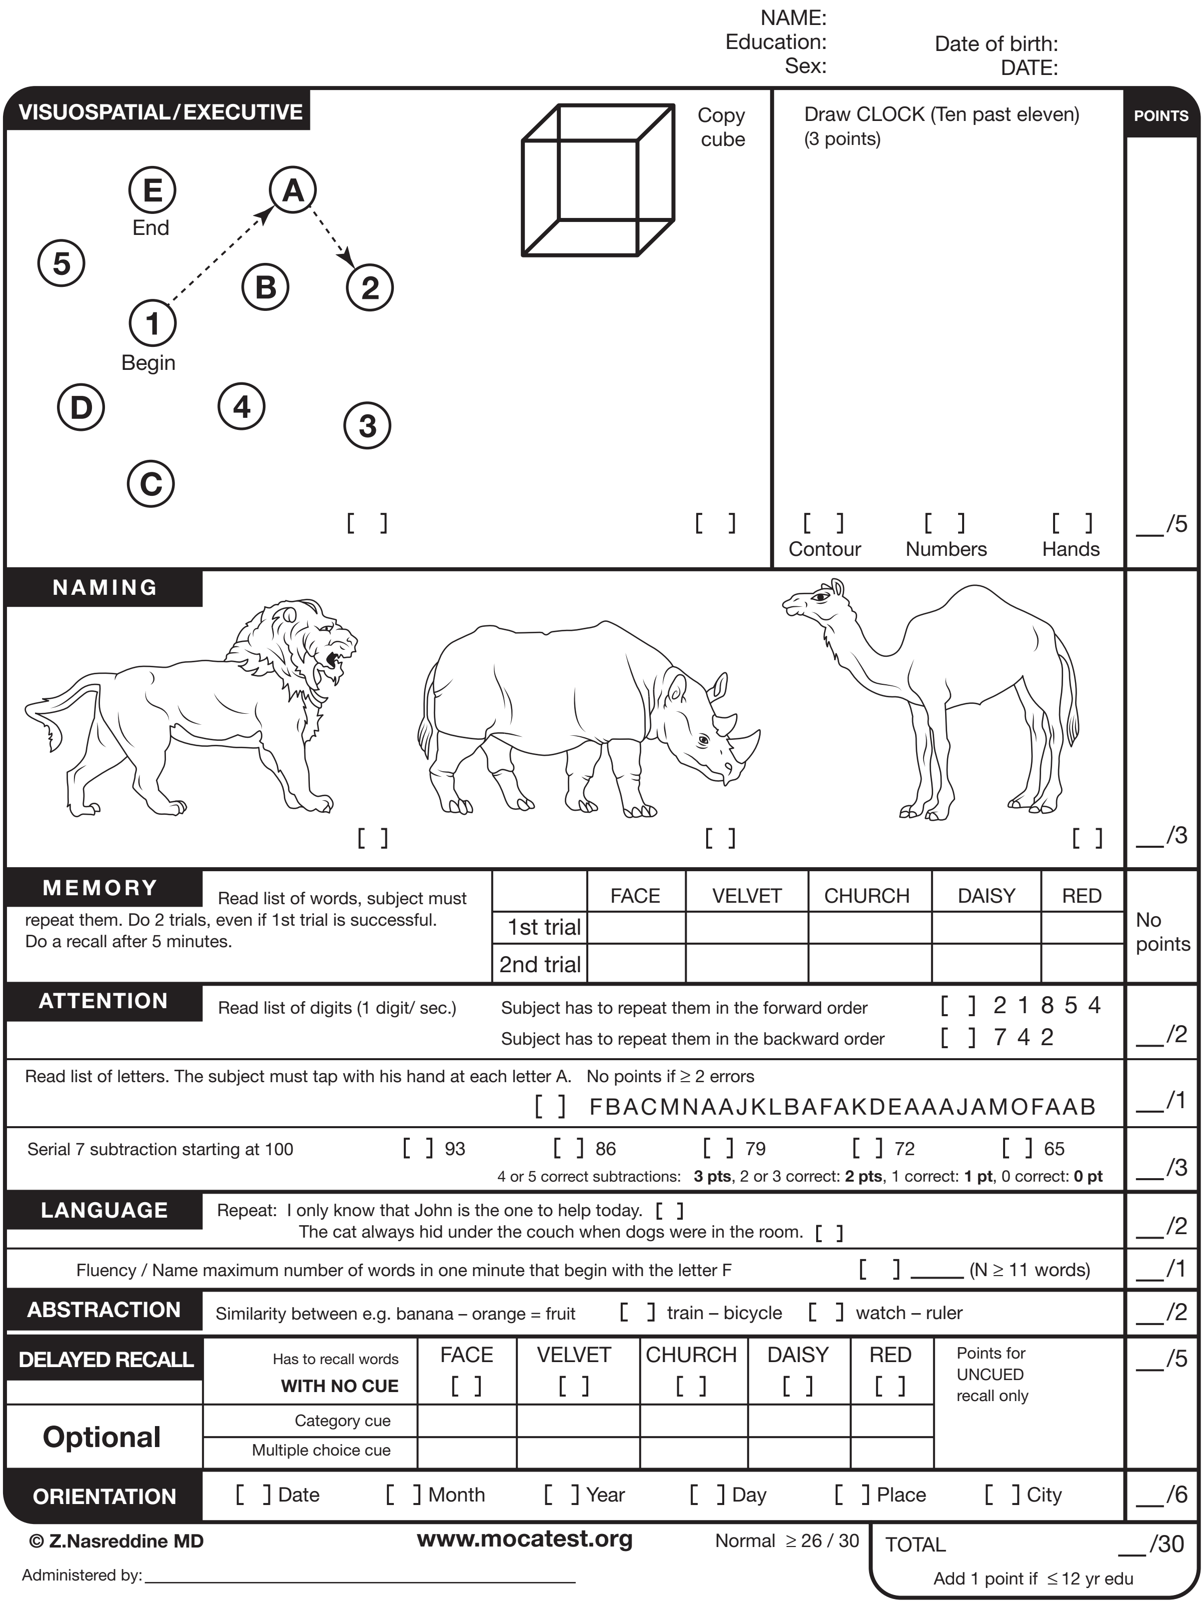
Thoughts

The content of thought can be elicited by asking 'What are your main concerns?'. Is thinking negative, guilty or hopeless, suggesting depression? Are there thoughts of self-harm? If so, enquiry should be made about plans. Are patients excessively worried about many things, suggesting anxiety? Do they think that they are especially powerful, important or gifted (grandiose thoughts), suggesting mania?

The form of thinking may also be abnormal. In schizophrenia, patients may display loosened associations between ideas, making it difficult to follow their train of thought. There may also be abnormalities of thought possession, when patients experience the intrusion of alien thoughts into their mind or the broadcasting of their own thoughts to other people (p. 1196).

Abnormal beliefs

A delusion is a false belief, out of keeping with a patient's cultural background, which is held with conviction despite evidence to the contrary (p. 1184).



Abnormal perceptions

Illusions are misperceptions of real stimuli. Hallucinations are sensory perceptions that occur in the absence of external stimuli, such as hearing voices when no one is present (p. 1184).

Cognitive function

Cognitive function has many components: memory, concentration, visuospatial abilities, executive function and so on. In most cases, a brief assessment of orientation (person, place and time – the patent is asked their name, age, date of birth, what building they are in, the current date and day of the week) and attention ('serial 7s' – the patient is asked to subtract 7 from 100 and then 7 from the answer, and so on) is sufficient to exclude clinically significant cognitive impairment. Where there is reason to suspect cognitive impairment, however, a standardised screening tool should be used. In delirium, cognitive impairment typically fluctuates over time so may be missed by a single assessment.

The Montreal Cognitive Assessment (MoCA) is a useful screening questionnaire that covers all the main domains of cognitive function (Fig. 28.1). It is designed to be easy to use and is freely available online in many different languages. Another widely used screening test is the Mini-Mental State Examination (MMSE), although this is subject to copyright, unlike the MoCA.

The Addenbrooke's Cognitive Examination – 3rd edition (ACE-III) offers a more comprehensive assessment and brief training courses for clinicians wishing to use it. These resources are available online (see 'Further information').

Patients' own understanding of their symptoms

Patients should be asked what they think their symptoms are due to and whether they warrant treatment. The failure of a patient to understand their own symptoms is referred to as 'lack of insight'. Psychotic patients characteristically have lack of insight and fail to accept that they are in need of treatment.

Investigations in medical psychiatry

In many areas of medicine, laboratory or radiological tests play a central role in diagnosis. Such tests are often performed in psychiatry but are typically used to exclude non-psychiatric illness rather than to confirm a psychiatric diagnosis. For example, in a patient presenting with symptoms of anxiety it may be appropriate to check thyroid function to exclude thyrotoxicosis as a cause of their symptoms. Specific investigations are recommended in certain psychiatric conditions such as dementia, delirium and substance misuse. These will be discussed later in this chapter.

Functional anatomy and physiology

Most psychiatric disorders result from a complex interplay between psychological, social, environmental and genetic factors. Each of these factors may play a role in predisposing to, precipitating or perpetuating a disorder (Box 28.4).

Biological factors

Genetic

Genetic factors play a predisposing role in many psychiatric disorders, including schizophrenia and bipolar affective disorder. However, while some disorders, such as Huntington's disease, are due to mutations in a single gene, the genetic contribution to most psychiatric disorders is polygenic in nature and mediated by the combined effects of several genetic variants, each with modest effects and modulated by environmental factors.

28.4 Classification of risk factors for psychiatric disorders

Classification	Examples
Predisposing	
Established in utero or in childhood	Genetic and epigenetic factors Congenital defects
Increase susceptibility to psychiatric disorder	Disturbed family background
Operate throughout patient's lifetime	Chronic physical illness
Precipitating	
Trigger an episode of illness	Stressful life events
Determine its time of onset	Acute physical illness Misuse of alcohol or drugs
Perpetuating	
Delay recovery from illness	Lack of social support Chronic physical illness

Brain structure and function

Brain structure is grossly normal in most psychiatric disorders, although abnormalities may be observed in some conditions, such as generalised atrophy in Alzheimer's disease and enlarged ventricles with a slight decrease in brain size in schizophrenia. The functioning of the brain, however, is commonly altered due to changes in neurotransmitters such as dopamine, noradrenaline (norepinephrine) and 5-hydroxytryptamine (5-HT, serotonin). Functional differences in specific areas of the brain are increasingly being recognised using advanced imaging techniques. For example, positron emission tomography (PET) studies of dopamine ligand binding in schizophrenia has consistently demonstrated increased dopamine synthesis in the striatum, even in untreated patients, while a smaller body of PET evidence points towards reductions in 5-HT transporter binding in the mid-brain and amygdala in depression.

Pattern classification approaches to structural magnetic resonance imaging (MRI) data can accurately predict the development of schizophrenia in at-risk populations, and generalised grey matter loss over time is a poor prognostic guide. Increased anterior cingulate activity in depression is a consistent predictor of good response to both antidepressants and cognitive behaviour therapy. While these and other imaging techniques show potential as diagnostic, prognostic and therapeutic aids, they remain research tools at the present time.

It is also increasingly clear that psychiatric disorders are associated with disruptions in neuronal systems rather than single sites. These can be characterised using diffusion tensor imaging (DTI) of white-matter projection fibres and resting-state/task-based functional MRI (fMRI) studies of inter-regional connectivity. For example, DTI has shown reduced white-matter density in limbic ('emotional') system tracts, such as the fornix and cingulum, in many disorders. Resting-state fMRI studies consistently identify 'default mode', salience and executive control networks of interconnected neuronal populations for certain mental activities. These pathways are implicated in several psychiatric disorders but, as yet, in non-specific ways.

Psychological and behavioural factors

Early environment

Early childhood adversity, such as emotional deprivation or abuse, predisposes to most psychiatric disorders, such as depression, eating disorders and personality disorders in adulthood.

Personality

The relationship between personality and psychiatric disorder can be difficult to assess because the development of psychiatric disorder can impact on a patient's personality. Some personality types predispose the individual to develop a psychiatric disorder, however; for example, an obsessional ('anankastic') personality increases the risk of obsessive–compulsive disorder. A disordered personality may also perpetuate a psychiatric disorder once it is established, leading to a poorer prognosis.

Behaviour

A person's behaviour may predispose to the development or perpetuation of a disorder. Examples include excess alcohol intake leading to dependence, dieting in anorexia or persistent avoidance of the feared situation in phobia.

Social and environmental factors

Social isolation

The lack of a close, confiding relationship predisposes to some psychiatric disorders, such as depression. The reduced social support resulting from having a psychiatric disorder may also act to perpetuate it.

Stressors

Social and environmental stressors often play an important role in precipitating psychiatric disorder in those who are predisposed, such as trauma in post-traumatic stress disorder, losses (such as bereavement) in depression, and events perceived as threatening (such as potential loss of employment) in anxiety.

Presenting problems in psychiatric illness

Delirium

Delirium is a medical disorder that is common in the elderly and in patients in high-dependency and intensive care units. The causes, assessment and management are described on page 209.

Alcohol misuse

Misuse of alcohol is a major problem worldwide. It presents in a multitude of ways, which are discussed further on page 1194 and in Box 28.22. In many cases, the link to alcohol is obvious; in others, it may not be, since denial and concealment of alcohol intake are common.

Clinical assessment

The patient should be asked to describe a typical week's drinking, quantified in terms of units of alcohol (1 unit contains approximately 8 g alcohol and is the equivalent of half a pint of beer, a single measure of spirits or a small glass of wine). The history from the patient may need corroboration by the GP, earlier medical records and family members.

Investigations

Abnormalities in routine biochemistry and haematology can support the diagnosis of alcohol excess (such as the finding of a raised mean cell volume (MCV) and/or raised γ-glutamyl transferase (GGT)), but such tests are abnormal in only half of problem drinkers; consequently, normal results on these tests do not exclude an alcohol problem. When abnormal, these measures may be helpful in challenging denial and monitoring treatment response. Transient elastography (also known as FibroScan) is an ultrasound-based technique that measures fibrosis and steatosis. It is used in specialist services to complement information derived from tests of MCV and GGT.

Management

The prevention and management of alcohol-related problems are discussed on page 1195.

Substance misuse

The misuse of drugs of all kinds is also widespread. As well as the general headings listed for alcohol problems in Box 28.22 (p. 1194), there are two additional sets of problems associated with drug misuse (Box 28.5):

- problems linked with the route of administration, such as intravenous injection
- problems arising from pressure applied to doctors to prescribe the misused substances.

Assessment and management are described on page 1195.

28.5 Substance misuse: additional presenting problems

Complications arising from the route of use
Intravenous
• Local: abscesses, cellulitis, thrombosis
• Systemic: bacterial (endocarditis), viral (hepatitis, human immunodeficiency virus (HIV))
Nasal ingestion
• Erosion of nasal septum, epistaxis
Smoking
• Oral, laryngeal and lung cancer
Inhalation
• Burns, chemical pneumonitis, rashes
Pressure to prescribe misused substance
• Manipulation, deceit and threats
• Factitious description of illness
• Malingering

Delusions and hallucinations

Delusions and hallucinations are abnormal beliefs and perceptions that have no rational basis. They are often due to psychiatric illness but can be secondary to substance misuse, physical illness or neurological disorders, such as epilepsy.

Delusions

A delusion is a false belief, out of keeping with a patient's cultural background, which is held with conviction despite evidence to the contrary. It is common to classify delusions on the basis of their content. They may be:

- persecutory – such as a conviction that others are out to harm one
- hypochondriacal – such as an unfounded conviction that one has cancer
- grandiose – such as a belief that one has special powers or status
- nihilistic – such as 'My head is missing', 'I have no body' or 'I am dead'.

Hallucinations

Hallucinations are defined as sensory perceptions occurring without external stimuli. They can occur in any sensory modality but most commonly are visual or auditory. Typical examples are hearing voices when no one else is present, or seeing 'visions'. Hallucinations have the quality of ordinary perceptions and are perceived as originating in the external world, not in the patient's own mind (when they are termed 'pseudo-hallucinations'). Those occurring when falling asleep ('hypnagogic') and on waking ('hypnopompic') are a normal phenomenon and not pathological. Hallucinations should be distinguished from illusions, which are misperceptions of real external stimuli (such as mistaking a shrub for a person in poor light).

Clinical assessment

Careful and tactful enquiry is required because agitation, terror or the fear of being thought 'mad' may make patients unable or unwilling to volunteer or describe their abnormal beliefs or perceptions. The nature of hallucinations can be important diagnostically; for example, 'running commentary' voices that discuss the patient are strongly associated with schizophrenia. In general, auditory hallucinations suggest schizophrenia, while hallucinations in other sensory modalities, especially vision but also taste and smell, suggest an organic cause, such as substance misuse, delirium or temporal lobe epilepsy.

Hallucinations and delusions often co-occur. If their content is consistent with coexisting emotional symptoms, they are described as 'mood-congruent'. Thus, patients with severely depressed mood may believe themselves responsible for all the evils in the world, and hear voices saying, 'You are worthless. Go and kill yourself.' In this case, the diagnosis of depressive psychosis is made on the basis of the congruence of different phenomena (mood, delusion and hallucination). Incongruence between hallucinations, delusions and mood suggests schizophrenia.

Investigations

The presence of hallucinations and/or delusions should not automatically trigger a round of expensive investigations; rather, careful clinical assessment of the nature, extent and time course of the patient's symptoms will generate a list of likely diagnoses, and investigations can then be intelligently deployed to differentiate between these. When hallucinations and/or delusions arise in the context of disturbed consciousness and impaired cognition, the diagnosis is usually an organic disorder, most commonly delirium and/or dementia, and should be investigated accordingly (pp. 184 and 1192).

Management

The management of hallucinations and/or delusions is primarily the management of the underlying condition (such as delirium, schizophrenia, mania or psychotic depression). Certain principles apply, however, whatever the underlying cause.

Hallucinations and delusions can be very real to, and often frightening for, the person who is experiencing them. Patients will often seek reassurance from the doctor. The doctor should acknowledge that these experiences are real *for the patient* while avoiding being drawn into colluding with the patient's false beliefs or perceptions. Statements such as 'Sometimes when we are unwell our brain plays tricks on us' can help to reassure a patient. Where the patient lacks insight, however, a more neutral 'We will have to agree to disagree' may be necessary to avoid conflict.

Antipsychotic medication can reduce psychotic symptoms, such as hallucinations and delusion, and is often used in combination with other sedating medication (such as a benzodiazepine) to alleviate acute distress and reduce behavioural disturbance (p. 1197).

Low mood

It is not uncommon for general hospital patients to report low mood. It is important to differentiate an understandable, self-limiting reaction to adversity (such as physical illness or bad news), which is normal and requires support rather than 'treatment', from a depressive disorder (p. 1198), which is characterised by a more severe and persistent disturbance of mood and requires specific treatment.

Clinical assessment

Depression is a relatively common illness, with a prevalence of approximately 5% in the general population and 10–20% in medical patients. It is important to note that depression has physical as well as mental symptoms (Box 28.6). The diagnosis of depression in the medically ill, who may have physical symptoms of disease such as weight loss, fatigue, disturbed sleep, reduced appetite and so on that overlap with the physical symptoms of depression, relies on detection of the core psychological symptoms of 'anhedonia' (inability to experience pleasure) and the negative cognitive triad (see Box 28.17).

In some cases, depression may occur as a result of a direct effect of a medical condition or its treatment on the brain, when it is referred to as an 'organic mood disorder' (Box 28.7).

Investigations

When a patient appears to be low in mood, it is good practice to ask them specifically about their mood. Do they *feel* low (nausea, over-sedation, parkinsonism and so on can all cause a patient to *appear* low in mood). If so, how long have they been feeling low? Are they still able to enjoy things? To what do they attribute their low mood? If the low mood is persistent, not adequately explained by circumstances and/or associated with anhedonia, the patient should be investigated for depression (p. 1199). Where a patient's mood is extremely low, the clinician should ask about suicide. Asking about suicide does not increase the risk of it occurring, whereas failure to enquire denies the opportunity to prevent it. The assessment of suicide risk is described on page 1185.

28.6 Symptoms of depressive disorders

Psychological
- Depressed mood
- Reduced self-esteem
- Pessimism
- Guilt
- Loss of interest
- Loss of enjoyment (anhedonia)
- Suicidal thinking

Somatic
- Reduced appetite
- Weight change
- Disturbed sleep
- Fatigue
- Loss of libido
- Bowel disturbance
- Motor retardation (slowing of activity)

28.7 Organic mood disorders*

Neurological
- Cerebrovascular disease
- Cerebral tumour
- Multiple sclerosis
- Parkinson's disease
- Huntington's disease
- Alzheimer's disease
- Epilepsy

Endocrine
- Hypothyroidism
- Hyperthyroidism
- Cushing's syndrome
- Addison's disease
- Hyperparathyroidism

Malignant disease

Infections
- Infectious mononucleosis
- Herpes simplex
- Brucellosis
- Typhoid
- Toxoplasmosis

Connective tissue disease
- Systemic lupus erythematosus

Drugs
- Phenothiazines
- Phenylbutazone
- Glucocorticoids, oral contraceptives
- Interferon

*Diseases that may cause organic affective disorders by direct action on the brain.

Management

The management of depression is discussed on page 1199. Where a patient's low mood is an understandable reaction to adversity, the clinical team can support the patient by minimising uncertainty through open and effective clinical communication and by addressing isolation (allowing access to visitors, telephone and so on).

Elevated mood

Elevated mood is much less common than depressed mood, and in medical settings is often secondary to drug or alcohol misuse, an organic disorder or medical treatment. Where none of these applies, the patient may be experiencing a manic (or, if less severe, 'hypomanic') episode as part of a bipolar affective disorder (p. 1199). Mania is the converse of depression. It may manifest as infectious joviality, over-activity, lack of sleep and appetite, undue optimism, over-talkativeness, irritability, and recklessness in spending and sexual behaviour. When elated mood is severe, psychotic symptoms are often evident, like delusions of grandeur such as believing erroneously that one is royalty.

Investigations

The first investigation for any medical patient presenting with persistent and inexplicable elevated mood in the absence of a history of bipolar affective disorder is a medication review. Mania is a relatively common side-effect of certain classes of drug, such as glucocorticoids, and is a rare side-effect of many other drugs. Recreational, herbal and over-the-counter preparations should also be considered. Second-line investigations include tests for Cushing's disease (p. 666), thyrotoxicosis (p. 635), syphilis (p. 337) and encephalitis (p. 1121).

Management

The management of bipolar affective disorder is discussed on page 1200. Management of organic mania involves identifying and addressing the underlying cause. The management of disturbed or aggressive behaviour is discussed on page 1188.

Anxiety

Anxiety may be transient, persistent, episodic or limited to specific situations. The symptoms of anxiety are both psychological and physical (Box 28.8). The differential diagnosis of anxiety is shown in Box 28.9. Most anxiety is part of a transient adjustment to stressful events: adjustment disorders (p. 1201). Other more persistent forms of anxiety are described in detail on page 1200.

Investigations

Anxiety may occasionally be a manifestation of a medical condition such as thyrotoxicosis (Box 28.9). Tests to exclude or confirm these conditions should be considered, particularly if anxiety is a new symptom that has arisen in the absence of an obvious stressor.

Management

The management of specific anxiety disorders is discussed later in this chapter (p. 1200). Benzodiazepines and related drugs, while extremely effective in the short term, cause tolerance and unpleasant or even dangerous withdrawal syndromes if used for more than a few weeks.

28.8 Symptoms of anxiety disorder

Psychological

- Apprehension
- Irritability
- Worry
- Poor concentration
- Fear of impending disaster
- Depersonalisation

Somatic

- Palpitations
- Fatigue
- Tremor
- Dizziness
- Sweating
- Diarrhoea
- Frequent desire to pass urine
- Chest pain
- Initial insomnia
- Breathlessness
- Headache

28.9 Differential diagnosis of anxiety

- Normal response to threat
- Adjustment disorder
- Generalised anxiety disorder
- Panic disorder
- Phobic disorder
- Organic (medical) cause:
  - Hyperthyroidism
  - Paroxysmal arrhythmias
  - Phaeochromocytoma
  - Alcohol and benzodiazepine withdrawal
  - Hypoglycaemia
  - Temporal lobe epilepsy

Psychological factors affecting medical conditions

Psychological factors may influence the presentation, management and outcome of medical conditions. Specific factors are shown in Box 28.10. The most common psychiatric diagnoses in the medically ill are anxiety and depressive disorders. Often these appear understandable as adjustments to illness and its treatment; however, if the anxiety and depression are severe and persistent, they may complicate the management of the medical condition and active management is required. Anxiety may present as an increase in somatic symptoms, such as breathlessness, tremor or palpitations, or as the avoidance of medical treatment. It is most common in those facing difficult or painful treatments, deterioration of their illness or death. Depression may manifest as increased physical symptoms, such as pain, fatigue and disability, as well as with depressed mood and loss of interest and pleasure. It is most common in patients who have suffered

28.10 Risk factors for psychological problems associated with medical conditions

- Previous history of depression or anxiety
- Lack of social support
- New diagnosis of a serious medical condition
- Deterioration of, or failure of treatment for, a medical condition
- Unpleasant, disabling or disfiguring treatment
- Change in medical care, such as discharge from hospital
- Impending death

actual or anticipated losses, such as receiving a terminal diagnosis or undergoing disfiguring surgery.

Treatment is by psychological and/or pharmacological therapies, as described on page 1189. Care is required when prescribing psychotropic drugs to the medically ill in order to avoid exacerbation of the medical condition and harmful interactions with other prescribed drugs.

Medically unexplained somatic symptoms

Patients commonly present to doctors with physical symptoms. While these symptoms may be an expression of a medical condition, they often are not (see Fig. 28.6). They may then be referred to as 'medically unexplained symptoms' (MUS), which are very common in patients attending general medical outpatient clinics. Almost any symptom can be medically unexplained. They include:

- pain (including back, chest, abdominal, pelvic and headache)
- fatigue
- fits, 'funny turns', dizziness and feelings of weakness.

Patients with MUS may receive a medical diagnosis of a so-called 'functional somatic syndrome', such as irritable bowel syndrome (Box 28.11), and may also merit a psychiatric diagnosis on the basis of the same symptoms. The most frequent psychiatric diagnoses associated with MUS are anxiety or depressive disorders. When these are absent, a diagnosis of somatoform disorder may be appropriate. Somatoform disorders are discussed in more detail on page 1202.

28.11 Functional somatic syndromes

Medical specialty	Somatic syndromes
Gastroenterology	Irritable bowel syndrome, functional dyspepsia
Gynaecology	Pre-menstrual syndrome, chronic pelvic pain
Rheumatology	Fibromyalgia
Cardiology	Atypical or non-cardiac chest pain
Respiratory medicine	Hyperventilation syndrome
Infectious diseases	Chronic (post-viral) fatigue syndrome
Neurology	Tension headache, non-epileptic attacks, functional gait disorder
Dentistry	Temporomandibular joint dysfunction, atypical facial pain
Ear, nose and throat	Globus syndrome
Allergy medicine	Multiple chemical sensitivity

Self-harm

Self-harm (SH) is a common reason for presentation to medical services. The term 'attempted suicide' is potentially misleading, as most of these patients are not trying to kill themselves. Most cases of SH involve overdose, of either prescribed or non-prescribed drugs (Ch. 7). Less common methods include asphyxiation, drowning, hanging, jumping from a height or in front of a moving vehicle, and the use of firearms. Methods that carry a high chance of being fatal are more likely to be associated with serious psychiatric disorder. Self-cutting is common and often repetitive, but rarely leads to contact with medical services.

The incidence of SH varies over time and between countries. In the UK, the lifetime prevalence of suicidal ideation is 15% and that of acts of SH is 4%. SH is more common in women than men, and in young adults than the elderly. (In contrast, completed suicide is more common in men and the elderly; Box 28.12.) There is a higher incidence of SH among lower socioeconomic groups, particularly those living in crowded, socially deprived urban areas. There is also an association with alcohol misuse, child abuse, unemployment and recently broken relationships.

Clinical assessment

The main differential diagnosis is from accidental poisoning and so-called 'recreational' overdose in drug users. It must be remembered that SH is not a diagnosis but a presentation, and may be associated with any psychiatric diagnosis, the most common being adjustment disorder, substance and alcohol misuse, depressive disorder and personality disorder. In many cases, however, no psychiatric diagnosis can be made.

Management

A thorough psychiatric and social assessment should be attempted in all cases (Fig. 28.2), although some patients will discharge themselves before this can take place. The need for psychiatric assessment should not delay urgent medical or surgical treatment, though, and may need to be deferred until the patient is well enough for interview. The purpose of the psychiatric assessment is to:

- establish the short-term risk of suicide
- identify potentially treatable problems, whether medical, psychiatric or social.

Topics to be covered when assessing a patient are listed in Box 28.13. The history should include events occurring immediately

28.12 Risk factors for suicide

- Psychiatric illness (depressive illness, schizophrenia)
- Older age
- Male sex
- Living alone
- Unemployment
- Recent bereavement, divorce or separation
- Chronic physical ill health
- Drug or alcohol misuse
- Suicide note written
- History of previous attempts (especially if a violent method was used)

28.13 Assessment of patients after self-harm

Current attempt

- Patient's account
- Degree of intent at the time: preparations, plans, precautions against discovery, note
- Method used, particularly whether violent
- Degree of intent now
- Symptoms of psychiatric illness

Background

- Previous attempts and their outcome
- Family and personal history
- Social support
- Previous response to stress
- Extent of drug and alcohol misuse

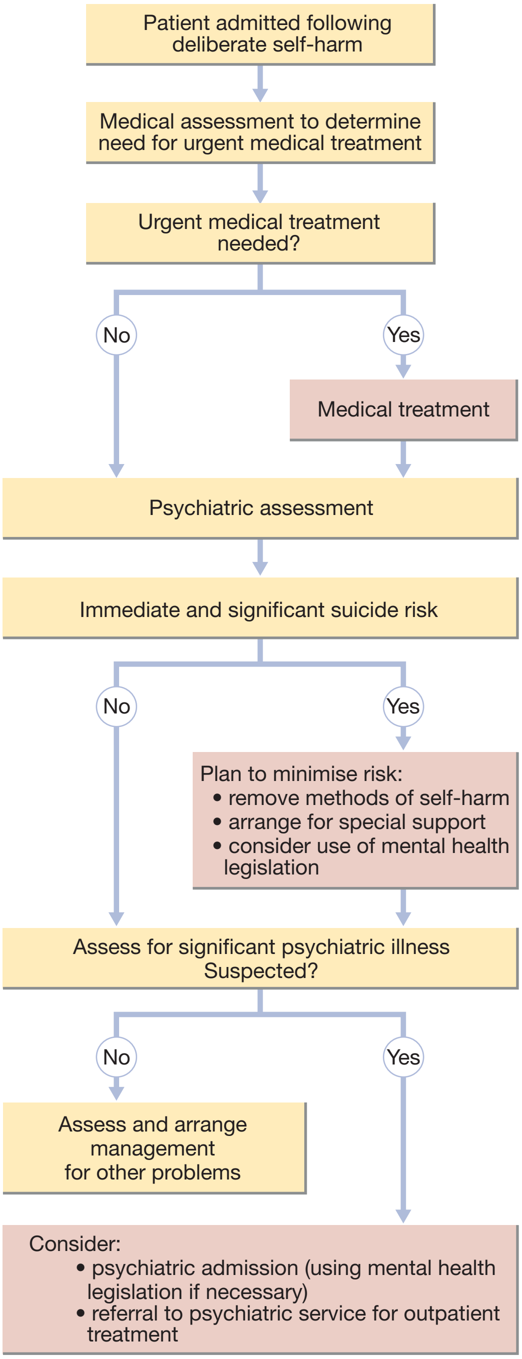

Fig. 28.2 **Assessment of patients admitted following self-harm.**

before and after the act, and especially any evidence of planning. The nature and severity of any current psychiatric symptoms must be assessed, along with the personal and social supports available to the patient outside hospital.

Most SH patients have depressive and anxiety symptoms on a background of chronic social and personal difficulties (often complicated by use of alcohol or other substances), but no psychiatric disorder. They do not usually require psychotropic medication or specialised psychiatric treatment but may benefit from personal support and practical advice from a GP, social worker or community psychiatric nurse. Admission to a psychiatric ward is necessary only for persons who display one or more of the following:

- an acute psychiatric disorder
- high short-term risk of suicide
- need for temporary respite from intolerable circumstances
- requirement for further assessment of their mental state.

Approximately 20% of SH patients make a repeat act during the following year and 1–2% kill themselves. Factors associated with suicide after an episode of SH are listed in Box 28.12.

Disturbed and aggressive behaviour

Disturbed and aggressive behaviour is common in general hospitals, especially in emergency departments. Most behavioural disturbance arises not from medical or psychiatric illness, but from alcohol intoxication, reaction to the situation and personality characteristics.

Clinical assessment

The key principles of management are, firstly, to establish control of the situation rapidly and thereby ensure the safety of the patient and others; and secondly, to try to determine the cause of the disturbance in order to remedy it. Establishing control requires the presence of an adequate number of trained staff, an appropriate physical environment and sometimes sedation (Fig. 28.3). The assistance of hospital security staff and sometimes the police may be required. In all cases, the staff approach is important; a calm, non-threatening manner expressing understanding of the patient's concerns is often all that is required to defuse potential aggression (Box 28.14).

An attempt should be made to try to identify the factors that are contributing to the disturbed behaviour. When the patient is cooperative, these are best determined at interview. Other sources of information about the patient include medical and psychiatric records, and discussion with nursing staff, family members and other informants, including the patient's GP. The following information should be sought:

- psychiatric, medical (especially neurological) and criminal history
- current psychiatric and medical treatment
- alcohol and drug misuse
- recent stressors
- the time course and accompaniments of the current episode in terms of mood, belief and behaviour.

Observation of the patient's behaviour may also yield useful clues. Do they appear to be responding to hallucinations? Are they alert or variably drowsy and confused? Are there physical features suggestive of drug or alcohol misuse or withdrawal? Are there new injuries or old scars, especially on the head? Do they smell of alcohol or solvents? Do they bear the marks of drug injection? Are they unwashed and unkempt, suggesting a gradual development of their condition?

Investigations

Depending on the results of clinical assessment, routine biochemistry, haematology and analysis of blood or urine for illicit drugs or alcohol may be required.

Management

Measures such as restraint and sedation may be required in patients with acute behavioural disturbance in order to

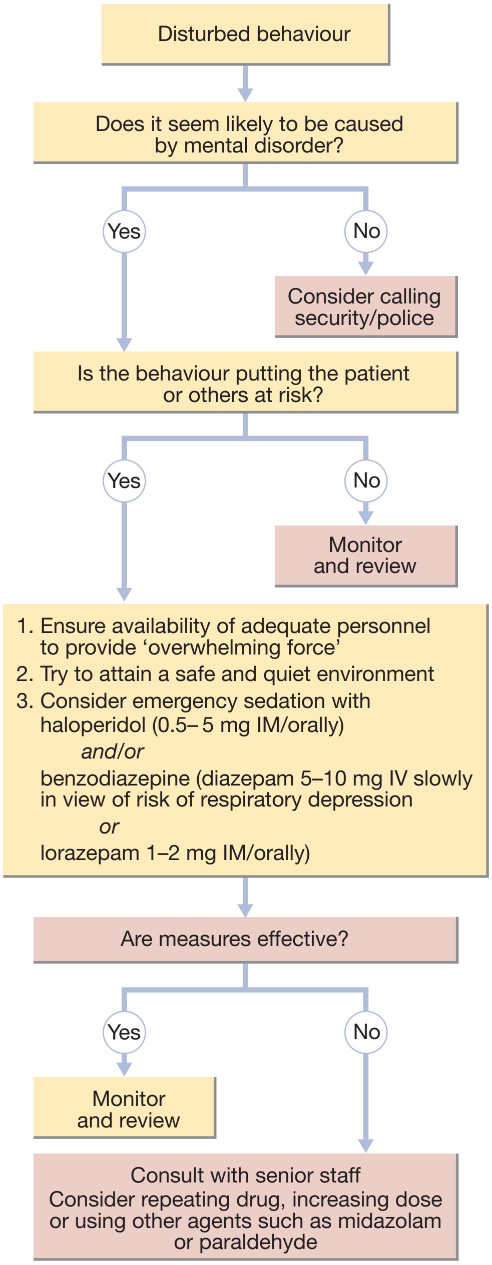

Fig. 28.3 **Acute management of disturbed behaviour.**

28.14 Psychiatric emergencies

- Intervene as necessary to reduce the risk of harm to the patient and to others
- Adopt a calm, non-threatening approach
- Arrange availability of other staff and parenteral medication
- Consider diagnostic possibilities of drug intoxication, acute psychosis and delirium
- Involve friends and relatives as appropriate

identify the cause and to protect the patient and other people from harm. While this potentially raises legal issues, in most countries, including the UK, common law confers on doctors the right, and indeed the duty, to intervene against a patient's wishes if this is necessary. Sedation may be required and

28.15 Medical psychiatry in old age

- **Organic psychiatric disorders**: especially common, so cognitive function should always be assessed; if impaired, an associated medical condition or adverse drug effect should be suspected.
- **Disturbed behaviour**: delirium is the most common cause.
- **Depression**: common. Just because a person is old and frail does not mean that depression is 'to be expected' and that it should not be treated.
- **Self-harm**: associated with an increased risk of completed suicide.
- **Medically unexplained symptoms**: common and often associated with depressive disorder.
- **Loneliness, poverty and lack of social support**: must be taken into consideration in management decisions.

can be achieved with antipsychotic drugs (such as haloperidol) and/or benzodiazepines (such as lorazepam or diazepam). The choice of drug, dose, route and rate of administration depends on the patient's age, gender and physical health, as well as the likely cause of the disturbed behaviour. The benefits of sedation must always be balanced against the potential risks. When prescribing benzodiazepines, consider the risk of respiratory depression (particularly in patients with lung disease) and encephalopathy (in those with liver disease). When prescribing antipsychotic drugs for acute sedation, consider the risk of acute dystonias (such as 'oculogyric crisis') and acute arrhythmias (in patients with heart disease). Thus for a frail elderly woman with emphysema and delirium, sedation may be achieved with a low dose (0.5 mg) of oral haloperidol, while for a strong young man with an acute psychotic episode, 10 mg or more of intravenous diazepam and a similar dose of haloperidol may be required. A parenterally administered anticholinergic agent, such as procyclidine, should be available to treat extrapyramidal effects from haloperidol if they arise. Flumazenil (p. 142) can be used to reverse respiratory depression caused by benzodiazepines.

If the initial assessment suggests that the patient has an acute psychiatric disorder, then admission to a psychiatric facility may be indicated. If a medical cause is more likely, psychiatric transfer is usually inappropriate and the patient should be managed in a medical setting, with whatever nursing and security support is required. Where it is clear that there is no medical or psychiatric illness, the person should be removed from the hospital, to police custody if necessary.

Many countries, such as the UK, also have specific mental health legislation that may be used to detain patients if necessary.

Principles of management of psychiatric disorders

The multifactorial origin of most psychiatric disorders means that there are multiple potential targets for treatment. It is useful to consider management strategies within a bio-psycho-social framework. This can help to address the biological factors that contribute to the illness with medication and other physical treatments such as electroconvulsive therapy, while also considering the potential role for psychological therapies and changes to the patient's social environment.

28.16 Classification of commonly used psychotropic drugs

Action	Main groups	Clinical use
Antipsychotic	Phenothiazines Butyrophenones Second-generation antipsychotics	Schizophrenia Bipolar mania Delirium
Antidepressant	Tricyclics and related drugs Serotonin and noradrenergic re-uptake inhibitors Monoamine oxidase inhibitors	Depression/anxiety Obsessive–compulsive disorder Depression/anxiety
Mood-stabilising	Lithium Valproate Lamotrigine	Treatment and prophylaxis of bipolar disorder Adjunctive therapy in depression
Anti-anxiety	Benzodiazepines β-adrenoceptor antagonists	Anxiety/insomnia (short term) Alcohol withdrawal (short term) Anxiety (somatic symptoms)

Pharmacological treatments

These aim to relieve psychiatric disorder by modifying brain function. The main biological treatments are psychotropic drugs. These are widely used for various purposes; a pragmatic classification is set out in Box 28.16. It should be noted that some drugs have applications to more than one condition; for example, antidepressants are also widely used in the treatment of anxiety *and* chronic pain. The specific subgroups of psychotropic drugs are discussed in the sections on the appropriate disorders below.

Electroconvulsive therapy

Electroconvulsive therapy (ECT) entails producing a convulsion by the brief administration of a high-voltage direct-current impulse to the head while the patient is anaesthetised and paralysed by muscle relaxant. If properly administered, it is remarkably safe, has few side-effects, and is of proven efficacy for severe depressive illness. There may be headaches and amnesia for events occurring a few hours before ECT (retrograde) and after it (anterograde). Pronounced amnesia can occur but is infrequent and difficult to distinguish from the effects of severe depression.

Other forms of electromagnetic stimulation

Clinical trials of transcranial magnetic stimulation (TMS) and vagal nerve stimulation (VNS) suggest they may have a limited role in patients with depression refractory to conventional treatments.

Surgery

Surgery to the brain (psychosurgery) has a very limited place and then only in the treatment of severe chronic psychiatric illness resistant to other measures. Frontal lobotomies are never done now, and pre-frontal leucotomies are very rare. Operations these days usually target specific sub-regions and tracts of the brain.

Psychological therapies

These treatments are useful in many psychiatric disorders and also in non-psychiatric conditions. They are based on talking with patients, either individually or in groups. Sometimes discussion is supplemented by 'homework' or tasks to complete between treatment sessions. Psychological treatments take a number of forms based on the duration and frequency of contact, the specific techniques applied and their underlying theory.

28.17 The negative cognitive triad associated with depression

Cognitive error	Example
Negative view of self	'I am no good'
Negative view of current life experiences	'The world is an awful place'
Negative view of the future	'The future is hopeless'

General psychotherapy

General psychotherapy should be part of all medical treatment. It involves empathic listening to the patient's account of their symptoms and associated fears and concerns, followed by the sympathetic provision of accurate information that addresses these.

Cognitive therapy

This therapy is based on the observation that some psychiatric disorders are associated with systematic errors in the patient's conscious thinking, such as a tendency to interpret events in a negative way or see them as unduly threatening. A triad of 'cognitive errors' has been described in depression (Box 28.17). Cognitive therapy aims to help patients to identify such cognitive errors and to learn how to challenge them. It is widely used for depression, anxiety and eating and somatoform disorders, and also increasingly in psychoses.

Behaviour therapy

This is a practically orientated form of treatment, in which patients are assisted in changing unhelpful behaviour, such as helping patients to implement carefully graded exposure to the feared stimulus in phobias.

Cognitive behaviour therapy

Cognitive behaviour therapy (CBT) combines the methods of behaviour therapy and cognitive therapy. It is the most widely available and extensively researched psychological treatment.

Problem-solving therapy

This is a simplified brief form of CBT, which helps patients actively tackle problems in a structured way (Box 28.18). It can be delivered by non-psychiatric doctors and nurses after appropriate training and is commonly used to help patients who self-harm in response to a situational crisis.

Psychodynamic psychotherapy

This treatment, also known as 'interpretive psychotherapy', was pioneered by Freud, Jung and Klein, among others. It is based on the theory that early life experience generates powerful but unconscious motivations. Psychotherapy aims to help the patient to become aware of these unconscious factors on the assumption that, once identified, their negative effects are reduced. The relationship between therapist and patient is used as a therapeutic tool to identify issues in patients' relationships with others, particularly parents, which may be replicated or transferred to their relationship with the therapist. Explicit discussion of this relationship (transference) is the basis for the treatment, which traditionally requires frequent sessions over a period of months or even years.

i 28.18 Stages of problem-solving therapy

- Define and list problems
- Choose one to work on
- List possible solutions
- Evaluate these and choose the best
- Try it out
- Evaluate the result
- Repeat until problems are resolved

Interpersonal psychotherapy

Interpersonal psychotherapy (IPT) is a specific form of brief psychotherapy that focuses on patients' current interpersonal relationships and is an effective treatment for mild to moderate depression.

Social interventions

Some adverse social factors, such as unemployment, may not be readily amenable to intervention but others, such as access to benefits and poor housing, may be. Patients can be helped to address these problems themselves by being taught problem-solving. Befrienders and day centres can reduce social isolation, benefits advisers can ensure appropriate financial assistance, and medical recommendations can be made to local housing departments to help patients obtain more appropriate accommodation.

Psychiatric disorders

Dementia

Dementia is a clinical syndrome characterised by a loss of previously acquired intellectual function in the absence of impairment of arousal. It affects 5% of those over 65 and 20% of those over 85. It is defined as a global impairment of cognitive function and is typically progressive and non-reversible. There are many subtypes (Box 28.19) but Alzheimer's disease and diffuse vascular dementia are the most common. Rarer causes of dementia should be actively sought in younger patients and those with short histories.

i 28.19 Subtypes and causes of dementia

Type	Common	Less common	Rare
Vascular	Diffuse small-vessel disease	Amyloid angiopathy Multiple emboli	Cerebral vasculitis Systemic lupus erythematosus
Inherited	Alzheimer's disease	Fronto-temporal dementia Leukodystrophies Huntington's disease Wilson's disease Dystrophia myotonica Lewy body dementia Progressive supranuclear palsy	Mitochondrial encephalopathies Cortico-basal degeneration
Neoplastic (p. 1110)	Secondary deposits	Primary cerebral tumour	Paraneoplastic syndrome (limbic encephalitis)
Inflammatory	–	Multiple sclerosis	Sarcoidosis
Traumatic	Chronic subdural haematoma Post-head injury	Punch-drunk syndrome	–
Hydrocephalus (p. 1132)		Communicating/non-communicating 'normal pressure' hydrocephalus	–
Toxic/nutritional	Alcohol	Thiamin deficiency Vitamin B_{12} deficiency	Anoxia/carbon monoxide poisoning Heavy metal poisoning
Infective	–	Syphilis HIV	Post-encephalitis Whipple's disease Subacute sclerosing panencephalitis
Prion diseases (p. 1126)	–	Sporadic Creutzfeldt–Jakob disease (CJD)	Variant CJD Kuru Gerstmann–Sträussler–Scheinker disease

Pathogenesis

Dementia may be divided into 'cortical' and 'subcortical' types, depending on the clinical features.

Clinical features

The usual presentation is with a disturbance of personality or memory dysfunction. A careful history is essential and it is important to interview both the patient and a close family member. Simple bedside tests, such as the MoCA (p. 1182), are useful in assessing the nature and severity of the cognitive deficit, although a more intensive neuropsychological assessment may sometimes be required, especially if there is diagnostic uncertainty. It is important to exclude a focal brain lesion. This is done by determining that there is cognitive disturbance in more than one area. Mental state assessment is important to seek evidence of depression, which may coexist with or occasionally cause apparent cognitive impairment. Many of the primary degenerative diseases that cause dementia have characteristic features that may allow a specific diagnosis during life. Creutzfeldt–Jakob disease, for example, is usually quickly progressive (over months) and is associated with myoclonus. The more slowly progressive dementias are more difficult to distinguish during life, but fronto-temporal dementia typically presents with signs of temporal or frontal lobe dysfunction, whereas Lewy body dementia may present with visual hallucinations. The course may also help to distinguish types of dementia. Gradual worsening suggests Alzheimer's disease, whereas stepwise deterioration is typical of vascular dementia.

Investigations

The aim is to seek treatable causes and to estimate prognosis. This is done using a standard set of investigations (Box 28.20). Imaging of the brain can exclude potentially treatable structural lesions, such as hydrocephalus, cerebral tumour or chronic subdural haematoma, though the only abnormality usually seen is that of generalised atrophy. An electroencephalogram (EEG) may be helpful if Creutzfeldt–Jakob disease is suspected, as characteristic abnormalities of generalised periodic sharp wave pattern are usually observed. If the initial tests are negative, more invasive investigations, such as lumbar puncture or, very rarely, brain biopsy, may be indicated.

Management

This is mainly directed at addressing treatable causes and providing support for patients and carers. Tackling risk factors may slow deterioration, e.g. effective management of hypertension in vascular dementia, or abstinence and vitamin replacement in toxic/nutritional dementias. Psychotropic drugs may have a role in alleviating symptoms, such as disturbance of sleep, perception or mood, but should be used with care because of an increased mortality in patients who have been treated long-term with these agents. Sedation is not a substitute for good care of patients and carers or, in the later stages, attentive residential nursing care. In the UK, incapacity and mental health legislation may be required to manage patients' financial and domestic affairs, as well as to determine their safe placement. If the diagnosis is Alzheimer-type dementia, cholinesterase inhibitors and memantine may slow progression for a time.

i 28.20 Initial investigation of dementia

In most patients

- Imaging of head (computed tomography and/or magnetic resonance imaging)
- Blood tests:
  - Full blood count, erythrocyte sedimentation rate
  - Urea and electrolytes, glucose
  - Calcium, liver function tests
  - Thyroid function tests
  - Vitamin B_{12}
  - Syphilis serology
  - ANA, anti-dsDNA
- Chest X-ray
- Electroencephalography

In selected patients

- Lumbar puncture
- HIV serology
- Brain biopsy

(ANA = antinuclear antibody; anti-dsDNA = anti-double-stranded DNA)

Alzheimer's disease

Alzheimer's disease is the most common form of dementia. It increases in prevalence with age and is rare in people under 45 years.

Pathogenesis

Genetic factors play an important role and about 15% of cases are familial. These cases fall into two main groups: early-onset disease with autosomal dominant inheritance and a later-onset group where the inheritance is polygenic. Mutations in several genes have been described but most are rare and/or of small effect. The inheritance of one of the alleles of apolipoprotein ε (apo ε4) is associated with an increased risk of developing the disease (2–4 times higher in heterozygotes and 6–8 times higher in homozygotes). Its presence is, however, neither necessary nor sufficient for the development of the disease and so genetic testing for ApoE4 is not clinically useful. The brain in Alzheimer's disease is macroscopically atrophic, particularly the cerebral cortex and hippocampus. Histologically, the disease is characterised by the presence of senile plaques and neurofibrillary tangles in the cerebral cortex. Histochemical staining demonstrates significant quantities of amyloid in the plaques (Fig. 28.4); these typically stain positive for the protein ubiquitin, which normally is involved in targeting unwanted or damaged proteins for degradation. This has led to the suggestion that the disease may be due to defects in the ability of neuronal cells to degrade unwanted proteins. Many different neurotransmitter abnormalities have also been described. In particular, there is impairment of cholinergic transmission, although abnormalities of noradrenaline (norepinephrine), 5-HT, glutamate and substance P have also been described.

Clinical features

The key clinical feature is impairment of the ability to remember new information. Hence, patients present with gradual impairment of memory, usually in association with disorders of other cortical functions. Short- and long-term memory are both affected but defects in the former are usually more obvious. Later in the course of the disease, typical features include apraxia, visuo-spatial impairment and aphasia. In the early stages of the disease, patients may notice these problems, but as the disease progresses it is common for patients to deny that there is anything wrong (anosognosia). In this situation, patients are

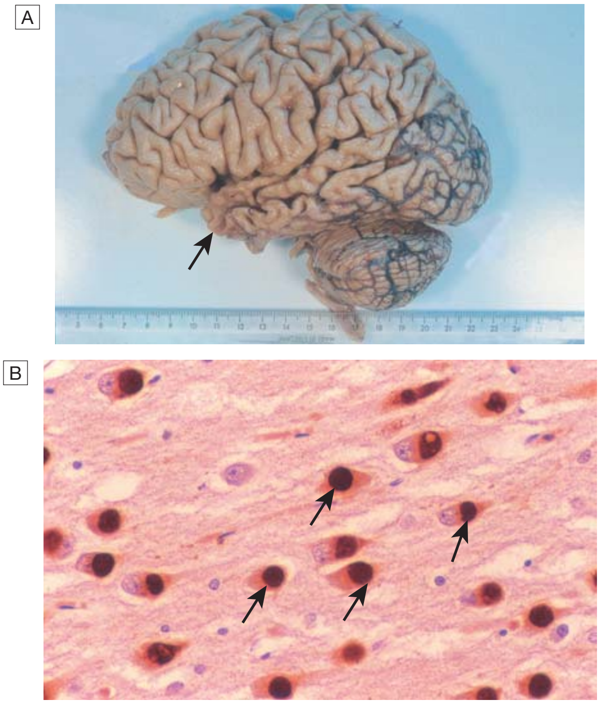

Fig. 28.5 **Fronto-temporal dementia.** **A** Lateral view of formalin-fixed brain from a patient who died of Pick's disease, showing gyral atrophy of frontal and parietal lobes and a more severe degree of atrophy affecting the anterior half of the temporal lobe (arrow). **B** High power (× 200) view of hippocampal pyramidal layer, prepared with monoclonal anti-tau antibody. Many neuronal cell bodies contain sharply circumscribed, spherical cytoplasmic inclusion bodies (Pick bodies, arrows). *A and B, Courtesy of Dr J. Xuereb.*

often brought to medical attention by their carers. Depression is commonly present. Occasionally, patients become aggressive, and the clinical features can be made acutely worse by intercurrent physical disease.

Patients typically present with subjective memory loss, sometimes getting lost in familiar locations. A history of progressive memory loss and associated functional impairment, corroborated by an informant, is the key to making the diagnosis. Cognitive testing and neuroimaging can be helpful but in themselves are not diagnostic.

Investigations

Investigation is aimed at excluding treatable causes of dementia (see Box 28.19), as histological confirmation of the diagnosis usually occurs only after death.

Management

Treatment with anticholinesterases, such as donepezil, rivastigmine and galantamine, has been shown to be of some benefit at slowing progression of cognitive impairment in the early stages of the disease while post-synaptic cholinergic receptors are still available. The *N*-methyl-D-aspartate (NMDA) receptor antagonist memantine slightly enhances learning and memory in early disease and can also be useful in selected patients with more advanced disease. Novel treatments are under development to block amyloid plaque formation directly, by inhibiting the enzyme γ-secretase. Non-pharmacological approaches include the provision of a familiar environment for the patient and support for the carers. Many patients are depressed, and if this is confirmed, treatment with antidepressant medication may be helpful.

Fronto-temporal dementia

Fronto-temporal dementia encompasses a number of different syndromes characterised by behaviour abnormalities and impairment of language. Symptoms usually occur before the age of 60 and the prevalence has been estimated at 15 per 100 000 in the population aged between 45 and 65 years. The three major clinical subtypes are behavioural-variant fronto-temporal dementia, primary progressive aphasia and semantic dementia. Pick's disease is a common cause of the first two in particular. Genetic factors play an important role and familial cases have been described caused by mutations in several genes, including *MAPT*, which encodes microtubule-associated protein tau, *GRN*, *TPD43*, *FUS*, *VCP* and *C9orf72*. The causal mutations trigger abnormal accumulation of tau and other proteins in brain tissue, which are seen as cytoplasmic inclusion bodies on histological examination (Fig. 28.5). It is of interest that many of the gene mutations that cause fronto-temporal dementia are also associated with amyotrophic lateral sclerosis (p. 1116), suggesting that these disorders share a similar pathogenic basis in which neuronal degeneration is caused by accumulation of abnormal proteins. The clinical presentation may be with personality change due to frontal lobe involvement or with language disturbance due to temporal lobe involvement. In contrast to Alzheimer's disease, memory is relatively preserved in the early stages. There is no specific treatment. Disinhibition and compulsive behaviours can

be helped by selective serotonin re-uptake inhibitors (SSRIs). Although Alzheimer's and fronto-temporal dementia share certain symptoms, they cannot be treated with the same pharmacological agents because the cholinergic systems are not affected in the latter.

Lewy body dementia

This neurodegenerative disorder is clinically characterised by dementia and signs of Parkinson's disease. It is often inherited and mutations in the α-synuclein and β-synuclein genes have been identified in affected patients. These mutations result in accumulation of abnormal protein aggregates in neurons that contain the protein α-synuclein in association with other proteins, including ubiquitin (see Fig. 25.31, p. 1112). The cognitive state often fluctuates and there is a high incidence of visual hallucinations. Affected individuals are particularly sensitive to the side-effects of anti-parkinsonian medication and also to antipsychotic drugs. There is no curative treatment but anticholinesterase drugs can be helpful in slowing progression of cognitive impairment.

Alcohol misuse and dependence

Alcohol consumption associated with social, psychological and physical problems constitutes misuse. The criteria for alcohol dependence, a more restricted term, are shown in Box 28.21. Approximately one-quarter of male patients in general hospital medical wards in the UK have a current or previous alcohol problem.

Pathogenesis

Availability of alcohol and social patterns of use appear to be the most important factors. Genetic factors predispose to dependence. The majority of people who misuse alcohol do not have an associated psychiatric disorder, but a few drink heavily in an attempt to relieve anxiety or depression.

Clinical features

The modes of presentation of alcohol misuse and complications are summarised below.

Social problems

Common features include absenteeism from work, unemployment, marital tensions, child abuse, financial difficulties and problems with the law, such as violence and traffic offences.

Low mood

Low mood is common since alcohol has a direct depressant effect and heavy drinking creates numerous social problems. Attempted and completed suicide are associated with alcohol misuse.

Anxiety

People who are anxious may use alcohol as a means of relieving anxiety in the short term and this can develop into dependence. Conversely, alcohol withdrawal increases anxiety.

Alcohol withdrawal syndrome

The features are described in Box 28.22. Symptoms usually become maximal about 2–3 days after the last drink and can include seizures. The term 'delirium tremens' is used to describe severe alcohol withdrawal syndrome characterised by both delirium (characteristically, agitation and visual hallucinations) and physiological hyper-arousal (tremor, sweating and tachycardia). It has a significant mortality and morbidity (Box 28.22).

Hallucinations

Hallucinations (characteristically visual but sometimes in other modalities) are common in delirium tremens. Less common is the phenomenon called 'alcoholic hallucinosis', where a patient with alcohol dependence experiences auditory hallucination in clear consciousness at a time when they are not withdrawing from alcohol.

i 28.21 Criteria for alcohol dependence

- Narrowing of the drinking repertoire
- Priority of drinking over other activities (salience)
- Tolerance of effects of alcohol
- Repeated withdrawal symptoms
- Relief of withdrawal symptoms by further drinking
- Subjective compulsion to drink
- Reinstatement of drinking behaviour after abstinence

i 28.22 Presentation and consequences of chronic alcohol misuse

Acute intoxication

- Emotional and behavioural disturbance
- Medical problems: hypoglycaemia, ketoacidosis, aspiration of vomit, respiratory depression
- Accidents, injuries sustained in fights

Withdrawal phenomena

- Psychological symptoms: restlessness, anxiety, panic attacks
- Autonomic symptoms: tachycardia, sweating, pupil dilatation, nausea, vomiting
- Delirium: agitation, hallucinations (classically 'Lilliputian'), illusions, delusions
- Seizures

Consequences of harmful use

Medical

- Neurological: peripheral neuropathy, cerebellar degeneration, cerebral haemorrhage, dementia
- Hepatic: fatty change and cirrhosis, liver cancer
- Gastrointestinal: oesophagitis, gastritis, pancreatitis, oesophageal cancer, Mallory–Weiss syndrome, malabsorption, oesophageal varices
- Respiratory: pulmonary tuberculosis, pneumonia
- Skin: spider naevi, palmar erythema, Dupuytren's contractures, telangiectasias
- Cardiac: cardiomyopathy, hypertension
- Musculoskeletal: myopathy, fractures
- Endocrine and metabolic: pseudo-Cushing's syndrome, hypoglycaemia, gout
- Reproductive: hypogonadism, fetal alcohol syndrome, infertility

Psychiatric and cerebral

- Depression
- Alcoholic hallucinosis
- Alcoholic 'blackouts'
- Wernicke's encephalopathy: nystagmus or ophthalmoplegia with ataxia and delirium
- Korsakoff's syndrome: short-term memory deficits leading to confabulation

Wernicke–Korsakoff syndrome

This is a rare but important indirect complication of chronic alcohol misuse. It is an organic brain disorder resulting from damage to the mamillary bodies, dorsomedial nuclei of the thalamus and adjacent areas of periventricular grey matter caused by a deficiency of thiamin (vitamin B_1). The syndrome most commonly results from long-standing heavy drinking and an inadequate diet but can also arise from malabsorption or even protracted vomiting. Wernicke's encephalopathy (nystagmus or ophthalmoplegia with ataxia and delirium) often presents acutely and, without prompt treatment (see below), can progress and become irreversible. Korsakoff's syndrome (severe short-term memory deficits and confabulation) can develop chronically or acutely (with Wernicke's).

Alcohol-related brain damage

The term alcohol-related brain damage (ARBD) is often used as a collective description of the many brain pathologies associated with alcohol excess, which often coexist in the same patient. Acute alcohol intoxication causes ataxia, slurred speech, emotional incontinence and aggression. Very heavy drinkers may experience periods of amnesia for events that occurred during bouts of intoxication, termed 'alcoholic blackouts'. Established alcohol dependence may lead to 'alcoholic dementia', a global cognitive impairment resembling Alzheimer's disease, but which does not progress and may even improve if the patient becomes abstinent. Heavy alcohol use can damage the brain indirectly through Wernicke–Korsakoff syndrome (see above), head injury, hypoglycaemia and encephalopathy (p. 864).

Effects on other organs

These are protean and virtually any organ can be involved (Box 28.22). These effects are discussed in detail in other chapters in this book.

Diagnosis

The diagnosis of alcohol excess may emerge while taking the patient's history, but many patients do not tell the truth about their alcohol intake. Alcohol misuse may also present through its effects on one or more aspects of the patient's life, as listed above. Alcohol dependence commonly presents with withdrawal in those admitted to hospital, as they can no longer maintain their high alcohol intake in this setting.

Management

For the person misusing alcohol, provision of clear information from a doctor about the harmful effects of alcohol and safe levels of consumption is often all that is needed. In more serious cases, patients may have to be advised to alter leisure activities or change jobs to help them to reduce their consumption. Psychological treatment is used for people who have recurrent relapses and is usually available at specialised centres. Support to stop drinking is also provided by voluntary organisations, such as Alcoholics Anonymous (AA) in the UK.

Alcohol withdrawal syndromes can be prevented, or treated once established, with long-acting benzodiazepines. Large doses may be required (such as diazepam 20 mg 4 times daily), tailed off over a period of 5–7 days as symptoms subside. Prevention of the Wernicke–Korsakoff syndrome requires the immediate use of high doses of thiamin, which is initially given parenterally in the form of Pabrinex (two vials 3 times daily for 48 hrs, longer if symptoms persist) and then orally (100 mg 3 times daily). There is no treatment for Wernicke–Korsakoff syndrome once it has arisen. The risk of side-effects, such as respiratory depression with benzodiazepines and anaphylaxis with Pabrinex, is small when weighed against the potential benefits of treatment.

Acamprosate (666 mg 3 times daily) may help to maintain abstinence by reducing the craving for alcohol. Disulfiram (200–400 mg daily) can be given as a deterrent to patients who have difficulty resisting the impulse to drink after becoming abstinent. It blocks the metabolism of alcohol, causing acetaldehyde to accumulate. When alcohol is consumed, an unpleasant reaction follows, with headache, flushing and nausea. Disulfiram is always an adjunct to other treatments, especially supportive psychotherapy. Treatment with antidepressants may be required if depression is severe or does not resolve with abstinence. Antipsychotics, such as chlorpromazine (100 mg 3 times daily), are needed for alcoholic hallucinosis. Although such treatment may be successful, there is a high relapse rate.

Prognosis

Between 80% and 90% of patients with established alcohol dependence syndrome who embark on medically supervised detoxification will successfully complete detoxification without encountering significant complications. Sustaining abstinence is more challenging than achieving it, however. Studies indicate that 1 year after successful detoxification, only 20% of patients will remain abstinent. This figure rises to approximately 30% for patients who are engaged with alcohol services, and to over 40% if such specialist support is combined with supervised disulfiram treatment.

Substance misuse disorder

Dependence on and misuse of both illegal and prescribed drugs is a major problem worldwide. Drugs of misuse are described in detail in Chapter 7. They can be grouped as follows.

Sedatives

These commonly give rise to physical dependence, the manifestations of which are tolerance and a withdrawal syndrome. Drugs include benzodiazepines, opiates (including morphine, heroin, methadone and dihydrocodeine) and barbiturates (now rarely prescribed). Overdosage with sedatives can be fatal, primarily as a result of respiratory depression (Ch. 7). Withdrawal from opiates is notoriously unpleasant, and withdrawal from benzodiazepines and barbiturates can cause prolonged anxiety and even hallucinations and/or seizures.

Intravenous opiate users are prone to bacterial infections, hepatitis B (p. 873), hepatitis C (p. 877) and HIV infection (Ch. 12) through needle contamination. Accidental overdose is common, mainly because of the varied and uncertain potency of illicit supplies of the drug. The withdrawal syndrome, which can start within 12 hours of last use, presents with intense craving, rhinorrhoea, lacrimation, yawning, perspiration, shivering, piloerection, vomiting, diarrhoea and abdominal cramps. Examination reveals tachycardia, hypertension, mydriasis and facial flushing.

28

Stimulants

Stimulant drugs include amphetamines and cocaine. They are less dangerous than the sedatives in overdose, although they can cause cardiac and cerebrovascular problems through their pressor effects. Physical dependence syndromes do not arise, but withdrawal causes a rebound lowering in mood and can give rise to an intense craving for further use, especially in any form

of drug with a rapid onset and offset of effect, such as crack cocaine. Chronic ingestion can cause a paranoid psychosis similar to schizophrenia. A 'toxic psychosis' (delirium) can occur with high levels of consumption. Unpleasant tactile hallucinations described as 'like ants crawling under the skin' (formication) may be prominent in either acute intoxication or withdrawal.

Hallucinogens

The hallucinogens are a disparate group of drugs that cause prominent sensory disturbances. They include cannabis, ecstasy, lysergic acid diethylamide (LSD), *Psilocybin* (magic mushrooms) and a variety of synthetic cannabinoids (as one of the so-called 'legal highs' or 'novel psychoactive substances'). A toxic confusional state can occur after heavy cannabis consumption. Acute psychotic episodes are well recognised, especially in those with a family or personal history of psychosis, and there is evidence that prolonged heavy use increases the risk of developing schizophrenia. Paranoid psychoses have been reported in association with ecstasy. A chronic psychosis has also been documented after regular LSD use.

Organic solvents

Solvent inhalation (glue sniffing) is popular in some adolescent groups. Solvents produce acute intoxication characterised by euphoria, excitement, dizziness and a floating sensation. Further inhalation leads to loss of consciousness; death can occur from the direct toxic effect of the solvent, or from asphyxiation if the substance is inhaled from a plastic bag.

Pathogenesis

Many of the causal factors for alcohol misuse also apply to substance misuse. The main factors are the psychological and behavioural vulnerabilities described above, cultural pressures, particularly within a peer group, and availability of a drug. In the case of some drugs such as opiates, medical over-prescribing has increased their availability, but there has also been a relative decline in the price of illegal drugs. Most drug users take a range of drugs – so-called polydrug misuse.

Diagnosis

As with alcohol, the diagnosis either may be apparent from the history and examination, or may be made only once the patient presents with a complication. Drug screening of samples of urine or blood can be valuable in confirming the diagnosis, especially if the patient persists in denial.

Management

The first step is to determine whether patients wish to stop using the drug. If they do not, they can still benefit from advice about how to minimise harm from their habit, such as how to obtain and use clean needles for those who inject. For those who are physically dependent on sedative drugs, substitute prescribing (using methadone, for example, in opiate dependence) may help stabilise their lives sufficiently to allow a gradual reduction in dosage until they reach abstinence. Some specialist units offer inpatient detoxification. For details of the medical management of overdose, see page 135. The drug lofexidine, a centrally acting α-agonist, can be useful in treating the autonomic symptoms of opiate withdrawal, as can clonidine, although this carries a risk of hypotension and is best used by specialists. Long-acting opiate antagonists, such as naltrexone, may also have a place, again in specialist hands, in blocking the euphoriant effects of the opiate, thereby reducing addiction.

In some cases, complete opiate withdrawal is not successful and the patient functions better if maintained on regular doses of oral methadone as an outpatient. This decision to prescribe long-term methadone should be taken only by a specialist, and carried out under long-term supervision at a specialist drug treatment centre.

Substitute prescribing is neither necessary nor possible for the hallucinogens and stimulants, but the principles of management are the same as those that should accompany prescribing for the sedatives. These include identifying problems associated with the drug misuse that may serve to maintain it, and intervening where possible. Intervention may be directed at physical illness, psychiatric comorbidity, social problems or family disharmony.

Relapsing patients and those with complications should be referred to specialist drug misuse services. Support can also be provided by self-help groups and voluntary bodies, such as Narcotics Anonymous (NA) in the UK.

Schizophrenia

Schizophrenia is characterised by delusions, hallucinations and lack of insight. Acute schizophrenia may also present with disturbed behaviour, disordered thinking, or with insidious social withdrawal and other so-called negative symptoms and less obvious delusions and hallucinations. Schizophrenia occurs worldwide in all ethnic groups with a prevalence of about 0.5%. It is more common in men (1.4 to 1). Children of an affected parent have an approximate 10% risk of developing the illness, but this rises to 50% if an identical twin is affected. The usual age of onset is the mid-twenties but can be older, particularly in women.

Pathogenesis

There is a strong genetic contribution, usually involving many susceptibility genes, each of small effect, but 2–3% of cases can be attributed to increased or decreased copies of genes (so-called 'copy number variations', p. 44). Environmental risk factors include a history of obstetric complications at the time of the patient's birth and urban upbringing. Brain imaging techniques have identified subtle structural abnormalities in groups of people with schizophrenia, including an overall decrease in brain size (by about 3% on average), with a relatively greater reduction in temporal lobe volume (5–10%). Episodes of acute schizophrenia may be precipitated by social stress and also by cannabis, which increases dopamine turnover. Consequently, schizophrenia is now viewed as a neurodevelopmental disorder, caused by abnormalities of brain development associated with genetic predisposition and early environmental influences, but precipitated by later triggers.

Clinical features

Acute schizophrenia should be suspected in any individual with bizarre behaviour accompanied by delusions and hallucinations that are not due to organic brain disease or substance misuse. The characteristic clinical features are listed in Box 28.23. Hallucinations are typically auditory but can occur in any sensory modality. They commonly involve voices from outside the head that talk to or about the person. Sometimes the voices repeat the person's thoughts. Patients may also describe 'passivity of thought', experienced as disturbances in the normal privacy of thinking, such as the delusional belief that their thoughts are being 'withdrawn' from them and perhaps 'broadcast' to others, and/or that alien thoughts are being 'inserted' into their mind.

28.23 Symptoms of schizophrenia

First-rank symptoms of acute schizophrenia

- A = Auditory hallucinations – second- or third-person/écho de la pensée
- B = Broadcasting, insertion/withdrawal of thoughts
- C = Controlled feelings, impulses or acts ('passivity' experiences/ phenomena)
- D = Delusional perception (a particular experience is bizarrely interpreted)

Symptoms of chronic schizophrenia (negative symptoms)

- Flattened (blunted) affect
- Apathy and loss of drive (avolition)
- Social isolation/withdrawal (autism)
- Poverty of speech (alogia)
- Poor self-care

Other characteristic symptoms are delusions of control: believing that one's emotions, impulses or acts are controlled by others. Another phenomenon is delusional perception, a delusion that arises suddenly alongside a normal perception, such as 'I saw the moon and I immediately knew he was evil.' Other, less common, symptoms may occur, including thought disorder, as manifest by incomprehensible speech, and abnormalities of movement, such as those in which the patient can become immobile or adopt awkward postures for prolonged periods (catatonia).

Diagnosis

The diagnosis is made primarily on clinical grounds but investigations may be required to rule out organic brain disease. The main differential diagnosis of schizophrenia (Box 28.24) includes:

- *Other functional psychoses*, particularly psychotic depression and mania, in which delusions and hallucinations are congruent with a marked mood disturbance (negative in depression and grandiose in mania). Schizophrenia must also be differentiated from specific delusional disorders that are not associated with the other typical features of schizophrenia.
- *Organic psychoses*, including delirium, in which there is impairment of consciousness and loss of orientation (not found in schizophrenia), typically with visual hallucinations; drug misuse, particularly in young people; and temporal lobe epilepsy with psychotic symptoms, in which olfactory and gustatory hallucinations may occur.

Many of those who experience acute schizophrenia go on to develop a chronic state in which the acute, so-called positive symptoms resolve, or at least do not dominate the clinical picture, leaving so-called negative symptoms that include blunt affect, apathy, social isolation, poverty of speech and poor self-care. Patients with chronic schizophrenia may also manifest positive symptoms, particularly when under stress, and it can be difficult for those who do not know the patient to judge whether or not these are signs of an acute relapse.

Investigations

As in dementia, investigations are focused on excluding a treatable cause, such as a slow-growing brain tumour, temporal lobe epilepsy, neurosyphilis or various autoimmune conditions. These are required only in patients with neurological or other organic symptoms or signs.

28.24 Differential diagnosis of schizophrenia

Alternative diagnosis	Distinguishing features
Other functional psychoses	
Delusional disorders	Absence of specific features of schizophrenia
Psychotic depression	Prominent depressive symptoms
Manic episode	Prominent manic symptoms
Schizoaffective disorder	Mood and schizophrenia symptoms both prominent
Puerperal psychosis	Acute onset after childbirth
Organic disorders	
Drug-induced psychosis	Evidence of drug or alcohol misuse
Side-effects of prescribed drugs	Levodopa, methyldopa, glucocorticoids, antimalarial drugs
Temporal lobe epilepsy	Other evidence of seizures
Delirium	Visual hallucinations, impaired consciousness
Dementia	Age, established cognitive impairment
Huntington's disease	Family history, choreiform movements, dementia

Management

First-episode schizophrenia usually requires admission to hospital because patients lack the insight that they are ill and are unwilling to accept treatment. In some cases, they may be at risk of harming themselves or others. Subsequent acute relapses and chronic schizophrenia are now usually managed in the community.

Drug treatment

Antipsychotic agents are effective against the positive symptoms of schizophrenia in the majority of cases. They take 2–4 weeks to be maximally effective but have some beneficial effects shortly after administration. Treatment is then ideally continued to prevent relapse. In a patient with a first episode of schizophrenia this will usually be for 1 or 2 years, but in patients with multiple episodes treatment may be required for many years. The benefits of prolonged treatment must be weighed against the adverse effects, which include extrapyramidal side-effects (EPSE) like acute dystonic reactions (which may require treatment with parenteral anticholinergics), akathisia and parkinsonism. For long-term use, antipsychotic agents are often given by slow-release (depot) injections to improve adherence.

A number of antipsychotic agents are available (Box 28.25). These may be divided into conventional (first-generation) drugs such as chlorpromazine and haloperidol, and novel or second-generation drugs such as olanzapine and clozapine. All work by blocking D_2 dopamine receptors in the brain. Patients who have not responded to conventional drugs may respond to newer agents, which are also less likely to produce unwanted EPSE but do tend to cause greater weight gain and metabolic disturbances, such as dyslipidaemia. Clozapine can be remarkably effective in those who do not respond to other antipsychotics but can cause agranulocytosis in about 1% of patients in the first few months. Prescription therefore requires regular monitoring of white blood cell count, initially on a weekly basis, then fortnightly and monthly thereafter. Clozapine should not be stopped suddenly because of the likelihood of relapse. Adverse effects of antipsychotic drugs are listed in Box 28.26. Two serious adverse effects deserve special mention.

Neuroleptic malignant syndrome This is a rare but serious condition characterised by fever, tremor and rigidity, autonomic instability

28.25 Antipsychotic drugs

Group	Drug	Usual adult dose[1]
Phenothiazines	Chlorpromazine	400–600 mg daily
Butyrophenones	Haloperidol	8–12 mg daily
Thioxanthenes	Flupentixol decanoate	40 mg fortnightly (depot injection)
Diphenylbutylpiperidines	Pimozide	8–10 mg daily
Substituted benzamides	Sulpiride	800–1200 mg daily
Dibenzodiazepines[2]	Clozapine	300–600 mg daily
Benzisoxazole[2]	Risperidone	4–6 mg daily
Thienobenzodiazepines[2]	Olanzapine	10–15 mg daily
Dibenzothiazepines[2]	Quetiapine	300–600 mg daily

[1]Lower or higher doses may be required in some patients. [2]Second-generation antipsychotics.

28.26 Adverse effects of antipsychotic drugs

Weight gain due to increased appetite

Effects due to dopamine blockade*
- Acute dystonia
- Akathisia (motor restlessness)
- Parkinsonism
- Tardive dyskinesia
- Gynaecomastia
- Galactorrhoea

Effects due to cholinergic blockade
- Dry mouth
- Blurred vision
- Impotence
- Constipation
- Urinary retention

Hypersensitivity reactions
- Blood dyscrasias (neutropenia with clozapine)
- Cholestatic jaundice
- Photosensitive dermatitis

Ocular complications
- Corneal and lens opacities (long-term use)

*Less severe with clozapine, quetiapine and olanzapine, possibly because of strong 5-hydroxytrytamine-blocking effect and relatively weak dopamine blockade.

and delirium. Characteristic laboratory findings are an elevated creatinine phosphokinase and leucocytosis. Antipsychotic medication must be stopped immediately and supportive therapy provided, often in an intensive care unit. Treatment includes ensuring hydration and reducing hyperthermia. Dantrolene sodium and bromocriptine may be helpful. Mortality is 20% untreated and 5% with treatment.

Cardiac arrhythmias Antipsychotic medications cause prolongation of the QTc interval, which may be associated with ventricular tachycardia, torsades de pointes and sudden death. If this occurs, treatment should be stopped, with careful electrocardiographic monitoring and treatment of serious arrhythmias if necessary (p. 479).

Psychological treatment

Psychological treatment, including general support for the patient and family, is now seen as an essential component of management. CBT may help patients to cope with symptoms. There is evidence that personal and/or family education, when given as part of an integrated treatment package, reduces the rate of relapse.

Social treatment

After an acute episode of schizophrenia has been controlled by drug therapy, social rehabilitation may be required. Recurrent illness is likely to cause disruption to patients' relationships and their ability to manage their accommodation and occupation; consequently, patients with schizophrenia often need help to obtain housing and employment. A graded return to employment and sometimes a period of supported accommodation are required.

Patients with chronic schizophrenia have particular difficulties and may need long-term, supervised accommodation. This now tends to be in supported accommodation in the community. Patients may also benefit from sheltered employment if they are unable to participate effectively in the labour market. Ongoing contact with a health worker allows monitoring for signs of relapse, sometimes as part of a multidisciplinary team working to agreed plans (the 'care programme approach'). Partly because of a tendency to inactivity, smoking and a poor diet, patients with chronic schizophrenia are at increased risk of cardiovascular disease, diabetes and stroke, and require proactive medical as well as psychiatric care.

Prognosis

About one-third of those who develop an acute schizophrenic episode have a good outcome. One-third develop chronic, incapacitating schizophrenia, and the remainder largely recover after each episode but suffer relapses. Most affected patients cannot work or live independently. Schizophrenia is associated with suicide and up to 10% of patients take their own lives.

Mood disorders

Mood or affective disorders include:

- *unipolar depression*: one or more episodes of low mood and associated symptoms
- *bipolar disorder*: episodes of elevated mood interspersed with episodes of depression
- *dysthymia*: chronic low-grade depressed mood without sufficient other symptoms to count as 'clinically significant' or 'major' depression.

Depression

Major depressive disorder has a prevalence of 5% in the general population and approximately 10–20% in chronically ill medical outpatients. It is a major cause of disability and suicide. If comorbid with a medical condition, depression magnifies disability, diminishes adherence to medical treatment and rehabilitation, and may even shorten life expectancy.

Pathogenesis

There is a genetic predisposition to depression, especially when of early onset. The genetic predisposition is mediated by variants in a large number of genes and loci of small effect rather than mutations in single genes. Adversity and emotional deprivation early in life also predispose to depression. Depressive episodes are often, but not always, triggered by stressful life events (especially those that involve loss or imposed change), including medical illnesses. Associated biological factors include

hypofunction of monoamine neurotransmitter systems, including 5-HT and noradrenaline (norepinephrine), and abnormalities of the hypothalamic–pituitary–adrenal (HPA) axis, which results in elevated cortisol levels that do not suppress with dexamethasone.

Diagnosis

The symptoms are listed in Box 28.6. Depression may be mild, moderate or severe. It may also be recurrent or chronic. It can be both a complication of a medical condition and a cause of MUS (see below), so physical examination is essential; an associated medical condition should always be considered, particularly where there is no past history of depression and no apparent psychological precipitant.

Investigations

Investigations are not usually required unless there are clinical grounds for suspicion of an underlying medical disorder, such as Cushing's syndrome or hypothyroidism.

Management

Pharmacological and psychological treatments both work in depression. In practice, the choice is determined by patient preference and local availability. Severe depression complicated by psychotic symptoms, dehydration or suicide risk may require ECT.

Drug treatment

Antidepressant drugs are effective in moderate and severe depression, whether it is primary or secondary to a medical illness. The most suitable drug for an individual patient will depend on their previous response, likely side-effects, their concurrent illnesses and potential drug interactions. Commonly used antidepressants are shown in Box 28.27.

The different classes of antidepressant have similar efficacy and about three-quarters of patients respond to treatment. Successful treatment requires the patient to take an appropriate dose of an effective drug for an adequate period. For those who do not respond, a proportion will do so if changed to another class of antidepressant. The patient's progress must be monitored and, after recovery, treatment should be continued for at least 6–12 months to reduce the high risk of relapse. The dose should then be tapered off over several weeks to avoid discontinuation symptoms. The Scottish Intercollegiate Guidelines Network (SIGN) and National Institute for Health and Clinical Excellence (NICE) have published treatment guidelines.

Tricyclic antidepressants Tricyclic antidepressant (TCA) agents inhibit re-uptake of the amines noradrenaline (norepinephrine) and 5-HT at synaptic clefts. The therapeutic effect is noticeable within a week or two. Adverse effects, such as sedation, anticholinergic effects, postural hypotension, lowering of the seizure threshold and cardiotoxicity, can be troublesome during this period. TCAs may be dangerous in overdose and should be used with caution in people who have coexisting heart disease, glaucoma and prostatism.

Selective serotonin re-uptake inhibitors Selective serotonin reuptake inhibitors (SSRIs) are less cardiotoxic and less sedative than TCAs, and have fewer anticholinergic effects. They are safer in overdose but can still cause QTc prolongation, headache, nausea, anorexia and sexual dysfunction. They can also interact with other drugs increasing serotonin (5-HT), to produce 'serotonin syndrome'. This is a rare syndrome of neuromuscular hyperactivity, autonomic hyperactivity and agitation, and potentially seizures, hyperthermia, delirium and even death.

Noradrenaline (norepinephrine) re-uptake inhibitors These agents inhibit noradrenaline uptake at the synaptic cleft but have additional pharmacological effects. Venlafaxine and duloxetine also act as serotonin re-uptake inhibitors, whereas mirtazapine also acts as an antagonist at 5-HT2a, 5-HT2c and 5-HT3 receptors. These drugs have similar efficacy to the agents listed above but a different adverse-effect profile.

Monoamine oxidase inhibitors Monoamine oxidase inhibitors (MAOIs) increase the availability of neurotransmitters at synaptic clefts by inhibiting metabolism of noradrenaline (norepinephrine) and 5-HT. They are now rarely prescribed in the UK, since they can cause potentially dangerous interactions with drugs such as amphetamines and certain anaesthetic agents, and with foods rich in tyramine (such as cheese and red wine). This is due to accumulation of amines in the systemic circulation, causing a potentially fatal hypertensive crisis.

Psychological treatment

Both CBT and interpersonal therapy are as effective as antidepressants for mild to moderate depression. Antidepressant drugs are, however, preferred for severe depression. Drug and psychological treatments can be used in combination.

Prognosis

Over 50% of people who have had one depressive episode and over 90% of people who have had three or more episodes will have another. The risk of suicide in an individual who has had a depressive disorder is 10 times greater than in the general population.

Bipolar disorder

Bipolar disorder is an episodic disturbance with interspersed periods of depressed and elevated mood; the latter is known

i 28.27 Antidepressant drugs

Group	Drug	Usual adult dose*
Tricyclic antidepressants	Amitriptyline Imipramine Dosulepin Clomipramine	75–150 mg daily 75–150 mg daily 75–150 mg daily 75–150 mg daily
Selective serotonin re-uptake inhibitors (SSRIs)	Citalopram Escitalopram Fluoxetine Sertraline Paroxetine	20–40 mg daily 10–20 mg daily 20–60 mg daily 50–100 mg daily 20–50 mg daily
Monoamine oxidase inhibitors	Phenelzine Tranylcypromine Moclobemide	45–90 mg daily 20–40 mg daily 300–600 mg daily
Noradrenaline (norepinephrine) re-uptake inhibitors and SSRIs	Venlafaxine Duloxetine	75–375 mg daily 60–120 mg daily
Noradrenaline and specific serotonergic inhibitor	Mirtazapine	15–45 mg daily

*Higher doses may be required in some patients: see guidelines.

28

as hypomania when mild or short-lived, or mania when severe or chronic. The lifetime risk of developing bipolar disorder is approximately 1–2%. Onset is usually in the twenties, and men and women are equally affected.

Pathogenesis

Bipolar disorder is strongly heritable (approximately 70%). Relatives of patients have an increased incidence of both bipolar and unipolar affective disorder. A number of genetic variants of small effect have been identified by genome-wide association studies. Life events, such as physical illness, sleep deprivation and medication, may also play a role in triggering episodes.

Diagnosis

The diagnosis is based on clear evidence of episodes of depression and mania. Isolated episodes of hypomania or mania do occur but they are usually preceded or followed by an episode of depression. Psychotic symptoms may occur in both the depressive and the manic phases, with delusions and hallucinations that are usually in keeping with the mood disturbance. This is described as an affective psychosis. Patients who present with symptoms of both bipolar disorder and schizophrenia in equal measure may be given a diagnosis of schizoaffective disorder.

Management

Depression should be treated as described above. If antidepressants are prescribed, however, they should be combined with a mood-stabilising drug (see below) to avoid 'switching' the patients into (hypo)mania. Manic episodes and psychotic symptoms usually respond well to antipsychotic drugs (see Box 28.25).

Prophylaxis to prevent recurrent episodes of depression and mania with mood-stabilising agents is important. The main drugs used are lithium and sodium valproate but lamotrigine, olanzapine, quetiapine and risperidone are increasingly employed. Caution must be exercised when stopping these drugs, as a relapse may follow.

Lithium carbonate is the drug of first choice. It is also used for acute mania, and in combination with a tricyclic as an adjuvant treatment for resistant depression. It has a narrow therapeutic range, so regular blood monitoring is required to maintain a serum level of 0.5–1.0 mmol/L. Toxic effects include nausea, vomiting, tremor and convulsions. With long-term treatment, weight gain, hypothyroidism, increased calcium and parathyroid hormone (PTH), nephrogenic diabetes insipidus (p. 687) and renal failure can occur. Thyroid and renal function should be checked before treatment is started and regularly thereafter. Lithium may be teratogenic and should not be prescribed during the first trimester of pregnancy.

Anticonvulsants, such as sodium valproate and lamotrigine, and the antipsychotic drug olanzapine can all be used as prophylaxis in bipolar disorder, usually as a second-line alternative to lithium. Valproate conveys a high risk of birth defects and should not be used in women of child-bearing age. Olanzapine can cause significant weight gain. (For a list of the adverse effects of antipsychotic drugs, see Box 28.26.)

Prognosis

The relapse rate of bipolar disorder is high, although patients may be perfectly well between episodes. After one episode, the annual average risk of relapse is about 10–15%, which doubles after more than three episodes. There is a substantially increased lifetime risk of suicide of 5–10%.

Anxiety disorders

These are characterised by the emotion of anxiety, worrisome thoughts, avoidance behaviours and the somatic symptoms of autonomic arousal. Anxiety disorders are divided into three main subtypes: phobic, paroxysmal (panic) and generalised (Box 28.28). The nature and prominence of the somatic symptoms often lead the patient to present initially to medical services. Anxiety may be stress-related and phobic anxiety may follow an unpleasant incident. Many patients with anxiety also have depression.

Clinical features

Phobic anxiety disorder

A phobia is an abnormal or excessive fear of a specific object or situation, which leads to avoidance of it (such as excessive fear of dying in an air crash, leading to avoidance of flying). A generalised phobia of going out alone or being in crowded places is called 'agoraphobia'. Phobic responses can develop to medical procedures such as venepuncture.

Panic disorder

Panic disorder describes repeated attacks of severe anxiety, which are not restricted to any particular situation or circumstances. Somatic symptoms, such as chest pain, palpitations and paraesthesia in lips and fingers, are common. The symptoms are in part due to involuntary over-breathing (hyperventilation). Patients with panic attacks often fear that they are suffering from a serious illness, such as a heart attack or stroke, and seek emergency medical attention. Panic disorder may coexist with agoraphobia.

Generalised anxiety disorder

This is a chronic anxiety state associated with uncontrollable worry. The associated somatic symptoms of muscle tension and bowel disturbance often lead to a medical presentation.

Diagnosis

The diagnosis is made on the basis of clinical history and typical symptoms, as described above. Where a diagnosis of panic disorder is suspected, it can be confirmed by asking the patient to hyperventilate deliberately for 1–2 minutes and observing whether the symptoms are reproduced. A finding of respiratory alkalosis on arterial blood gas measurement is indicative of chronic hyperventilation.

Management

Psychological treatment

Explanation and reassurance are essential, especially when patients fear they have a serious medical condition. Specific

i 28.28 Classification of anxiety disorders

	Phobic anxiety disorder	Panic disorder	Generalised anxiety disorder
Occurrence	Situational	Paroxysmal	Persistent
Behaviour	Avoidance	Escape	Agitation
Cognitions	Fear of situation	Fear of symptoms	Worry
Symptoms	On exposure	Episodic	Persistent

treatment may be needed. Treatments include relaxation, graded exposure (desensitisation) to feared situations for phobic disorders, and CBT.

Drug treatment

Antidepressants are the drugs of first choice (p. 1199). The therapeutic dose is usually higher for anxiety disorders than for depression and there is some evidence that, within their respective classes, paroxetine (SSRI) and clomipramine (TCA) have greatest efficacy against anxiety disorders. Early side-effects of antidepressants can lead to a worsening of anxiety symptoms in the first 2 weeks and patients should be warned of this.

Benzodiazepines are useful in the short term but regular (>3 doses per week) long-term use carries a very high risk of dependence. Regular prescriptions should therefore be limited to 3 weeks; beyond that, prescriptions should be restricted to occasional use as required, with periodic review to guard against dose escalation. Short-acting benzodiazepines, such as lorazepam, have a rapid onset and provide symptomatic relief for up to 2 hours but have the greatest potential for dependence. Longer-acting drugs, such as diazepam, can take an hour to take effect when given orally but provide symptomatic relief for up to 12 hours. A β-blocker, such as propranolol, can help when somatic symptoms are prominent.

Obsessive–compulsive disorder

Obsessive–compulsive disorder (OCD) is characterised by 'obsessions' – thoughts, images or impulses that are recurrent, unwanted and usually anxiety-provoking, but recognised as one's own. In many cases, the obsessions give rise to 'compulsions, which are repeated acts performed to relieve the anxiety. Unlike the anxiety disorders discussed above, which are more common in women, OCD is equally common in men and women.

Clinical features

Common examples include thoughts of contamination, giving rise to repeated and ritualised hand-washing, and thoughts of having forgotten something, giving rise to time-consuming repeated checking. The differential diagnoses include normal checking behaviour and delusional beliefs about thought possession.

Diagnosis

The diagnosis is made on the basis of the typical history, as described above.

Management

OCD usually responds to some degree to antidepressant drugs (high-dose clomipramine or SSRI; see Box 28.27) and to 'exposure response prevention' – a form of CBT in which patients are encouraged to expose themselves to the feared thought or situation without performing the anxiety-relieving compulsions. Relapses are common, however, and the condition often becomes chronic.

Stress-related disorders

Acute stress reaction

Following a stressful event, such as a serious medical diagnosis or a major accident, some people develop a characteristic pattern of symptoms: an initial state of 'daze' or bewilderment is followed by altered activity (withdrawal or agitation), often with anxiety. The symptoms are transient and usually resolve completely within a few days. The lay media often describes this as 'shock'.

Adjustment disorder

A more common psychological response to a major stressor is a less severe but more prolonged emotional reaction.

Clinical features

The predominant symptom is usually depression and/or anxiety, which is insufficiently persistent or intense to merit a diagnosis of depressive or anxiety disorder. There may also be anger, aggressive behaviour and associated excessive alcohol use. Symptoms develop within a month of the onset of the stress, and their duration and severity reflect the course of the underlying stressor. Grief reactions following bereavement are a particular type of adjustment disorder. They manifest as a brief period of emotional numbing, followed by a period of distress lasting several weeks, during which sorrow, tearfulness, sleep disturbance, a sense of futility, anger and 'bargaining' are common. Perceptual distortions may occur, including misinterpreting sounds as the dead person's voice or 'seeing' the dead person. 'Pathological grief' describes a grief reaction that is abnormally intense or persistent.

Diagnosis

The diagnosis is made on the basis of the typical history following a stressful life event, as described above.

Management

Ongoing contact with and support from a doctor or another person who can listen, reassure, explain and advise are often all that is needed. Most patients do not require psychotropic medication, although benzodiazepines reduce arousal in acute stress reactions and can aid sleep in adjustment disorders.

Post-traumatic stress disorder

Post-traumatic stress disorder (PTSD) is a delayed and/or protracted response to a stressful event of an exceptionally threatening or catastrophic nature. Examples of such events include natural disasters, terrorist activity, serious accidents and witnessing violent deaths. PTSD may also sometimes occur after distressing medical treatments or intensive care.

Clinical features

The development of PTSD is usually delayed from a few days to several months between the traumatic event and the onset of symptoms. Typical symptoms are recurrent intrusive memories (flashbacks) of the trauma; sleep disturbance, especially nightmares (usually of the traumatic event) from which the patient awakes in a state of anxiety; symptoms of autonomic arousal (anxiety, palpitations, enhanced startle); emotional blunting; and avoidance of situations that evoke memories of the trauma. Anxiety and depression are often associated and excessive use of alcohol or drugs frequently complicates the clinical picture.

Diagnosis

The diagnosis is made on the basis of the typical clinical features following a traumatic life event.

Management

In the immediate aftermath of a significant trauma, the main aim is to provide support, direct advice and the opportunity

for emotional catharsis (debriefing may actually be harmful). In established PTSD, structured psychological approaches (CBT, eye movement desensitisation and reprocessing (EMDR), and stress management) are effective. Antidepressant drugs are moderately effective.

Prognosis

The condition runs a fluctuating course, with most patients recovering within 2 years. In a small proportion, the symptoms become chronic.

Somatoform disorders

The essential feature of these disorders is that the somatic symptoms are not explained by a medical condition (medically unexplained symptoms), nor better diagnosed as part of a depressive or anxiety disorder. The derivation of the term 'somatoform' is 'body-like'. Several syndromes are described within this category; there is considerable overlap between them, both in the underlying causes and in the clinical presentation.

Pathogenesis

The cause of somatoform disorders is incompletely understood but contributory factors include depression and anxiety, the erroneous interpretation of somatic symptoms as evidence of disease, excessive concern with physical illness and a tendency to seek medical care. A family history or previous history of a particular condition may have shaped the patient's beliefs about illness. Doctors may exacerbate the problem, either by dismissing the complaints as non-existent or by over-emphasising and investigating the possibility of disease.

Clinical features

Somatoform disorders can present in several different ways, as described below.

Somatoform autonomic dysfunction

This describes somatic symptoms referable to bodily organs that are largely under the control of the autonomic nervous system. The most common examples involve the cardiovascular system ('cardiac neurosis'), respiratory system ('psychogenic hyperventilation') and gut ('psychogenic vomiting' and 'irritable bowel syndrome'). Antidepressant drugs and CBT may be helpful.

Somatoform pain disorder

This describes severe, persistent pain that cannot be adequately explained by a medical condition. Antidepressant drugs (especially tricyclics and dual action drugs such as duloxetine) are helpful, as are some of the anticonvulsant drugs, particularly carbamazepine, gabapentin and pregabalin. CBT and multidisciplinary pain management teams are also useful.

Chronic fatigue syndrome

Chronic fatigue syndrome (CFS) is characterised by excessive fatigue after minimal physical or mental exertion, poor concentration, dizziness, muscular aches and sleep disturbance. This pattern of symptoms may follow a viral infection such as infectious mononucleosis, influenza or hepatitis. Symptoms overlap with those of depression and anxiety. There is good evidence that many patients improve with carefully graded exercise and with CBT, as long as the benefits of such treatment are carefully explained.

28.29 Common presentations of dissociative (conversion) disorder

- Gait disturbance
- Loss of function in limbs
- Aphonia
- Non-epileptic seizures
- Sensory loss
- Blindness

Dissociative conversion disorders

Dissociative conversion disorders are characterised by a loss or distortion of neurological functioning that is not fully explained by organic disease. These may be psychological functions such as memory ('dissociative amnesia'), sensory functions such as vision ('dissociative blindness'), or motor functions ('functional gait disorder') (Box 28.29). The cause is unknown but there is an association with recent stress and with adverse childhood experiences, including physical and sexual abuse. Organic disease may precipitate dissociation and provide a model for symptoms. For example, non-epileptic seizures often occur in those with epilepsy. Treatment with CBT may be of benefit.

Somatisation disorder

This is defined as the occurrence of multiple medically unexplained physical symptoms affecting several bodily systems. It is also known as Briquet's syndrome after the physician who first described the presentation. Symptoms often start in early adult life but somatisation disorder can arise later, usually following an episode of physical illness. The disorder is much more common in women. Patients may undergo a multitude of negative investigations and unhelpful operations, particularly hysterectomy and cholecystectomy. There is no proven treatment except to try to ensure that unnecessary investigations and surgical procedures are avoided to minimise iatrogenic harm.

Hypochondriacal disorder

Patients with this condition have a strong fear or belief that they have a serious, often fatal, disease (such as cancer), and that fear persists despite appropriate medical reassurance. They are typically highly anxious and seek many medical opinions and investigations in futile but repeated attempts to relieve their fears.

Hypochondriacal disorder often resembles OCD, but in a small proportion of cases the conviction that disease is present reaches delusional intensity. The best-known example is that of parasitic infestation ('delusional parasitosis'), which leads patients to consult dermatologists. Treatment with CBT can be helpful. Patients who suffer delusions may benefit from antipsychotic medication. The condition may become chronic.

Body dysmorphic disorder

This is defined as a preoccupation with bodily shape or appearance, with the belief that one is disfigured in some way (previously known as 'dysmorphophobia'). People with this condition may make inappropriate requests for cosmetic surgery. Treatment with CBT or antidepressants may be helpful. The belief in disfigurement may sometimes be delusional, in which case antipsychotic drugs can help.

Management

The management of the various syndromes of medically unexplained complaints described above is based on the general principles outlined in Box 28.30 and discussed in more detail below.

i 28.30 General management principles for medically unexplained symptoms

- Take a full sympathetic history
- Exclude disease but avoid unnecessary investigation or referral
- Seek specific treatable psychiatric syndromes
- Demonstrate to patients that you believe their complaints
- Establish a collaborative relationship
- Give a positive explanation for the symptoms, including but not over-emphasising psychological factors
- Encourage a return to normal functioning

Reassurance

Patients should be asked what they are most worried about. Clearly, it may be unwise to state categorically that the patient does not have any disease, as that is difficult to establish with certainty. However, it can be emphasised that the probability of having a disease is low and that doctors often see patients with physical symptoms but no physical disease. If patients repeatedly ask for reassurance about the same health concern despite reassurance, they may have hypochondriasis.

Explanation

Patients need a positive explanation for their symptoms. It is unhelpful to say that symptoms are psychological or 'all in the mind'. Rather, a term such as 'functional' (meaning that the symptoms represent a reversible disturbance of bodily function) may be more acceptable. When possible, it is useful to describe a plausible physiological mechanism that is linked to psychological factors such as stress and implies that the symptoms are reversible. For example, in irritable bowel syndrome, psychological stress results in increased activation of the autonomic nervous system, which leads to constriction of smooth muscle in the gut wall, which in turn causes pain and bowel disturbance.

Advice

This should focus on how to overcome factors perpetuating the symptoms: for example, by resolving stressful social problems or by practising relaxation. The doctor can offer to review progress, to prescribe (for example) an antidepressant drug and, if appropriate, to refer for physiotherapy or psychological treatments such as CBT. The attitudes of relatives may need to be addressed if they have adopted an over-protective role, unwittingly reinforcing the patient's disability.

Drug treatment

Antidepressant drugs are often helpful, even if the patient is not depressed.

Psychological treatment

There is evidence for the effectiveness of CBT. Other psychological treatments such as IPT may also have a role.

Rehabilitation

Where there is chronic disability, particularly in dissociative (conversion) disorder, conventional physical rehabilitation may be the best approach.

Shared care

Ongoing planned care is required for patients with chronic intractable symptoms, especially those of somatisation disorder. Review by the same specialist, interspersed with visits to the same GP, is probably the best way to avoid unnecessary multiple re-referral for investigation, to ensure that treatable aspects of the patient's problems, such as depression, are actively managed and to prevent the GP from becoming demoralised.

Eating disorders

There are two well-defined eating disorders, anorexia nervosa (AN) and bulimia nervosa (BN); they share some overlapping features. Ninety per cent of people affected are female. There is a much higher prevalence of abnormal eating behaviour in the population that does not meet diagnostic criteria for AN or BN but may attract a diagnostic label such as 'binge eating disorder'. In developed societies, obesity is arguably a much greater problem but is usually considered to be more a disorder of lifestyle or physiology than a psychiatric disorder.

Anorexia nervosa

The lifetime risk of anorexia nervosa for women living in Europe is approximately 1–2% (for men it is <0.5%) with a peak age of onset of 15–19 years. Predisposing factors include familiality (both genetic and shared environmental factors appear to play a role) and 'neurotic' personality traits. The illness is often precipitated by weight loss, whether due to non-pathological dieting/increased exercise or physical illness such as gastrointestinal disorders or diabetes mellitus. Many sufferers do not engage with specialist services and it is not uncommon for the first presentation to be with a medical problem (Box 28.31) rather than to psychiatric services.

Clinical features

There is marked weight loss, arising from food avoidance, often in combination with bingeing, purging, excessive exercise and/or the use of diuretics and laxatives. Body image is profoundly disturbed so that, despite emaciation, patients still feel overweight and are terrified of weight gain. These preoccupations are intense and pervasive, and the false beliefs may be held with a conviction approaching the delusional. Anxiety and depressive symptoms are common accompaniments. Downy hair (lanugo) may develop on the back, forearms and cheeks. Extreme starvation is associated with a wide range of physiological and pathological bodily changes. All organ systems may be affected, although the most serious problems are cardiac and skeletal (Box 28.31).

Pathogenesis

The underlying cause is unclear but probably includes personality (high neuroticism), genetic (twin studies indicate heritability of 0.3–0.5) and environmental factors, including, in many societies, the social pressure on women to be thin.

Diagnosis

Diagnostic criteria are shown in Box 28.32. Differential diagnosis is from other causes of weight loss, including psychiatric disorders such as depression, and medical conditions such as inflammatory bowel disease, malabsorption, hypopituitarism and cancer, although it is important to remember that AN can coexist with any of these. The diagnosis is based on a pronounced fear of fatness despite being thin, and on the absence of an adequate alternative explanation for weight loss.

Management

The aims of management are to ensure patients' physical well-being while helping them to gain weight by addressing the

28.31 Medical consequences of eating disorders

Cardiac

- ECG abnormalities: T-wave inversion, ST depression and prolonged QTc interval
- Arrhythmias, including profound sinus bradycardia and ventricular tachycardia

Haematological

- Anaemia, thrombocytopenia and leucopenia

Endocrine

- Pubertal delay or arrest
- Growth retardation and short stature
- Amenorrhoea
- Sick euthyroid state

Metabolic

- Uraemia
- Renal calculi
- Osteoporosis

Gastrointestinal

- Constipation
- Abnormal liver function tests

28.32 Diagnostic criteria for eating disorders

Anorexia nervosa

- Weight loss of at least 15% of total body weight (or body mass index ≤17.5)
- Avoidance of high-calorie foods
- Distortion of body image so that patients regard themselves as fat even when grossly underweight
- Amenorrhoea for at least 3 months

Bulimia nervosa

- Recurrent bouts of binge eating
- Lack of self-control over eating during binges
- Self-induced vomiting, purgation or dieting after binges
- Weight maintained within normal limits

beliefs and behaviours that maintain the low weight. Treatment is usually given on an outpatient basis. Inpatient treatment should be reserved for those at risk of death from medical complications or from suicide. There is a limited evidence base for CBT-based psychological treatments. Family behaviour therapy (FBT) has efficacy among adolescent but not adult patients. Psychotropic drugs are of no proven benefit in AN but antidepressant medication may be indicated in those with clear-cut comorbid depressive disorder.

Weight gain is best achieved in a collaborative fashion. Compulsory admission and refeeding (including tube feeding) are very occasionally resorted to when patients are at risk of death and other measures have failed. While this may produce a short-term improvement in weight, it rarely changes long-term prognosis.

Prognosis

Two-thirds of patients with AN no longer meet diagnostic criteria at 5-year follow-up. However, long-term follow-up studies suggest that many sufferers continue to have a relatively low body mass index (BMI), suggesting that the symptoms do not completely resolve. Approximately 20% of patients develop a chronic, intractable disorder. Long-term follow-up studies demonstrate that minimum lifetime BMI is the strongest prognostic indicator (BMI <11.5 is associated with an standardised mortality ratio of 4–5). Other indicators of poor prognosis are comorbid BN and atypical demographics (very early or relatively late onset, male gender). Forty per cent of additional deaths are due to suicide, the remainder being due to complications of starvation.

Bulimia nervosa

The prevalence of BN is difficult to determine with precision, as only a small proportion of sufferers come to medical attention. It is believed to be more common than AN, with a similar gender ratio. Peak age of onset is slightly later than for AN, typically late adolescence or early adult life.

Clinical features

Patients with BN are usually at or near normal weight (unlike in AN), but display a morbid fear of fatness associated with disordered eating behaviour. They recurrently embark on eating binges, often followed by corrective measures such as self-induced vomiting.

Diagnosis

Diagnostic criteria are shown in Box 28.32. Physical signs of repeated self-induced vomiting include pitted teeth (from gastric acid), calluses on knuckles ('Russell's sign') and parotid gland enlargement. There are many associated physical complications, including the dental and oesophageal consequences of repeated vomiting, as well as electrolyte abnormalities, cardiac arrhythmias and renal problems (see Box 28.31).

Investigations

Self-induced vomiting and/or abuse of laxatives and diuretics can lead to clinically significant electrolyte disturbances, including hypokalaemia leading to cardiac arrhythmias. Hence it is good practice to measure urea and electrolytes and obtain an ECG whenever these behaviours are prominent in any patient and when BN is suspected in any medical inpatient. Repeated vomiting can also give rise to Mallory–Weiss tears and even oesophageal rupture; if symptoms are suggestive of these, an endoscopy should be performed.

Management

Treatment of bulimia with CBT achieves both short-term and long-term improvements. Guided self-help and IPT may also be of value. There is also evidence for benefit from the SSRI fluoxetine, but high doses of up to 60 mg daily may be required for a prolonged period of up to 1 year; this appears to be independent of the antidepressant effect.

Prognosis

Bulimia is not associated with increased mortality but a proportion of sufferers go on to develop anorexia. At 10-year follow-up, approximately 10% are still unwell, 20% have a subclinical degree of bulimia, and the remainder have recovered.

Personality disorders

Personality refers to the set of characteristics and behavioural traits that best describes an individual's patterns of interaction with the world. The intensity of particular traits varies from person to person, although certain ones, such as shyness or irritability, are displayed to some degree by most people. A personality disorder (PD) is diagnosed when an individual's personality causes persistent and severe problems for the person or for others.

Pathogenesis

Some PDs appear to have an inherited aspect (especially schizotypal and paranoid subtypes) but most are more clearly related to an unsatisfactory upbringing and adverse childhood experiences.

Clinical features

PD can present in various ways. For example, anxiety may be so pronounced that the individual rarely ventures into any situation where they fear scrutiny. Dissocial traits, such as disregard for the well-being of others and a lack of guilt concerning the adverse effects of one's actions on others, may occur. If pronounced, they may lead to damage to others, to criminal acts or to successful careers, such as in politics.

Diagnosis

It is possible to classify PD into several subtypes (such as emotionally unstable, antisocial or dependent), depending on the particular behavioural traits in question. A patient who meets diagnostic criteria for one subtype may also meet criteria for others. As allocation to one particular subtype gives little guidance to management or prognosis, classification is of limited value. Diagnosis requires a longitudinal perspective, with clear evidence that the patient's behavioural traits and pattern of interaction with the world have been present throughout their adult life, have been evident across a range of settings and have caused repeated and persistent problems. It can be difficult to achieve this during a single interview, and most psychiatrists warn against making a diagnosis of personality disorder until the patient has been seen several times and corroborative accounts have been obtained. It is common for PD to accompany other psychiatric conditions, making treatment of the latter more difficult and therefore affecting their prognosis.

Management

PDs usually persist throughout life and are not readily treated. They typically become less extreme with age but can re-emerge in the context of cognitive decline. Treatment options are limited but there is some evidence that emotionally unstable PD may respond to dialectical behavioural therapy (DBT). Anxious (avoidant) and obsessional (anankastic) PD may benefit from prescription of anxiolytic drugs, while paranoid/schizotypal PD may be improved by treatment with low doses of antipsychotic agents.

The problematic and inflexible patterns of interaction that characterise a PD are often apparent in the patient's interaction with health services and can present a challenge to both the service and the patient. Clear clinical communication supported by robust documentation can help to minimise any potential disruption.

Factitious disorder and malingering

Factitious disorder describes the repeated and deliberate production of the signs or symptoms of disease to obtain medical care.

Pathogenesis

It is difficult to understand what motivates a person to act in this way. Several theories have been proposed but the deception that lies at the heart of the condition makes it impossible to gather accurate data from which to draw reliable conclusions.

Clinical features

The disorder feigned is usually medical but can be a psychiatric illness (for example false reports of hallucinations or symptoms of depression). An example of a medical factitious disorder is dipping of a thermometer into a hot drink to fake a fever. Factitious disorder is uncommon and is important to distinguish from somatoform disorders. A suggested diagnostic algorithm is shown in Figure 28.6.

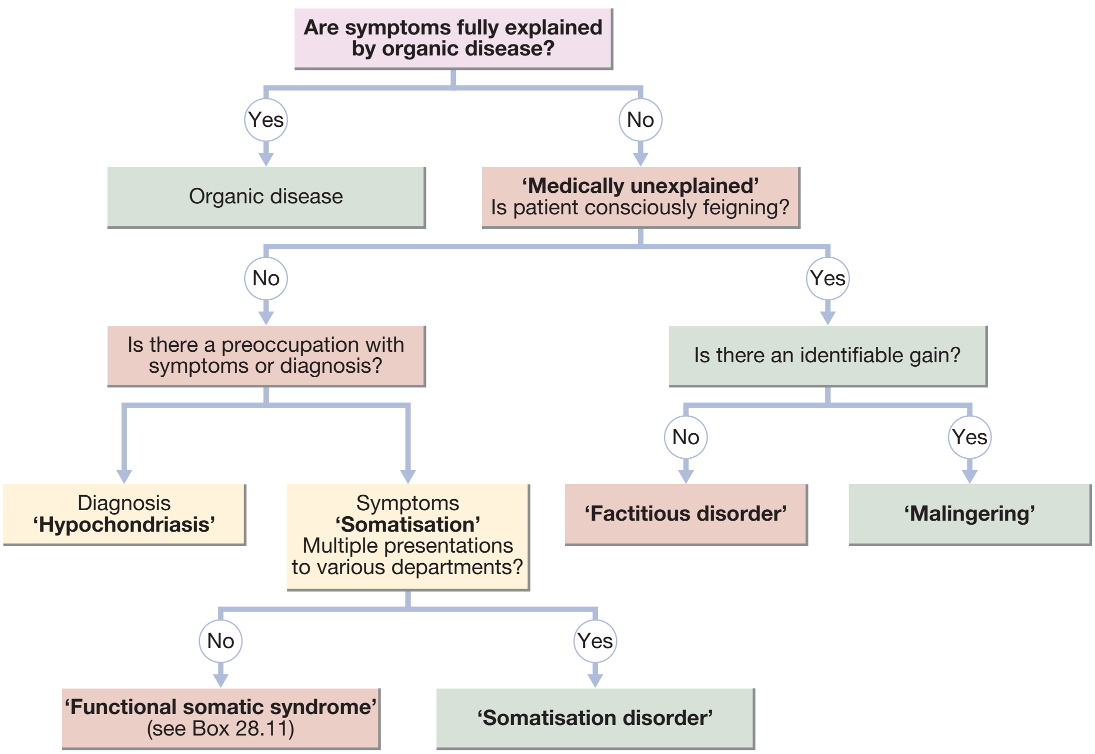

Fig. 28.6 Diagnosis of medically unexplained symptoms (MUS).

Münchausen's syndrome

This refers to a severe chronic form of factitious disorder. Patients characteristically travel widely, sometimes visiting several hospitals in one day. Although the condition is rare, such patients are memorable because they present so dramatically. The history can be convincing enough to persuade doctors to undertake investigations or initiate treatment, including exploratory surgery. It may be possible to trace the patient's history and show that they have presented similarly elsewhere, often changing name several times. Some emergency departments hold lists of such patients.

Malingering

Malingering is a description of behaviour, not a psychiatric diagnosis. It refers to the deliberate and conscious simulation of signs of disease and disability for an identifiable gain (patients have motives that are clear to them but which they initially conceal from doctors). Examples include the avoidance of burdensome responsibilities (such as work or court appearances) or the pursuit of financial gain (fraudulent claims for benefits or compensation). Malingering can be hard to detect at clinical assessment but is suggested by evasion or inconsistency in the history.

Management

Management is by gentle but firm confrontation with clear evidence of the fabrication of illness, together with an offer of psychological support. Treatment is usually declined but recognition of the condition may help to avoid further iatrogenic harm.

Puerperal psychiatric disorders

There are three important psychiatric presentations following childbirth. When managing these conditions, it is important always to consider both the mother and the baby, and their relationship (Box 28.33).

Post-partum blues

This is characterised by irritability, labile mood and tearfulness. About 80% of women are affected to some degree. Symptoms begin soon after childbirth, typically peak on about the fourth day and then resolve spontaneously within a few weeks. While the aetiology of baby blues is not fully understood, it is likely to be related to hormonal or physiological changes associated with childbirth. No treatment is required, other than to reassure the mother and to remain vigilant for development of post-partum depression.

28.33 Psychiatric illness and pregnancy

- **Psychiatric disorder and pregnancy**: always consider effects on mother, fetus and child.
- **Bipolar disorder**: women should have pre-conceptual advice because there is a very high risk of relapse following delivery and some mood stabilisers are teratogenic.
- **Psychiatric treatments and pregnancy**: always make an individual assessment of the risks and benefits taking into consideration effects on mother, fetus and child.
- **Post-partum low mood ('blues')**: weeks 1–3; most cases are transient.
- **Persistent low mood and anhedonia**: may indicate depressive illness.
- **Puerperal psychosis**: progresses rapidly and is an indication for psychiatric admission.

Post-partum depression

This occurs in 10–15% of women, with onset typically within a month of delivery (although women often suffer for some time before presenting). It can usually be differentiated from post-partum blues by the duration and severity of the symptoms, in particular anhedonia (loss of capacity for pleasure) and negative thoughts. Risk factors include a previous history of depression, a previous history of post-partum depression, antenatal depression and antenatal anxiety. Unlike depression arising at other times, post-partum depression is not more common in lower socioeconomic groups; the prevalence is similar across all social backgrounds. Diagnosis, explanation and reassurance are important. The usual psychological and drug treatments for depression should be considered (p. 1199) to minimise the impact on the mother and child at what is a very important time for both. A number of helpful guidelines are available to inform prescribing decisions. The potential risks to both mother and child should be considered and, if hospital admission is required, it should ideally be to a mother and baby unit.

Puerperal psychosis

This has its peak onset in the first 2 weeks after childbirth but can arise several weeks later. It is a rare but serious complication affecting approximately 1 in 500 women. There is a strong association with a personal or familial history of bipolar disorder. It usually takes the form of a manic or depressive psychosis but with sudden onset and fluctuation in severity. Delirium is rare with modern obstetric management but should still be considered in the differential diagnosis. Suspiciousness, concealment and impulsivity are common features of puerperal psychosis; hence the risks to both mother and baby are considerable. The clinical priority is to ensure the safety of both mother and baby and so psychiatric admission, ideally to a psychiatric mother and baby unit, is usually necessary. Pharmacological treatment reflects the clinical picture; antipsychotic medication is almost always indicated, augmented by antidepressants if the picture is of psychotic depression and/or by mood stabilisers if the picture is bipolar. Most women recover but the risk of recurrence following subsequent deliveries is 50% and some women will progress to psychotic episodes not associated with childbirth, usually bipolar disorder.

Psychiatric disorders during pregnancy

Pregnancy can affect the course of psychiatric illnesses and of bipolar affective disorder in particular. Mood-stabilising drugs such as lithium and valproate, which are prescribed for prophylaxis in bipolar disorder (p. 1200), are teratogenic and should be avoided whenever possible. Most guidelines recommend deferring conception until mood-stabilising medication is not required, or replacing the mood stabiliser with an antipsychotic such as chlorpromazine. Furthermore, the immediate post-partum period is associated with a dramatically increased risk of relapse in bipolar disorder: studies report relapse rates of up to 60% in the first 3 months after delivery in the absence of prophylactic medication. When relapse occurs following childbirth, not only are the stakes higher than at other times but also the onset of illness is more rapid, the symptoms more severe and concealment more pronounced. Post-partum relapse of bipolar affective

disorder requires urgent specialist treatment, usually comprising admission to a psychiatric mother and baby unit. Ideally, women with major mental disorders such as bipolar affective disorder should be offered expert pre-conception advice to help them make informed decisions about medication and other aspects of their psychiatric care. A comprehensive post-partum risk management plan should be agreed during pregnancy.

Psychiatry and the law

Medicine takes place in a legal framework, made up of legislation (statute law) drafted by parliament or other governing bodies, precedent built up from court judgements over time (case law), and established tradition (common law). Psychiatry is similar to other branches of medicine in the applicability of common and case law but differs in that patients with psychiatric disorders can also be subject to legislative requirements to remain in hospital or to undergo treatments they refuse, such as the administration of antipsychotic drugs to a patient with acute schizophrenia who lacks insight and whose symptoms and/or behaviour pose a risk to himself/herself or to others.

The UK has three different Mental Health Acts, covering England and Wales, Scotland, and Northern Ireland, and all of these have recently been revised. Other countries may have very different provisions. It is important for practitioners to be familiar with the relevant provisions that apply in their jurisdictions and are likely to arise in the clinical settings in which they work.

All the countries that make up the UK have also introduced Incapacity Acts in recent years, with detailed provisions covering medical treatments for patients incapable of consenting, whether this incapacity arises from physical or mental illness. In general, the guiding principle in British law is that people should be free to make their own decision about any proposed medical treatment, except where their ability to make and/or communicate that decision is demonstrably impaired (by mental illness or physical incapacity). Any restrictions or compulsions applied should be the minimum necessary, they should be applied only for as long as is necessary, and there should be a benefit to the patient that balances the restrictions imposed. There should also be provisions for appeals and oversight.

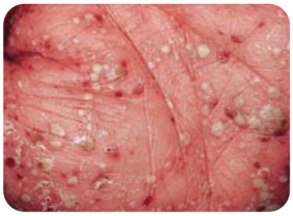
Dermatology



Clinical examination in skin disease

8 Detailed morphology of individual lesions

Use a magnifying lens in good lighting to assist
Use correct terminology (see definitions throughout text)

▲ Magnifying lens image of benign naevus

▲ Palmoplantar pustulosis

7 Overall description of individual lesions

Discrete, grouped, confluent, reticulate (lace-like), linear

6 Morphology of rash

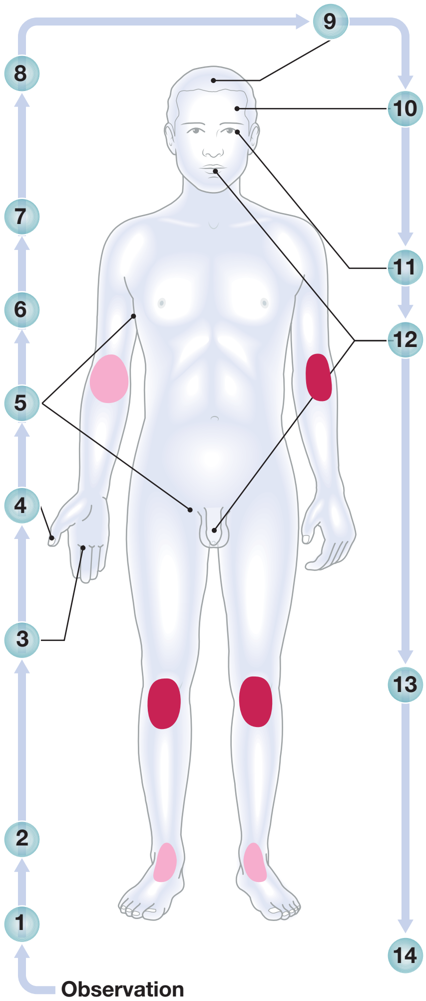
Monomorphic or polymorphic

5 Involvement of axillae/groins

e.g. hidradenitis suppurativa

4 Nail involvement

▲ Psoriatic changes in nails and peri-ungual involvement



3 Involvement of hands, including nail folds and finger webs

2 If symmetrical

- Extensor, e.g. psoriasis
- Flexor, e.g. eczema

1 Distribution of rash

Symmetrical vs asymmetrical
Proximal vs distal vs facial
Localised vs widespread

Observation

The patient must be undressed, with make-up and dressings removed, and examined in good lighting.
Consider the following:
- Age
- General health
- Distress
- Scratching

9 Examination of scalp

Hair loss
Scalp changes

Alopecia areata ◄

10 Involvement of face

Central
Hairline
Cheeks and nasal bridge: 'butterfly' distribution
Sparing of light-protected sites, e.g. behind ears, under chin

11 Eye involvement

e.g. Conjunctivitis/blepharitis in rosacea or eyelash loss in alopecia areata

12 Oral and genital involvement

▲ Reticulate (lacy) network on buccal mucosa in lichen planus. May also be genital involvement

13 Joint involvement

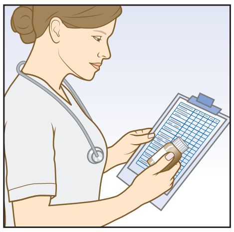
e.g. Psoriatic arthritis

▲ Arthritis, plaque psoriasis and psoriatic nail dystrophy

14 General medical examination

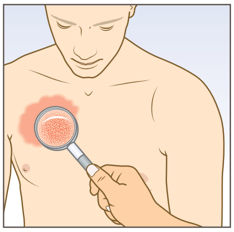
Including lymph nodes and other systems as indicated

It is tempting to examine the skin first. This is a mistake; take a history, then examine the skin and the rest of the patient.



1. History-taking

Include:

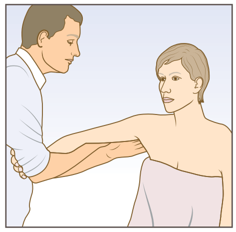


- Onset and course
- Exacerbating/relieving factors
- Past history of skin disease, atopy or autoimmune disease
- Social history, occupation, recreation
- Psychological impact, gauged by health-related life quality indices

2. Drug/allergy history

- Always take a detailed drug and allergy history
- Include all systemic and topical drugs, and over-the-counter preparations

3. Examination of skin



- Examine skin, hair, nails and mucous membranes
- Is it a rash or a lesion?
- Distribution and morphology important for rash

4. Closer inspection

- Use of a magnifying lens and/or dermatoscope may be invaluable
- Site, size and detailed morphology of a lesion are essential factors to elicit

5. General examination

- General examination, incl. peripheral lymph nodes, may be indicated/important
- Skin diseases may have systemic features (e.g. cardiovascular disease in psoriasis); many systemic diseases have dermatological features (e.g. diabetes)

6. Define type of lesion using correct terminology

Helps in differential diagnosis and allows colleagues to visualise the process. Other definitions are provided in the chapter.

Macule/patch

Macule: circumscribed flat area of colour change ≤ 1 cm diameter; patch: > 1 cm

Papule

Discrete elevation ≤ 1 cm diameter

Nodule

Like papule but deeper (into dermis or subcutaneous layer), > 1 cm diameter

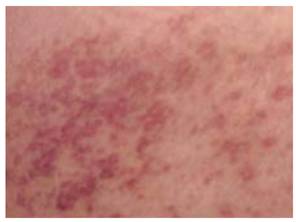
Plaque

Raised area > 1 cm diameter with flat top

Vesicle

Small (≤ 1 cm diameter) fluid-filled blister

Blisters/bullae



Large (> 1 cm diameter) fluid-filled blister

Pustule

Visible accumulation of pus in blister

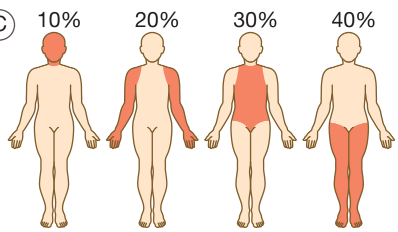
Petechiae/purpura

Petechiae: tiny macules due to extravascular blood in dermis; purpura: larger, may be palpable

7. Score activity

Tools for objective assessment of disease severity (e.g. Psoriasis Area and Severity Index, PASI) are important in assessing severity and treatment responses.

Four body parts are each scored individually



(A) Each of the four body parts is scored:

Redness (erythema)	0–4
Thickness (induration)	0–4
Scaling (desquamation)	0–4

(B) The area of each involved body part is scored:

0	0%
1	< 10%
2	10–29%
3	30–49%
4	50–69%
5	70–89%
6	90–100%

(C)

To find the PASI score, add together: (A) Sum for each part × (B) % of that part involved × (C) % weighting of that body part

Minimum = 0; maximum = 72

29

Diseases affecting the skin are common, and important because the absence of normal skin function, as well as sometimes being life-threatening, can severely impair quality of life. This may be exacerbated by the fact that people with skin disease can suffer the effects of stigma, often brought about by the ill-informed understanding of others with respect to skin diseases, particularly as regards visually disfiguring skin changes or the belief that they are contagious.

Skin diseases affect all ages and there are more than 2000 different types and presentations. Assessment of the skin is valuable in the management of anyone presenting with a medical problem and, conversely, assessment of the other body systems is important when managing primary skin diseases. This chapter concentrates on common skin diseases and those that are important components of general medical conditions. Skin infections, including those related to the human immunodeficiency virus (HIV), tuberculosis, leprosy (Hansen's disease) and syphilis are also discussed in Chapters 12, 17, 11 and 13, respectively.

Functional anatomy and physiology

The skin covers just under 2 m^2 in the average adult. The outer layer is the epidermis, a stratified squamous epithelium consisting mainly of keratinocytes. The epidermis is attached to, but separated from, the underlying dermis by the basement membrane. The dermis is less cellular and supports blood vessels, nerves and epidermal-derived appendages (hair follicles and sweat glands). Below it is the subcutis, consisting of adipose tissue.

Epidermis

In most sites, the epidermis is only 0.1–0.2 mm thick, except on the palms or soles, where it can extend to several millimetres. Keratinocytes make up approximately 90% of epidermal cells (Fig. 29.1). The main proliferative compartment is the basal layer. Keratinocytes synthesise a range of structural proteins, such as keratins, loricrin and filaggrin (filament aggregating protein), which play key roles in maintaining the skin's barrier function. Keratinocytes are also responsible for synthesis of vitamin D under the influence of ultraviolet B (UVB) light (p. 1049). There are more than 50 types of keratin and their expression varies by body site, site within the epidermis and disease state. Mutations of certain keratin genes can result in blistering disorders (p. 1254) and ichthyosis (characterised by scale without major inflammation). As keratinocytes migrate from the basal layer, they differentiate, producing a variety of protein and lipid products. Keratinocytes undergo apoptosis in the granular layer before losing their nuclei and becoming the flattened corneocytes of the stratum corneum (keratin layer). The epidermis is a site of lipid production, and the ability of the stratum corneum to act as a hydrophobic barrier is the result of its 'bricks and mortar' design; dead corneocytes with highly cross-linked protein membranes ('bricks') lie within a metabolically active lipid layer synthesised by keratinocytes ('mortar'). Terminal differentiation of keratinocytes relies on the keratin filaments being aggregated and this is, in part, mediated by filaggrin. Mutations of the filaggrin gene are found in icthyosis vulgaris and in some patients with atopic eczema (p. 1245).

The skin is a barrier against physical stresses. Cell-to-cell attachments must be able to transmit and dissipate stress, a function performed by desmosomes. Diseases that affect desmosomes, such as pemphigus (p. 1256), result in blistering due to keratinocyte separation.

The remaining 10% of epidermal cells are:

- *Langerhans' cells*: these are dendritic, bone marrow-derived cells that circulate between the epidermis and local lymph nodes. Their prime function is antigen presentation to lymphocytes. Other dermal antigen-presenting dendritic cells are also present.
- *Melanocytes*: these occur predominantly in the basal layer and are of neural crest origin. They synthesise the pigment melanin from tyrosine, package it in melanosomes and transfer it to surrounding keratinocytes via their dendritic processes.
- *Merkel cells*: these occur in the basal layer and are thought to play a role in signal transduction of fine touch. Their embryological derivation is unclear.

Basement membrane

The basement membrane (Fig. 29.1) is an anchor for the epidermis and allows movement of cells and nutrients between dermis and epidermis. The cell membrane of the epidermal basal cell is attached to the basement membrane via hemi-desmosomes. The lamina lucida lies immediately below the basal cell membrane and is composed predominantly of laminin. Anchoring filaments extend through the lamina lucida to attach to the lamina densa. This electron-dense layer consists mostly of type IV collagen; from it extend loops of type VII collagen, forming anchoring fibrils that fasten the basement membrane to the dermis.

Dermis

The dermis is vascular and supports the epidermis structurally and nutritionally. It varies in thickness from just over 1 mm on the inner forearm to 4 mm on the back. Fibroblasts are the predominant cells but others include mast cells, mononuclear phagocytes, T lymphocytes, dendritic cells, neurons and endothelial cells. The acellular part of the dermis consists mainly of collagen I and III, elastin and reticulin, synthesised by fibroblasts. Support is provided by an amorphous ground substance (mostly glycosaminoglycans, hyaluronic acid and dermatan sulphate), whose production and catabolism are altered by hormonal changes and ultraviolet radiation (UVR). Based on the pattern of collagen fibrils, the superficial dermis is termed the 'papillary dermis', and the deeper, coarser part is the 'reticular dermis'.

Epidermal appendages

Hair follicles

There are 3–5 million hair follicles, epidermal invaginations that develop during the second trimester. They occur throughout the skin, with the exception of palms, soles and parts of the genitalia (glabrous skin). The highest density of hair follicles is on the scalp (500–1000/cm^2). Newborns are covered with fine 'lanugo' hairs, which are usually non-pigmented and lack a central medulla; these are subsequently replaced by vellus hair, which is similar but more likely to be pigmented. By contrast, scalp hair becomes terminal hair, which is thicker with a central medulla, is usually pigmented and grows longer. At puberty, vellus hairs in hormonally sensitive regions, such as the axillary and genital areas, become terminal hairs.

Human hairs grow in a cycle with three phases: anagen (active hair growth), catagen (transitional phase) and telogen (resting phase). The duration of each phase varies by site. On the scalp, anagen lasts several years, catagen a few days and

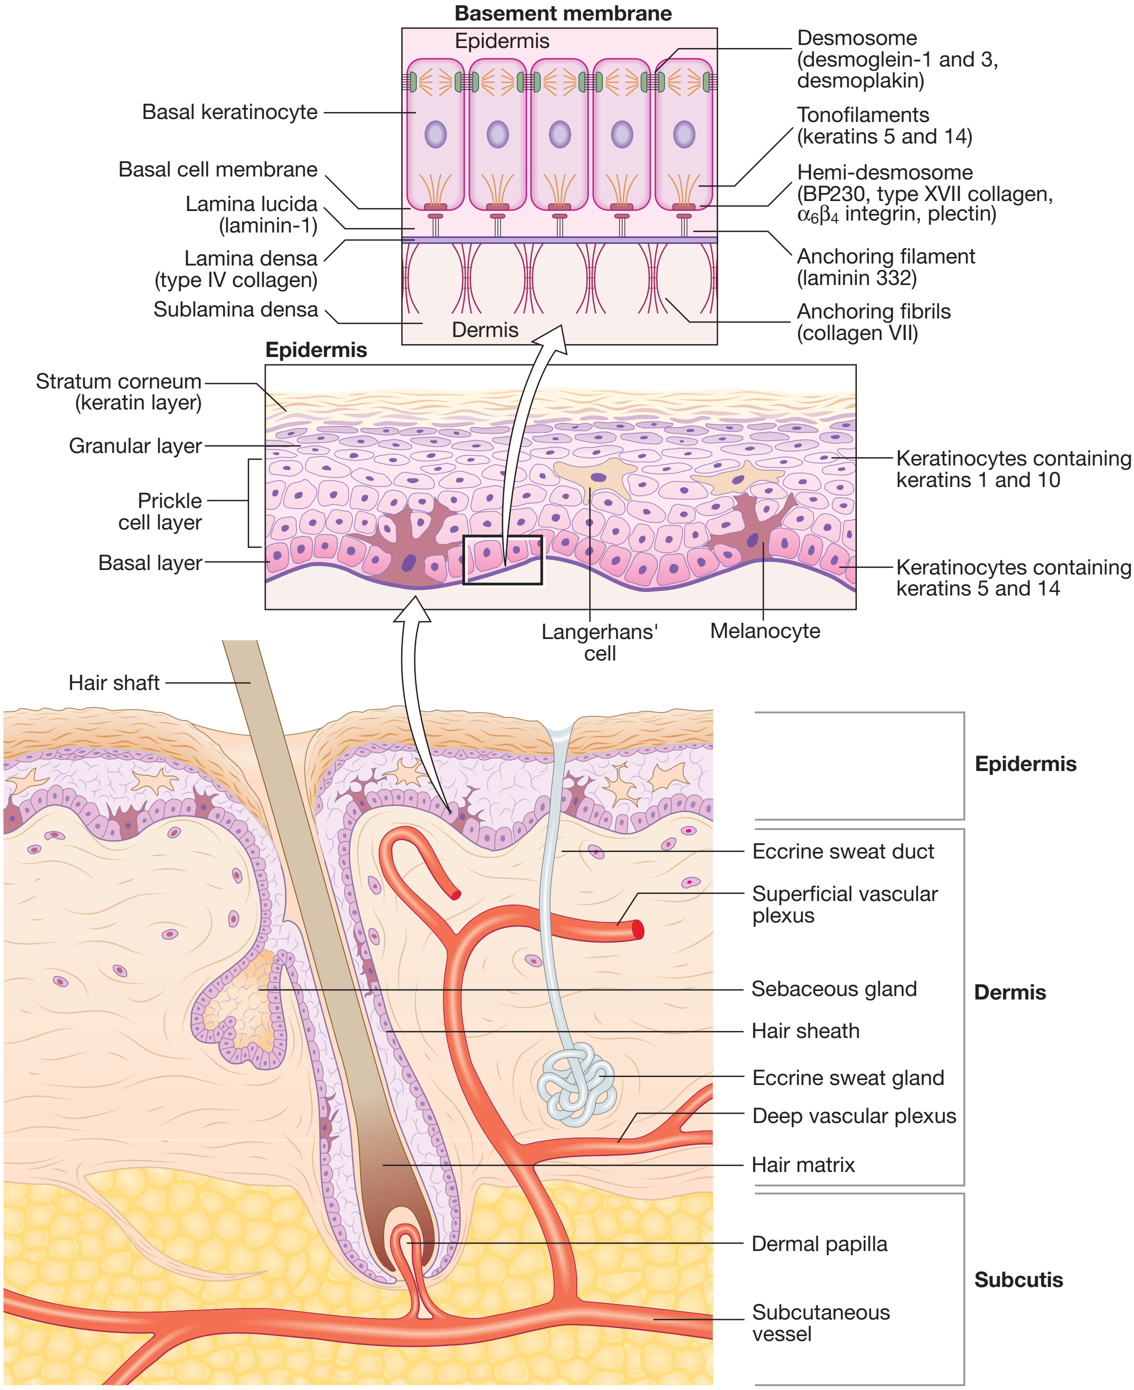


Fig. 29.1 Structure of normal skin.

telogen around 3 months. The length of hair at different sites reflects the differing lengths of anagen.

Sebaceous glands

Sebaceous glands are epidermal downgrowths, usually associated with hair follicles and composed of modified keratinocytes. The cells of the sebaceous gland (sebocytes) produce a range of lipids, discharging the contents into the duct around the hair follicle. Sebum excretion is under hormonal control, with androgens increasing it (as do progesterones, to a lesser degree) and oestrogens reducing it. In animals, sebum is important for hair waterproofing but its role in humans is unclear.

Sweat glands

Eccrine sweat glands develop in the second trimester and are also epidermal invaginations found all over the body. Their coiled ducts open directly on to the skin surface. They play a major role in thermoregulation and, unusually, are innervated by cholinergic fibres of the sympathetic nervous system. Eccrine glands of the palms and soles are innervated differently and are activated in the

'fight or flight' response. Apocrine sweat glands are restricted to the axillae and the mammary and genital areas, are connected to hair follicles and are not involved in thermoregulation.

Nails

Fingernail growth commences at approximately 8 weeks of gestation and is complete by 32 weeks. Toenails develop slightly later. The anatomy of the nail apparatus is covered later in the chapter (p. 1260).

Blood vessels and nerves

Human skin has a plentiful blood supply, arranged in superficial and deep plexuses consisting of arterioles, arterial and venous capillaries, and venules. The upper plexus in the papillary dermis communicates with the lower plexus at the junction between the dermis and the subcutis. Capillary loops arise from terminal arterioles in the horizontal papillary plexus. Blood vessels are supplied by sympathetic and parasympathetic nerves, with the relative contributions of the pathways differing by site. Sympathetic signals are important in mediating autonomic-induced vasoconstriction. The blood supply of skin is far greater than that required for normal skin physiology and reflects the importance of skin in thermoregulation.

Functions of the skin

The skin has many functions, all of which can be affected by disease (Box 29.1). Skin changes associated with ageing are shown in Box 29.2.

i 29.1 Functions of the skin

Function	Structure/cell involved
Protection against:	
Chemicals, particles, desiccation	Stratum corneum
Ultraviolet radiation	Melanin produced by melanocytes and transferred to keratinocytes Stratum corneum hyperproliferation
Antigens, haptens	Langerhans' cells, lymphocytes, mononuclear phagocytes, mast cells, dermal dendritic cells
Microorganisms	Stratum corneum, Langerhans' cells, mononuclear phagocytes, mast cells, dermal dendritic cells
Maintenance of fluid balance	
Prevents loss of water, electrolytes and macromolecules	Stratum corneum
Shock absorber	
Strong, elastic and compliant covering	Dermis and subcutaneous fat
Sensation	Specialised nerve endings mediating pain and withdrawal Itch leading to scratch and removal of a parasite
Metabolism	Predominantly keratinocytes
Detoxification of xenobiotics, retinoid metabolism, isomerisation of urocanic acid	
Temperature regulation	Eccrine sweat glands and blood vessels
Protection, and fine manipulation of small objects	Nails
Hormonal	
Steroidogenesis, testosterone synthesis and conversion to other androgenic steroids	Hair follicles, sebaceous glands
Conversion of thyroxine (T_4) to triiodothyronine (T_3)	Keratinocytes
Conversion of 7-dehydrocholesterol to vitamin D	Keratinocytes
Pheromonal	
Importance unknown in humans	Apocrine sweat glands, possibly sebaceous glands
Psychosocial, grooming and sexual behaviour	Appearance, tactile quality of skin, hair, nails

Investigation of skin disease

Magnifying glass

A hand-held or freestanding magnifying lens used under good lighting conditions (ideally daylight) is valuable for examination of the skin.

Wood's light

Wood's light is a long-wavelength UVA/short-wavelength visible (violet) light source that can be used in various ways. In hypopigmentation, such as in vitiligo, it can help in appreciating the extent of disease. In pigmented conditions, such as melasma, it can determine whether pigmentation is mainly epidermal (sharp cut-off under Wood's lamp) or mixed epidermal and dermal (ill-defined cut-off). Wood's lamp can also be used to help with the diagnosis of some fungal infections because of their characteristic fluorescence.

Dermatoscopy and diascopy

Dermatoscopy (also known as dermoscopy and epiluminescence microscopy) is increasingly performed with hand-held dermatoscopes. What makes dermatoscopy unique is the fact that it allows visualisation through contact of a glass plate on the instrument with a liquid film applied to the skin, or through special optics to allow non-contact dermatoscopy, enabling deeper structures to be seen without interference from reflection and refraction of light in the epidermis.

Diascopy is simply pressing on the lesion with a glass slide. This provides some of the effect of dermatoscopy, but is mainly used to remove blood from vascular lesions to make the appearance of the lesion clearer. Granulomatous skin diseases may have a characteristic appearance under diascopy, such as in lupus vulgaris (cutaneous tuberculosis), in which 'apple jelly nodules' are typically seen on diascopy.

Skin biopsy

Skin biopsy is a mainstay investigation in dermatology and can be used in a range of dermatological presentations. In the most common scenario, a skin biopsy is undertaken in order to obtain tissue on which to perform standard histopathology. However, tissue may also be subjected to a variety of staining and culture techniques, including immunostaining. Histopathological examination of skin biopsies is especially

> **29.2 Skin changes in old age**
>
> - **Chronological ageing**: due to the intrinsic ageing process.
> - **Photo-ageing**: due to cumulative ultraviolet radiation (UVR) exposure and superimposed on intrinsic ageing.
> - **Typical changes**: include atrophy, laxity, yellow discoloration, wrinkling, dryness, irregular pigmentation, and thinning and greying of hair.
> - **Causes**: age-related alterations in structure and function of the skin, cumulative effects of environmental insults, especially UVR and smoking, cutaneous consequences of disease in other organ systems.
> - **Consequences**: reduction in immune and inflammatory responses, reduction in absorption and clearance of topical medications, reduced healing, increased susceptibility to irritants, dermatitis, adverse drug effects (including topical glucocorticoid-induced atrophy and purpura) and diseases such as skin cancer.

useful for tumour diagnosis. When a dermatologist or pathologist with dermatopathology expertise is involved, it can also assist in the diagnosis of inflammatory skin diseases. It is rare for histopathology of a previously undiagnosed inflammatory skin disease to provide a diagnosis on its own; clinico-pathological correlation is critical. Most biopsies are stained with haematoxylin and eosin but other stains may be useful in special situations, such as for fungal hyphae, iron or mucin. Direct immunofluorescence can also be undertaken on a fresh skin biopsy, allowing antigen visualisation using fluorescein-labelled antibodies; this is especially important in the diagnosis of autoimmune bullous disorders or connective tissue disease, such as cutaneous lupus.

Microbiology

Bacteriology

Bacterial swabs may identify a causative infective agent. However, organisms identified from the skin surface may not be the cause of the skin disease but instead may simply reflect colonisation of skin that has already been damaged by a primary skin disease.

Virology

A number of techniques, including immunofluorescence and polymerase chain reaction (PCR), are available to diagnose herpes simplex or herpes zoster viruses from vesicle fluid (p. 106).

Mycology

Scale, nail clippings (or scrapings of crumbly subungual hyperkeratosis) and plucked hairs can be examined by light microscopy. If potassium hydroxide and a simple light microscope are available, this can be performed in any outpatient clinic. Microbiology laboratories will also routinely undertake microscopy and culture for fungi and yeasts.

Patch testing

Patch testing is the investigation of choice for delayed, cell-mediated, type IV hypersensitivity, which clinically manifests as dermatitis. Potential allergens (see Box 29.22, p. 1247) are applied as patches to the back under occlusion for 48 hours, in vehicles and at concentrations that minimise false-positive and false-negative reactions. After 48 hours the patches are removed and patch-test readings are undertaken at time points of up to 7 days after patch-test application, with the most typical time point being at 96 hours. When interpreting patch test readings, it is important to determine the clinical relevance of any allergic reactions before giving avoidance advice.

Photopatch testing is similar to patch testing but investigates delayed hypersensitivity to an agent (usually a sunscreen or a non-steroidal anti-inflammatory drug (NSAID)) after the absorption of UVR. It involves applying substances in duplicate and irradiating one set with UVR (typically UVA, 5 J/cm^2), readings then being conducted in a similar manner to patch testing.

Prick tests and specific immunoglobulin E testing

Prick tests are used to investigate cutaneous type I (immediate) hypersensitivity to various antigens such as pollen, house dust mite or dander. The skin is pricked with commercially available stylets through a dilution of the appropriate antigen solution (p. 86). Alternatively, specific immunoglobulin E (IgE) levels to antigens can be measured in serum. If challenge tests are undertaken for patients with suspected allergy, these must be performed under controlled conditions due to the potential risk of triggering a severe reaction (p. 86).

Phototesting

Phototesting is extremely valuable in the assessment of suspected photosensitivity. The mainstay investigation is monochromator phototesting, which involves exposing the patient's back to increasing doses of irradiation using narrow wavebands across the solar spectrum and then assessing responses, using the minimal erythema dose (MED) at each waveband. This is the dose required to cause just perceptible skin reddening and is compared with values for the normal population. If a patient has reduced MED (develops erythema at lower doses than healthy subjects), this indicates abnormal photosensitivity. Thus, monochromator phototesting can be used to determine whether a patient is abnormally photosensitive, which wavebands are involved and how sensitive the patient is (p. 1220). Provocation testing can be performed with a broadband (usually UVA) source to induce rash at a test site (most useful for polymorphic light eruption) and can be helpful for diagnosis. Provocation testing to a variety of light sources, including artificial compact fluorescent lamps, may also be indicated, the latter being most relevant in patients with severe photosensitivity.

Patients who are referred for phototherapy will also commonly undergo an MED test, in which they are exposed to a series of test doses of the light source that will be used therapeutically (often narrowband UVB); the MED is determined 24 hours later (or 72–96 hours for the psoralen–ultraviolet A (PUVA) minimal phototoxic dose; p. 1227). This allows treatment regimens to be individualised, based on a patient's erythemal responses, and may detect abnormal photosensitivity.

Blood tests

Although most patients presenting with a skin problem do not need blood tests as part of their investigations, there are many systemic diseases that can present with skin features and, indeed, blood tests may also be indicated in the investigation of primary skin disease. A wide range of possible investigations may be required and some examples include haemoglobin, iron studies and thyroid function tests in pruritus or hair loss; autoantibody screening if lupus is suspected; porphyrin plasma scan for skin fragility and hypertrichosis; and hepatitis screening in lichen

planus. These diverse examples emphasise the importance of considering an underlying systemic disease when assessing a patient with a dermatological presentation.

Imaging

Imaging techniques are not typically required but X-rays, ultrasound, magnetic resonance imaging (MRI) or computed tomography (CT) may occasionally be indicated in specific situations, such as in metastatic melanoma or in a patient presenting with a diagnosis of cutaneous sarcoid.

Presenting problems in skin disease

The major presentations in dermatology are outlined below. Detail of the underlying disorders is mostly provided in the disease-specific sections further on in the chapter.

Lumps and lesions

The term lump or lesion is typically used to describe a papule or nodule, although sometimes may refer to a macule or plaque (p. 1211). A new or changing lump is one of the key dermatology presentations.

Clinical assessment

Detailed history-taking and examination are essential:

- *Change*: Is the lump new or has there been a change in a pre-existing lesion? What is the nature of the change – size, colour, shape or surface change? Has change been rapid or slow? Are there other features – pain, itch, inflammation, bleeding or ulceration (**definition** of 'ulcer': an area from which the epidermis and at least the upper part of the dermis have been lost – see Fig. 29.9, p. 1223)?
- *Patient*: What is the patient's age? Are they fair-skinned and freckled? Has there been much sun exposure? Have they used sunbeds or lived in sunny climates? Have they used photoprotection?
- *Site*: Is it on a sun-exposed or covered site? The scalp, face, upper limbs and back in men, and face, hands and lower legs in women, are the most chronically sun-exposed sites.
- *Are there other similar lesions?* These might include actinic keratoses (see Fig. 29.13, p. 1231) or basal cell papillomas (see Fig. 29.17, p. 1234).
- *Morphology*: Tenderness, size, symmetry, regularity of border, colour, surface characteristics and the presence of features such as crust (**definition**: dried exudate of blood or serous fluid – see Fig. 29.19, p. 1235), scale (**definition**: a flake arising from the stratum corneum; any condition with a thickened stratum corneum can cause scaling – see Fig. 29.13, p. 1231) and ulceration must be assessed. Stretching the skin and using a magnifying lens can be helpful, such as for detecting the raised, pearled edge of a basal cell carcinoma (see Fig. 29.11, p. 1229).
- *Dermatoscopy*: This can be used to detect the presence of abnormal vessels, such as in basal cell carcinoma or the characteristic keratin cysts in basal cell papillomas. It is invaluable for assessing pigmented and vascular lesions (Fig. 29.2).

i 29.3 ABCDE features of malignant melanoma

- **A**symmetry
- **B**order irregular
- **C**olour irregular
- **D**iameter >0.5 cm
- **E**levation irregular

(+ Loss of skin markings)

Is it a melanocytic naevus or a malignant melanoma?

This is a common clinical scenario and one that it is critical to resolve correctly.

- The precise nature of the change should be determined (as above). Listen to the patient and pay attention to subtle changes, as people know their skin well.
- If the patient has other pigmented lesions, then these should be examined too, as they may be informative. For example, if the presenting lesion looks different from the others, then suspicion of melanoma is increased; conversely, if the patient has multiple basal cell papillomas, this may be reassuring – although do not be falsely reassured.
- Is there a positive family history of melanoma? A suspicious naevus in a patient with a first-degree relative with melanoma probably warrants excision.

The ABCDE 'rule' is a guide to the characteristic features of melanoma (Box 29.3 and see Figs 29.2 and 29.15), although melanomas should ideally be diagnosed before the diameter is greater than 0.5 cm. Loss of normal skin markings in a pigmented lesion may be suggestive of melanoma. Conversely, normal skin markings and fine hairs dispersed evenly over a lesion are reassuring but do not exclude melanoma. The Glasgow seven-point checklist is another useful guide:

- *major features*: change in size, shape and colour
- *minor features*: diameter >0.5 cm, inflammation, oozing, bleeding, itch or altered sensation.

Patients with one major or one minor feature should be referred for further evaluation.

Investigations and management

If a benign diagnosis, such as basal cell papilloma, is made on clinical grounds, then the patient can be reassured and the lesion either left or treated: for example, with cryotherapy. If there are concerns about the diagnosis or malignancy is suspected on clinical grounds, then skin biopsy in order to obtain a tissue diagnosis is the usual approach. An incisional biopsy may be indicated, although if the lesion is small, excision may be most appropriate. If significant concern exists about the possibility of malignant melanoma, initial excision with a 2 mm margin would usually be undertaken prior to more definitive management once histology was confirmed. Further management of a changed lesion would, of course, depend on the histology of the diagnostic biopsy.

Rash

A rash is the other common presentation in dermatology. The main categories of scaly rashes are listed in Box 29.4. The most common type of rash presentation is maculopapular. Diagnosis can often be made on clinical grounds, although a biopsy may be required.

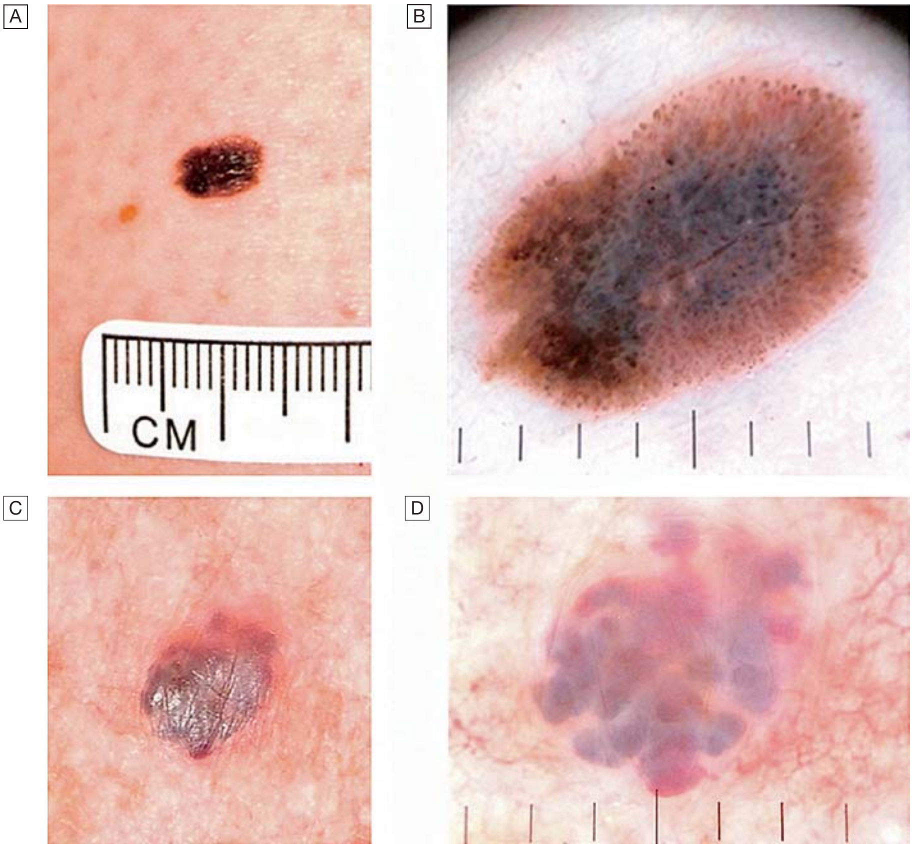

Fig. 29.2 Dermatoscopy. A A changing lesion. B Dermatoscopy highlights the abnormal pigment network and other features suggestive of melanoma. Excision biopsy confirmed the diagnosis of superficial spreading malignant melanoma (Breslow thickness 0.8 mm). C Another changing lesion. D Dermatoscopy highlights the vascular lacunae of this benign angioma and the patient was reassured.

i 29.4 Causes and clinical features of common scaly rashes

Diagnosis	Distribution	Morphology	Associated signs
Atopic eczema (p. 1245)	Face and flexures	Poorly defined erythema, scaling Vesicles Lichenification if chronic	Shiny nails Infra-orbital crease 'Dirty neck' (grey–brown discoloration)
Psoriasis (p. 1247)	Extensor surfaces Lower back	Well-defined Erythematous plaques Silvery scale	Nail pitting, onycholysis Scalp involvement Axillae and genital areas often affected Joint involvement Köbner phenomenon (p. 1252)
Pityriasis rosea (p. 1251)	'Fir tree' pattern on trunk	Well-defined Small, erythematous plaques Collarette of scale	Herald patch
Drug eruption (p. 1265)	Widespread	Macules and papules Erythema and scale Exfoliation	Possible mucosal involvement or erythroderma
Pityriasis versicolor (p. 1240)	Upper trunk and shoulders	Hypo- and hyper-pigmented scaly patches	
Lichen planus (p. 1252)	Distal limbs Flexural aspect of wrists Lower back	Shiny, flat-topped, violaceous papules Wickham's striae	White, lacy network on buccal mucosa Nail changes Scarring alopecia Köbner phenomenon
Tinea corporis (p. 1240)	Asymmetrical Often isolated lesions	Erythematous, often annular plaques Peripheral scale (sometimes pustules) Expansion with central clearing	Possible nail, scalp, groin involvement
Secondary syphilis (p. 337)	Trunk and proximal limbs Palms and soles	Red macules and papules, which become 'gun-metal' grey	History of chancre Systemic symptoms, e.g. malaise and fever

Clinical assessment

Important aspects of the history include:

- *Age at onset and duration of rash.* Atopic eczema often starts in early childhood and psoriasis between 15 and 40 years, and both may be chronic. Infective or drug-induced rashes are more likely to be of short duration and the latter to occur in relation to drug ingestion. Duration of individual lesions is also important, as in urticaria, for example.
- *Body site at onset and distribution.* Flexural sites are more typically involved in atopic eczema, and extensor surfaces and scalp in psoriasis. Symmetry is often indicative of an endogenous disease, such as psoriasis, whereas asymmetry is more common with exogenous causes, such as contact dermatitis or infections like herpes zoster.
- *Itch.* Eczema is usually extremely itchy and psoriasis may be less so.
- *Preceding illness and systemic symptoms*. Guttate psoriasis may be precipitated by a β-haemolytic streptococcal throat infection; almost all patients with infectious mononucleosis (p. 241) treated with amoxicillin will develop an erythematous maculopapular eruption; a history of chancre at the site of inoculation may be elicited in a presentation of secondary syphilis; malaise and arthralgia are common in drug eruptions and vasculitis.

The morphology of the rash and the characteristics of individual lesions are important (Box 29.4).

Investigations and management

It is important to have a short differential diagnosis based on clinical assessment in order to direct investigations. For example, in psoriasis, no investigations may be needed and initial management with patient counselling and topical therapies may suffice. If the diagnosis is unclear, then a diagnostic skin biopsy and other targeted investigations based on the clinical picture may be required. An initial management plan should also be implemented. For example, in a child presenting with a rash that has features suggestive of impetigo, skin and nasal swabs should be performed and, once these have been taken, topical or systemic antibiotics should be introduced, depending on clinical extent of disease, and management should be adjusted accordingly, dependent on investigation findings and clinical course. In contrast, if a patient presents with a maculopapular rash shortly after introduction of a new drug, then drug withdrawal, diagnostic biopsy, full blood count, including eosinophil count, and liver and renal function tests, in parallel with topical emollients and glucocorticoids, may be indicated.

Blisters

A blister is a fluid-filled collection in the skin. The term vesicle is used for small lesions and bulla for larger lesions (p. 1211). Blistering occurs due to loss of cell adhesion within the epidermis or subepidermal region (see Fig. 29.1). The clinical presentation depends on the site or level of blistering within the skin, which in turn reflects the underlying cause (p. 1254). There are a limited number of conditions that present with blisters (Box 29.5):

- Intact blisters are not often seen if the split is high in the epidermis (below the stratum corneum), as the blister roof is so fragile that it ruptures easily, leaving erosions (**definition**: an area of skin denuded by complete or partial loss of the epidermis). This occurs in pemphigus foliaceus, staphylococcal scalded skin syndrome (see Fig. 29.20, p. 1236) and bullous impetigo.
- If the split is lower in the epidermis, then intact flaccid blisters and erosions may be seen, as occurs in pemphigus vulgaris and toxic epidermal necrolysis (see Fig. 29.41, p. 1254).
- If the split is subepidermal, then tense-roofed blisters are seen. This occurs in bullous pemphigoid (see Fig. 29.42, p. 1256), epidermolysis bullosa acquisita and porphyria cutanea tarda (see Fig. 29.52, p. 1264).
- If there are foci of separation at different levels of the epidermis, as in dermatitis (p. 1244), then multilocular bullae made up of coalescing vesicles can occur.

29.5 Causes of acquired blisters

	Localised	Generalised
Vesicular	Herpes simplex Herpes zoster Impetigo Pompholyx	Eczema herpeticum* Dermatitis herpetiformis Acute eczema
Bullous	Impetigo Cellulitis Stasis oedema Acute eczema Insect bites Fixed drug eruption	Toxic epidermal necrolysis* Erythema multiforme Stevens–Johnson syndrome* Bullous pemphigoid Pemphigus* Epidermolysis bullosa acquisita Lupus erythematosus Porphyria cutanea tarda Pseudoporphyria Drug eruptions

*Usually with mucosal involvement too.

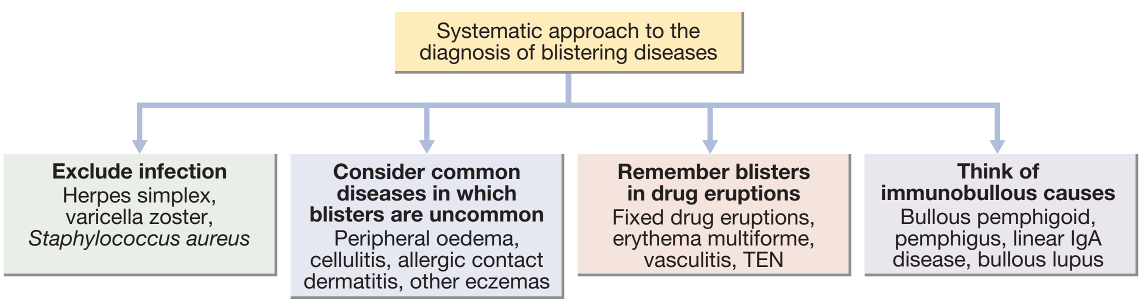

Fig. 29.3 A systematic approach to the diagnosis of blistering diseases. (TEN = toxic epidermal necrolysis)

Clinical assessment

Detailed history-taking and examination are critical. A history of onset, progression, mucosal involvement, drugs and systemic symptoms should be sought. Clinical assessment of the distribution, extent and morphology of the rash should be made. The Nikolsky sign is useful: sliding lateral pressure from a finger on normal-looking epidermis can dislodge and detach the epidermis in conditions with intra-epidermal defects, such as pemphigus and toxic epidermal necrolysis. A systematic approach to diagnosis is required (Fig. 29.3).

Investigations and management

Investigations and initial management will be guided by the clinical presentation and differential diagnosis, and are described in more detail under the specific diseases. For example, an initial approach may include directed investigations, such as incisional diagnostic skin biopsy for histology and direct immunofluorescence, indirect immunofluorescence and other targeted blood tests or skin swabs. Management should be based on the likely diagnosis and begin in parallel with investigations, until the diagnosis is confirmed.

Itch

Itch describes the unpleasant sensation that leads to scratching or rubbing. The terms 'itch' and 'pruritus' are synonymous; however, 'pruritus' is often used when itch is generalised. Itch can arise from primary cutaneous disease or be secondary to systemic disease, which may cause itch by central or peripheral mechanisms. Even when the mechanism is peripheral, there are not always signs of primary skin disease.

The nerve endings that signal itch are in the epidermis or near the dermo-epidermal junction. The underlying mechanisms of itch are not fully understood. Transmission is by unmyelinated slow-conducting C fibres through the spinothalamic tract to the thalamus and then the cortex. Aδ fibres also seem to be involved in transmitting signals to the spinal cord, and the heat-sensitive transient receptor potential (TRP) channels 1–4 are important. There is an inhibitory relationship between pain and itch. Scratching may relieve the symptom of itch after the sensation has ceased and this is either by stimulation of ascending sensory pathways that inhibit itch-transmitting neurons at the spinal cord (Wall's 'gate' mechanism), or by direct damage to cutaneous sensory nerves.

The mechanisms of itch in most systemic diseases remain unclear. The itch of kidney disease, for example, may be mediated by circulating endogenous opioids. The clinical observation that peritoneal dialysis helps reduce itch more frequently than haemodialysis is consistent with this, with smaller molecules generally being dialysed more readily if the peritoneal membrane is used rather than a dialysis machine membrane.

Clinical assessment

It is important to determine whether skin changes are primary (a process in the skin causing itch) or secondary (skin changes caused by rubbing and scratching because of itch). This requires a thorough history and examination, sometimes with investigations, to exclude systemic disease. Many common primary skin disorders are associated with itch (Box 29.6). If itch is not connected with primary skin disease, other causes should be considered (Box 29.7). These include liver diseases (mainly cholestatic diseases, such as primary biliary cirrhosis), malignancies (generalised itch may be the presenting feature

i 29.6 Primary skin diseases causing pruritus

Generalised pruritus

- Scabies
- Eczemas
- Pre-bullous pemphigoid
- Urticarias
- Xeroderma of old age
- Psoriasis

Localised pruritus

- Eczemas
- Lichen planus
- Dermatitis herpetiformis
- Pediculosis
- Tinea infections

i 29.7 Secondary causes of pruritus

Medical condition	Cause of pruritus	Treatment*
Liver disease	Central opioid effect Elevation in bile salts may contribute	Naltrexone Colestyramine Rifampicin Sedative antihistamines UVB
Renal failure	Unknown; uraemia contributes	UVB Oral activated charcoal
Haematological disease		
Anaemia	Iron deficiency	Iron replacement
Polycythaemia rubra vera	Unknown (often aquagenic pruritus)	
Lymphoma Laukaemia Myeloma	Unknown	
Endocrine disease		
Diabetes mellitus	Increased infection risk, e.g. candidiasis, tinea	Treatment of infection
Thyrotoxicosis	Unknown	
Hypothyroidism	Unknown	
Carcinoid syndrome (p. 678)	5-HT-mediated	
HIV infection	Infection, infestation	Treatment of infection
	Eosinophilic folliculitis	Local corticosteroids, UVB
	Seborrhoeic dermatitis	Anti-pityrosporal treatment
	Unknown	UVB
Malignancy	Unknown	
Psychogenic	Unknown	Psychotherapy, anxiolytics, antidepressants

*In addition to specific treatment of the primary condition and symptomatic treatments, such as emollients. (5-HT = 5-hydroxytryptamine, serotonin; UVB = ultraviolet B)

29.8 Causes of pruritus in pregnancy

Diagnosis	Pregnancy, gestation and features	Treatment
Polymorphic eruption of pregnancy (pruritic urticarial papules and plaques, PUPP)	Typically first pregnancy and uncommonly recurs 3rd trimester, after delivery Polymorphic urticated papules and plaques, start in striae	Chlorphenamine, emollients Topical glucocorticoids
Acute cholestasis of pregnancy (p. 1284)	3rd trimester and commonly recurs in subsequent pregnancies Abnormal liver function tests Increased fetal and maternal risk	Emollients Chlorphenamine Colestyramine UVB Early delivery
Pemphigoid gestationis	Any stage, often 2nd trimester and commonly recurs in subsequent pregnancies Urticated erythema, blistering initially periumbilical Characteristic histology and immunofluorescence	Topical or oral glucocorticoids
Prurigo gestationis	2nd trimester Excoriated papules	Emollients Topical glucocorticoids Chlorphenamine UVB
Pruritic folliculitis	3rd trimester Sterile pustules on trunk	Topical glucocorticoids UVB

(UVB = ultraviolet B)

of lymphoma), haematological conditions (generalised itch in chronic iron deficiency or water contact-provoked (aquagenic) intense itch in polycythaemia), endocrine diseases (including hypo- and hyperthyroidism), chronic kidney disease (in which severity of itch is not always clearly associated with plasma creatinine concentration) and psychogenic causes (such as in 'delusions of infestation'). Itch is common in pregnancy and may be due to one of the pregnancy-specific dermatoses. Making a correct diagnosis is particularly important in pregnancy, as some disorders can be associated with increased fetal risk (Box 29.8).

Investigations and management

Investigations should be directed towards finding an underlying cause and there will be a different approach for itch with rash, as opposed to itch with no signs of primary skin disease (Fig. 29.4). If there are no signs of primary skin disease, investigations should be undertaken to exclude systemic disease or iatrogenic causes. Psychogenic itch should be considered only if organic disease has been ruled out. There are no consistently effective therapies to suppress itch, and so establishing the underlying cause is critical. If a clear-cut diagnosis cannot be made, non-specific approaches can be used for symptom relief. These include sedation, often with H_1 receptor antihistamines, along with emollients and counter-irritants (such as topical menthol-containing preparations). UVB phototherapy is useful for generalised itch due to a variety of causes but the only randomised controlled study of efficacy is in chronic kidney disease. Other treatments include low-dose tricyclic antidepressants (probably through similar mechanisms to those involved when these drugs are used for chronic pain) and opiate antagonists. If a psychogenic itch is considered likely, antidepressants and/or cognitive behavioural therapy may be effective. Itch of any cause can be severe and its potentially major adverse effects on quality of life are not always fully appreciated. Assessments of impact on quality of life, such as Dermatology Life Quality Index (DLQI) scores, are essential.

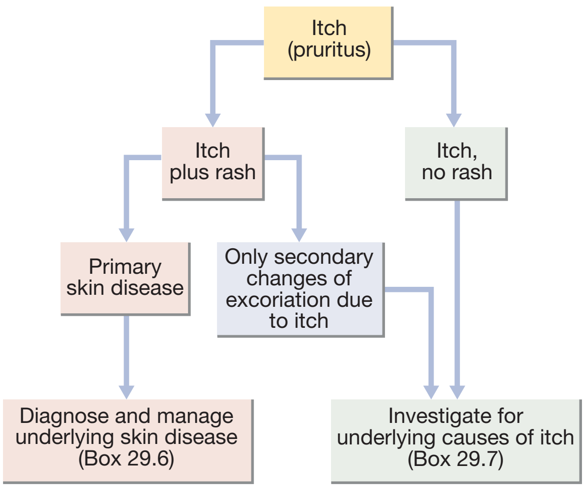

Fig. 29.4 An overall approach to the investigation and management of itch (pruritus).

Photosensitivity

Cutaneous photosensitivity is an abnormal response of the skin to UVR or visible radiation. The sun is the natural source but patients may also be exposed to artificial sources of UVR through the use of sunbeds and/or phototherapy (p. 1227). Chronic UVR exposure increases skin cancer risk and photo-ageing (p. 1215). Acute exposure can induce erythema (redness) as a normal response (Fig. 29.5). However, abnormal photosensitivity occurs when a patient reacts to lower doses than would normally cause a response, either with a heightened erythemal reaction or the development of a rash. Photo-aggravated skin diseases are exacerbated by sunlight but not caused by it. The main photosensitive and photo-aggravated diseases are listed in Box 29.9.

i 29.9 The photosensitivity and photo-aggravated diseases

Cause	Condition	Clinical features
Immunological (previously known as idiopathic)	Polymorphic light eruption (PLE)	Seasonal, itchy, papulovesicular rash on photo-exposed sites; face and back of hands often spared. Often hours of UVR exposure needed to provoke; lasts a few days; affects about 20% in Northern Europe, more common in young women
	Chronic actinic dermatitis (CAD)	Chronic dermatitis on sun-exposed sites. Most common in elderly males. Predominantly UVB, but also often UVA and visible light photosensitivity. Most also have contact allergies
	Solar urticaria	Immediate-onset urticaria on photo-exposed sites. Usually UVA and visible light photosensitivity. Can occur at any age
	Actinic prurigo	Uncommon, presents in childhood. Often familial, with strong HLA association. Some similarities to PLE, although scarring occurs
	Hydroa vacciniforme	Rare childhood photodermatosis. Varioliform scarring
Drugs (variety of mechanisms)	Phototoxicity	Usually UVA (and visible light) photosensitivity Most common. Exaggerated sunburn and exfoliation. Many drugs such as thiazides, tetracyclines, fluoroquinolones, quinine, NSAIDs
	Pseudoporphyria	NSAIDs, retinoids, tetracyclines, furosemide are examples
	Photoallergy	Usually to topical agents, particularly sunscreens and NSAIDs
Metabolic	Porphyrias	Mainly porphyria cutanea tarda and erythropoietic protoporphyria (p. 378).
	Pellagra	Photo-exposed site dermatitis due to tryptophan deficiency (see Fig. 14.15, p. 378)
Photogenodermatoses	Xeroderma pigmentosum	Rare. Defect in DNA excision repair, abnormal photosensitivity, photo-ageing and skin cancer. There may be neurological features
Photo-aggravation of pre-existing conditions	Lupus erythematosus	Can also be drug-induced (see Box 29.35, p. 1266)
	Erythema multiforme	p. 1264
	Rosacea	p. 1243

(HLA = human leucocyte antigen; NSAID = non-steroidal anti-inflammatory drug; UVA/UVB = ultraviolet A/B; UVR = ultraviolet radiation)

Fig. 29.5 Sunburn. Acute exposure to ultraviolet radiation results in an erythemal response that peaks 12–24 hours later. Sensitivity depends on the individual's constitutive skin phototype.

Sunlight consists mainly of visible light, and the UVR component is divided into three wavebands (Fig. 29.6), according to the Commission Internationale de l'Eclairage (CIE):

- *UVC* (200–280 nm), which is absorbed by ozone and does not reach the Earth's surface.
- *UVB* (280–315 nm), which constitutes less than 10% of UVR exposure but is around 1000-fold more potent than UVA and so accounts for the erythemal 'sunburning' effects of sunlight.
- *UVA* (315–400 nm), which is the most abundant UVR component reaching the Earth's surface.

The arbitrary division between UVB and UVA regions is more often considered to be at 320 nm by photobiologists, and the UVA region can be further subdivided into UVA2 (320–340 nm) and UVA1 (340–400 nm). UVA2 behaves biologically more like UVB, and UVA1 can be used therapeutically for several skin conditions, such as morphoea and eczema.

Patients with photosensitivity diseases can be abnormally sensitive to UVB, UVA, visible light (over 400 nm) or, commonly, a combination of wavebands. UVB is absorbed by window glass, whereas UVA and visible light are transmitted through glass.

Clinical assessment

Taking a careful history is essential, as the patient may not have the rash when assessed. Seasonal pattern and distribution of rash are important. Key sites are the face (particularly nose, cheeks and forehead), top of ears, neck (Fig. 29.7), bald scalp, back of hands and forearms. Sparing is often seen under the chin and nose, behind the ears, on the upper eyelids and the distal digits – as we normally walk about with our eyes open and fingers flexed! It can be misleading if there is covered site involvement. Patients who are sensitive to UVA and visible light may be affected through clothing. These patients commonly experience perennial symptoms and may not be aware of the association with daylight exposure. Other photosensitive conditions, such as actinic prurigo or chronic actinic dermatitis, may also involve covered sites. Sparing of habitually exposed sites, such as the face and back of hands, occurs most commonly in polymorphic light eruption (PLE) and is called the 'hardening phenomenon'. Importantly, some conditions, such as solar urticaria, develop rapidly after sunlight exposure, whereas others, such as cutaneous lupus, can take several days to evolve.

Investigations and management

If photosensitivity is suspected, the patient should be referred to a specialist centre for monochromator phototesting (p. 1215), if feasible. Other investigations will often include provocation,

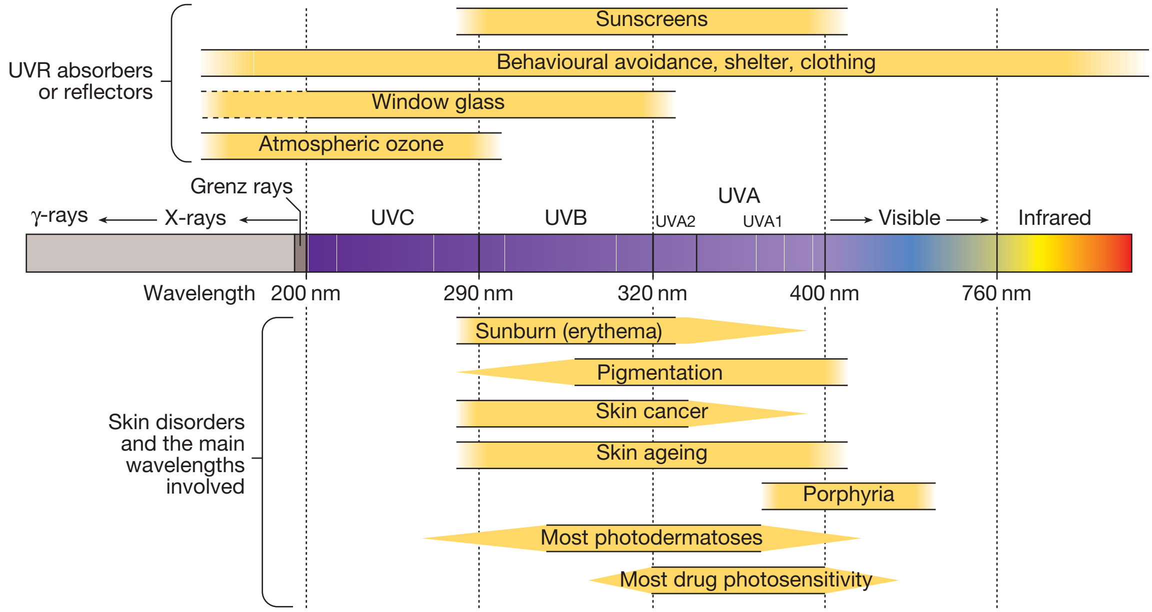

Fig. 29.6 The electromagnetic spectrum. The action spectrum is not well defined for many conditions and, for some, is approximate and may vary between patients. The action spectrum for non-melanoma skin cancer mirrors that for erythema. The action spectrum for melanoma is not known but includes ultraviolet (UV) B. Photoprotection measures vary, depending on condition, although the mainstay always includes behavioural modification, clothing cover and appropriate sunscreen choices. (UVR = ultraviolet radiation)

Fig. 29.7 Chronic actinic dermatitis. Note the sharp cut-off and sparing behind the ear in the shadow cast by the earlobe (Wilkinson's triangle).

patch or photopatch testing and screening for lupus and the porphyrias (p. 1263). Rarely, investigations such as human leucocyte antigen (HLA) typing in suspected actinic prurigo, or DNA excision repair functional activity or genotyping in suspected xeroderma pigmentosum, may be required.

Management depends on the cause. If there is a phototoxic drug or chemical cause, this must be addressed: for instance, by stopping the drug or treating the porphyria. Counselling in regard to sun avoidance is essential: keeping out of direct sun in the middle of the day, covering up with clothing, wearing hats with a wide brim and careful use of high-factor sunscreens. Paradoxically, in some conditions, particularly PLE and solar urticaria, phototherapy can be used to induce 'hardening'; the mechanism of desensitisation is uncertain. Other approaches may be necessary, depending on disease and severity, and may include antihistamines (useful in two-thirds of patients with solar urticaria) and systemic immunosuppression (sometimes required in the immunological photodermatoses). Patients with photosensitivity are at risk of vitamin D deficiency because of reduced synthesis in the skin and should be advised to optimise dietary vitamin D intake or take supplements (p. 1052).

Sunscreens

Sunscreens can be divided into two categories: chemical sunscreens, which absorb specific wavelengths of UVR, and physical sunscreens, which reflect UVR and the shorter visible wavelengths (see Fig. 29.6). Sunscreens are now highly sophisticated and most offer protection against UVB and most UVA wavelengths. If a patient is abnormally photosensitive to the longer wavelengths of UVA and the visible part of the spectrum (for example, in cutaneous porphyrias and solar urticaria), then conventional sunscreens are not beneficial and specific reflectant sunscreens are required. Historically, these agents were less cosmetically acceptable due to visible light reflection, but current formulations, some of which are tinted, have reduced this problem.

Sunscreen protection levels are described by sun protection factor (SPF). This is the ratio of the dose of UVR required to produce skin erythema in the presence and absence of the sunscreen. A sunscreen of SPF20 means that it would take 20 times as long for a person to develop sunburn in the presence of the sunscreen, as compared to not using it. Therefore, SPF is really a sunburn protection factor and is not a good guide to how well a sunscreen will perform in protecting against other reactions (such as skin pain in erythropoietic protoporphyria or UVR-induced immunosuppression). SPF values are determined under experimental conditions whereas, in practice, people tend to use 25–33% of the amount of sunscreen required to achieve

the stated SPF. Patient counselling is therefore important with regard to adequate application of sunscreen. All sunscreens offer, at best, partial protection only and are no substitute for modifying behaviour and covering up.

Leg ulcers

Leg ulcer is not a diagnosis, but a symptom of an underlying disease in which there is complete loss of the epidermis, leaving dermal layers exposed. Ulcers on the lower leg are frequently caused by vascular disease but there are other causes, as summarised in Box 29.10.

Clinical assessment

A detailed history of the onset and course of leg ulceration and predisposing conditions should be elicited. The site and surrounding skin should be assessed. Varicose veins are often present, although not inevitably. Assessment of the venous and arterial vasculature and neurological examination are critical. The site of ulceration may also help to indicate the underlying primary cause (Fig. 29.8). Full clinical examination is essential as the ulcer may be arising in the context of systemic disease, such as vasculitis.

Leg ulceration due to venous disease

Varicose veins, a history of deep venous thrombosis and obesity are predisposing factors. Incompetent valves in the deep and perforating veins of the lower leg result in retrograde flow of blood to the superficial system, and a rise in capillary pressure ('venous hypertension'). Pericapillary fibrin cuffing occurs, leading to impairment of local tissue oxygenation and homeostasis.

The first symptom in venous ulceration is often heaviness of the legs, followed by oedema. Haemosiderin pigmentation, pallor and firmness of surrounding skin, and sometimes venous/gravitational eczema (p. 1247) subsequently develop. This progresses to lipodermatosclerosis – firm induration due to fibrosis of the dermis and subcutis, which may produce the well-known 'inverted champagne bottle' appearance. Ulceration, often precipitated by trauma or infection, follows. Venous ulcers typically occur on the medial lower leg (Fig. 29.9).

Complications of venous leg ulceration include bacterial colonisation and infection, and contact allergic dermatitis to topical medicaments, dressings and bandages. Lipodermatosclerosis may cause lymphoedema and hyperkeratosis; rarely, a squamous cell carcinoma (SCC) may develop in a long-standing venous ulcer (Marjolin's ulcer).

Leg ulceration due to arterial disease

Deep, painful, punched-out ulcers on the lower leg, especially the shin and foot and in the context of intermittent claudication, are

i 29.10 Causes of leg ulceration

Venous hypertension	
• Sometimes following deep vein thrombosis	
Arterial disease	
• Atherosclerosis • Vasculitis	• Buerger's disease
Small-vessel disease	
• Diabetes mellitus	• Vasculitis
Haematological disorders	
• Sickle-cell disease • Cryoglobulinaemia • Spherocytosis • Polycythaemia	• Myeloma • Waldenström's macroglobulinaemia • Immune complex disease
Neuropathy	
• Diabetes mellitus • Leprosy (Hansen's disease)	• Syphilis
Tumour	
• Squamous cell carcinoma • Basal cell carcinoma	• Malignant melanoma • Kaposi's sarcoma
Trauma	
• Injury	• Factitious

29

likely to be due to arterial disease. Risk factors include smoking, hypertension, diabetes and hyperlipidaemia. The foot is cold and dusky, and the skin atrophic and hairless. Peripheral pulses are absent or reduced. A vascular surgical assessment should be sought urgently (p. 502).

Leg ulceration due to vasculitis

Vasculitis can cause leg ulceration either directly through epidermal necrosis due to damage to the underlying vasculature, or indirectly due to neuropathy.

Leg ulceration due to neuropathy

The most common causes of neuropathic ulcers are diabetes and leprosy. Microangiopathy also contributes to ulceration in diabetes (p. 758). The ulcers occur over weight-bearing areas, such as the heel. In the presence of neuropathy, protection of skin from trauma is essential to prevent ulceration.

Investigations

Appropriate investigations include:

- *Full blood count* to detect anaemia and blood dyscrasias.
- *Urea and electrolytes* to assess renal function.
- *Urinalysis* for glycosuria.
- *Bacterial swab* if there is a purulent discharge, rapid extension, cellulitis, lymphangitis or sepsis. This can guide antibiotic therapy for secondary infection but pathogenic bacteria are not always the same as those identified from the ulcer surface.
- *Doppler ultrasound* to assess arterial circulation. An ankle systolic pressure to brachial systolic pressure index (ABPI) of below 0.8 suggests significant arterial disease and a vascular surgery opinion should be sought. However, arterial calcification, such as in diabetes, can produce a spuriously high ABPI. Pulse oximetry may also be useful, although ABPI is the preferred investigation if feasible.

Management

General advice on exercise, weight loss and smoking cessation is important in all cases. Specific management depends on making the correct diagnosis to identify the cause(s) of ulceration. Underlying factors, such as diabetes or anaemia, must be treated. Oedema must be reduced by leg elevation and, if there is no arterial compromise, graduated compression bandaging from toes to knees to enhance venous return and improve healing. Compression bandaging is effective for individuals with an ABPI of more than 0.8 but should be avoided if the ABPI is less than 0.8.

If the ulcer is purulent, weak potassium permanganate soaks may help, and exudate and slough can be removed with normal saline or clean water. Dressings do not themselves heal leg ulcers, but can reduce discomfort and odour and, by reducing colonisation by potential pathogens, may reduce the frequency of secondary infection. A variety of dressings may be used, including non-adherent and absorbent (alginates, hydrogels, hydrocolloids) types. The frequency of dressing changes varies; heavily exudative ulcers may need daily dressings, whereas changes once weekly may suffice for drier ulcers. Occasionally, leeches may be used topically for ulcers with heavy adherent exudate.

Surrounding eczema should be suppressed with a topical glucocorticoid. Commonly, this is venous eczema, but there should be a low threshold for referral for patch testing, as contact allergy to topical applications is common (p. 1215). Systemic antibiotics are indicated only if there is evidence of infection, as opposed to colonisation. Various techniques of split-thickness grafting (such as pinch and mince grafts) may hasten healing of clean ulcers but do not reduce recurrence risk. Leg ulcers can be very persistent. Symptomatic relief, including oral analgesics and sometimes chronic pain management, is important. Once the ulcer has healed, ongoing use of compression hosiery may limit the risk of recurrence.

Abnormal pigmentation

Loss of skin pigmentation (depigmentation), reduction in pigmentation (hypopigmentation) and increased pigment (hyperpigmentation) are features of a variety of disorders. A detailed history and examination, including use of a Wood's light, are required to establish the diagnosis. Investigations will depend on the presentation. For example, microscopy of skin scrapings should be undertaken if hypopigmentation is associated with inflammation and scaling; screening for autoimmune disease may be required if vitiligo is suspected; and investigation for endocrine disease or the porphyrias may be appropriate in hyperpigmentation. Further details of the specific conditions are included on page 1257.

Hair and nail abnormalities

Many conditions affect the skin appendages, particularly hair and nails. Conditions causing hair loss (alopecia) are listed in Box 29.30 (p. 1259). Nail changes may be a marker for systemic disease (e.g. iron deficiency) or be a feature of certain skin conditions (e.g. psoriasis).

Acute skin failure

Acute skin failure is a medical emergency. Several conditions can cause widespread and acute failure of many skin functions (see Box 29.1, p. 1214), including thermoregulation, fluid balance control and barrier to infection. Many of these conditions involve widespread dilatation of the dermal vasculature and can provoke high-output cardiac failure; they are also associated with increased protein loss from the skin and often from the gut. Many lead to acute skin failure by causing erythroderma (erythema affecting at least 90% of the body surface area), although severe autoimmune blistering diseases and the spectrum of Stevens–Johnson syndrome/toxic epidermal necrolysis (TEN) disease can produce acute skin failure without erythroderma (p. 1254).

Clinical assessment

Detailed history-taking and full examination are required. Particular attention should be paid to drug history, chronology and history of any preceding skin disease. Eczema, psoriasis, drug eruptions and cutaneous T-cell lymphoma (Sézary's syndrome, p. 1232) are among the diseases that can either present with, or progress to, erythroderma. Other causes include the psoriasis-like condition, pityriasis rubra pilaris, and rare types of ichthyosis. Erythroderma may occur at any age and is associated with severe morbidity and significant mortality (see Fig. 29.35D, p. 1249). Older people are at greatest risk, especially if they have comorbidities. Erythroderma may appear suddenly or evolve slowly. In dark skin, the presence of pigmentation may mask erythema, giving a purplish hue.

Erythrodermic patients are usually systemically unwell with shivering and hypothermia, secondary to excess heat loss. They may also be pyrexial, however, and unable to lose heat due to damage to sweat gland function and sweat duct occlusion.

Tachycardia and hypotension may be present because of volume depletion. Peripheral oedema is common in erythroderma, owing to low albumin and high-output cardiac failure. Lymph nodes may be enlarged, either as a reaction to skin inflammation or, rarely, due to lymphomatous infiltration.

Investigations and management

Investigations are required to establish the underlying cause and to identify any systemic impact, such as hypoalbuminaemia and electrolyte disturbances. Skin biopsy may be necessary if the cause is unclear. Regardless of the cause, important aspects of the management of erythroderma include supportive measures to ensure adequate hydration, maintenance of core temperature and adequate nutrition. Insensible fluid loss can be many litres above normal losses. Protein may be lost directly from the skin and through the gut because of the protein-losing enteropathy that often accompanies conditions such as erythrodermic psoriasis. To reduce the risks of infection, any intravenous cannulae should be sited in peripheral veins, if possible. In the initial management of acute erythroderma, urinary catheterisation is often required (for patient comfort and accurate fluid balance monitoring) but catheters should be removed as soon as possible. Frequent application of a simple ointment emollient (such as white soft paraffin/liquid paraffin mix) is usually appropriate.

Principles of management of skin disease

General measures

General measures that apply in all skin diseases include establishment of the correct diagnosis, removal of precipitating or aggravating factors, use of safe, effective treatments and consideration of the patient holistically, taking into account the impact of the disease on quality of life and the person's support network. The psychological impact of chronic skin diseases should not be under-estimated and it is important to remember that psychiatric illness can also manifest as a skin disease, such as in delusions of infestation or trichotillomania. Careful clinical assessment, taking psychological factors into account, is essential and any management strategy must include approaches to address the psychological well-being of the patient.

Topical treatments

Topical treatments are first-line therapy for most skin diseases and many can be treated effectively by topical therapies alone. Selection of the appropriate active drug/ingredient and vehicle is essential. Ointments are preferred to creams for dry skin conditions, such as chronic eczemas, as they are more hydrating and contain fewer preservatives than creams, and so allergy risk is reduced. However, patients find creams easier to apply and so adherence may be better. Gels and lotions can be easier to use on hair-bearing sites. The molecular weight and lipid–water coefficient of a drug determine its skin penetration, with larger, water-soluble, polar molecules penetrating poorly. In skin disease, if the stratum corneum is impaired – as in eczema – increased drug absorption occurs. Occlusion under dressings also increases absorption. Drugs can be used in different potencies or concentrations, or in combination with other active ingredients, and many are available in more than one formulation. The properties of different vehicles are listed in Box 29.11. Overall, adherence to topical treatments can be problematic, so it is essential for patients to know exactly what is required of them and for regimens to be kept as simple as possible. Emollients, topical glucocorticoids and other selected key topical therapies that are widely used in a diverse range of skin conditions are detailed below. For the more disease-specific therapies, detailed descriptions are included in the disease sections.

29.11 Characteristics of vehicles used in topical treatments

Vehicle	Definition	Use	Site	Cosmetic acceptability	Risk of contact sensitisation
Creams	Emulsions of oil and water (aqueous cream)	Acute presentations Cooling, soothing Well absorbed Mild emollients	All sites, including mucous membranes and flexures, but not hair-bearing areas	Very good Helps adherence	Significant, due to preservatives, antimicrobials and often lanolin
Ointments	Greasy preparations Insoluble in water (white soft paraffin) Soluble (emulsifying ointment)	Chronic dry skin conditions Occlusive and emollient Hydrating Mildly anti-inflammatory	Avoid hair-bearing areas and flexures	Moderate	Low
Lotions	Water-based Liquid formulations Often antiseptic and astringent (potassium permanganate)	Cooling effect Cleans the skin and removes exudates	Large areas of the skin and the scalp	Good, but can sting if in an alcoholic base	Rare
Gels	Thickened lotions Hydrophilic and hydrophobic bases	For specific sites	Hair-bearing areas and the face	Good	Low
Pastes	Semi-solid preparations consisting of finely powdered solids suspended in an ointment	Occlusive, protective Hydrating Circumscribed skin lesions, (psoriasis, lichen simplex chronicus)	Any area of skin Often used in medicated bandages	Moderate	Moderate

Emollients

These are mainstays in the treatment of eczema, psoriasis and many other conditions, and are used to moisturise, lubricate, protect and 'soften' skin. They are essentially vehicles without active drug and are available in many formulations: creams, ointments, gels and bath, shower and soap substitutes. White soft paraffin is the most effective and is widely used.

Topical glucocorticoids

Glucocorticoids are available in a variety of formulations, potencies and strengths, most commonly as creams and ointments (Box 29.12). Selection of the correct product depends on the condition being treated, body site and duration of expected use. Mild topical glucocorticoids are used in delicate areas, such as the face or genitals, and close supervision of glucocorticoid use at these sites is required. In contrast, very potent glucocorticoids may be required under occlusion for chronic resistant disease such as nodular prurigo.

Adverse cutaneous effects of chronic glucocorticoid use include atrophy (**definition**: an area of thin, translucent skin caused by loss of epidermis, dermis or subcutaneous fat – Fig. 29.10), striae (**definition**: linear, atrophic, pink, purple or white bands caused by connective tissue changes – Fig. 29.10), petechiae and purpura (**definition**: haemorrhagic macules or papules caused by extravasated blood – see p. 1211) and telangiectasiae (**definition**: visible dilatations of small cutaneous blood vessels – see Fig. 29.11A), increased risk of infection and systemic absorption, causing Cushingoid features and suppression of the hypothalamic–pituitary–adrenal axis. However, under-treatment with glucocorticoids is more common than over-treatment in routine clinical practice. In general, the lowest potency of glucocorticoid should be used for the shortest period to gain control of the disease; this can be achieved by initial use of a more potent glucocorticoid, with reduction in potency or frequency of application as control is gained. Tolerance or tachyphylaxis can develop with chronic use, so intermittent courses of treatment are advised. Caution is required with glucocorticoids in psoriasis, as rebound, unstable or pustular psoriasis can occur with sudden cessation of use. Nevertheless, glucocorticoids are invaluable for many sites, particularly the flexures. Topical glucocorticoids are often formulated in combination with antiseptics, antibiotics or antifungals, and their controlled use may be appropriate in infected eczema or flexural psoriasis. Intralesional injections of glucocorticoids can be used in a variety of indications, including nodular prurigo, keloid scar (**definition** of 'scar': replacement of normal structures by fibrous tissue at the site of an injury, although keloid scar describes a pathological process extending beyond the site of injury), acne cysts and alopecia areata.

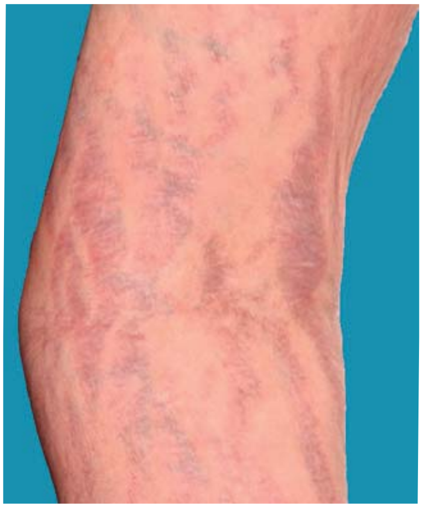

Fig. 29.10 Striae and atrophy induced by excess prolonged potent topical glucocorticoid use.

i 29.12 Potencies and strengths of commonly used topical glucocorticoid preparations*

Mild
• Hydrocortisone 0.5%, 1%, 2.5%
• Hydrocortisone 1% and fusidic acid 2% (Fucidin H)
Moderate
• Clobetasone butyrate 0.05% (Eumovate)
• Betamethasone valerate 0.025% (Betnovate-RD)
• Fluocinolone acetonide 0.00625% (Synalar 1 : 4)
Potent
• Betamethasone valerate 0.1% (Betnovate)
• Betamethasone valerate 0.1% and clioquinol 3% (Betnovate-C)
• Fluocinolone acetonide 0.025% (Synalar)
• Hydrocortisone butyrate 0.1% (Locoid)
• Mometasone furoate 0.1% (Elocon)
Very potent
• Clobetasol propionate 0.05% (Dermovate)
*UK trade names are given in brackets.

Anti-infective agents

Antiseptics should be considered before antibiotics, as they cover a wide range of organisms and help to reduce the risk of antibiotic resistance. Antibiotics can be used either for their anti-infective properties (p. 1236) or for their anti-inflammatory properties (pp. 1242 and 1244). Topical antiviral and antifungal agents are also widely used for a range of mild skin infections (p. 1239).

Calcineurin inhibitors

The topical calcineurin inhibitors, tacrolimus and pimecrolimus, can be used to treat eczema and a variety of other conditions, through local cutaneous immunosuppression (p. 1244).

Immune response modifiers

Topical imiquimod was introduced for the treatment of anogenital warts but can be used for a diverse range of other skin diseases, including actinic keratosis, Bowen's disease, basal cell carcinoma, lentigo maligna, cutaneous lupus and common and planar warts. Its mechanism of action is via stimulation of endogenous Th2 immune responses and release of cytokines, including interferon-gamma (IFN-γ). It can cause significant inflammation, requiring dose adjustments, but subclinical disease may respond to treatment.

Dressings

A 'wound' covering is called a dressing. Box 29.13 shows the indications for their use. The active agent, vehicle and 'wound' type should be considered. Wet lesions should be treated with

i 29.13 Indications for dressings

- Protection
- Symptomatic relief from pain or itch
- Maintenance of direct application of topical treatment
- Possible improvement in healing time
- Reduction of exudate
- Reduction of odour

wet dressings. Paste bandages can be used in conjunction with topical emollients and glucocorticoids to soothe and cool, ease pruritus and scratching, and reduce inflammation. Dressings for venous leg ulcers are described on page 1224.

Phototherapy and photochemotherapy

Ultraviolet radiation (UVR) treatments (most commonly, narrowband ultraviolet B and psoralen–ultraviolet A (PUVA)) are used in the management of many different diseases. The best evidence for their efficacy is in psoriasis, atopic eczema, vitiligo and chronic urticaria, although there is also evidence that UVB is helpful in treating generalised itch associated with chronic kidney disease and a range of other diverse skin conditions.

Psoralens are natural photosensitisers found in a number of plants. They intercalate between the strands of DNA and, on excitation with UVA, cross-link the DNA strands. Psoralens are therefore prodrugs that are activated only in skin that is exposed to UVA. Psoralens can also be applied topically in a bath before irradiation with UVA (bath PUVA) or can be applied in creams or gels for localised topical PUVA. PUVA is a more complex treatment than UVB and has more adverse effects; in particular, cumulative exposure to PUVA increases the risk of skin cancer, particularly squamous cell carcinoma. Therefore, PUVA is generally used for poor responders to UVB, or in diseases such as plaque-stage cutaneous T-cell lymphoma or pityriasis rubra pilaris, where it is the phototherapy of first choice. Phototherapy or PUVA may be offered as a whole-body or localised treatment.

Longer-wavelength UVA1 (340–400 nm) is also used for several conditions, particularly the fibrosing skin diseases such as morphoea, where efficacy has been shown and there is a lack of other well-proven therapies. The evidence base for its place in the management of several diseases, such as eczema, is not fully proven and availability of UVA1 is mainly through centres of specialist expertise.

Systemic therapies

General information is provided here for drugs used in a range of skin diseases; details of other drugs are provided in disease-specific sections.

Antibiotics

Antibiotics are generally used for their anti-infective properties, particularly for staphylococcal and streptococcal skin infections. In these indications, the correct antibiotic should be selected, based on bacterial sensitivity and patient factors. As examples, oral flucloxacillin may be indicated for clinically infected eczema, intravenous flucloxacillin for cellulitis, and clarithromycin for a patient with a staphylococcal carbuncle who is penicillin-allergic. Optimal therapeutic doses and courses must be chosen, based on local antimicrobial prescribing guidelines. Several antibiotics, such as tetracyclines, erythromycin and co-trimoxazole are used predominantly for their anti-inflammatory effects in indications such as acne vulgaris, bullous pemphigoid and pyoderma gangrenosum.

Antihistamines

A range of H_1 and H_2 receptor antagonists are used in dermatology. For diseases in which histamine in the skin is relevant (such as urticaria), non-sedating antihistamines should be given: for example, fexofenadine or cetirizine. For pruritic conditions such as eczema, the sedating effect of antihistamines like hydroxyzine or chlorphenamine is important. However, antihistamines are widely used in older patients for the symptom of pruritus due to a variety of causes such as xeroderma, metabolic impairment, malignancy or concomitant drugs. Sedating antihistamines should be used with caution in older patients, as they may increase the risk of falls and accidents in the home, with disastrous consequences. Careful choice of drug and dose is therefore essential. Leukotriene receptor antagonists, such as montelukast, may be added to antihistamine regimes.

Retinoids

Oral retinoids are used in a range of conditions, including acne, psoriasis and other keratinisation disorders. They promote differentiation of skin cells and have anti-inflammatory effects. Isotretinoin (13-*cis*-retinoic acid) is widely used for moderate to severe acne (p. 1243). Acitretin can be effective in psoriasis and other keratinisation disorders, such as ichthyosis, as can alitretinoin (9-*cis*-retinoic acid) in hand and foot eczema and bexarotene in cutaneous T-cell lymphoma.

Adverse effects of retinoids include dryness of the skin and mucous membranes, abnormalities in liver function or hepatitis, increase in serum triglycerides (levels should be checked before and during therapy) and mood disturbances. Alitretinoin and bexarotene can cause hypothyroidism. Systemic retinoids are teratogenic and must be prescribed along with a robust form of contraception. Females must have a negative pregnancy test before, during and after therapy, and pregnancy must be avoided for 2 months after stopping isotretinoin and 2 years after stopping acitretin.

Immunosuppressants

Systemic glucocorticoids, particularly prednisolone, are widely used in inflammatory skin diseases, such as eczema, immunobullous disease and connective tissue disorders. Methotrexate, azathioprine and mycophenolate mofetil are effective in eczema and psoriasis either alone or as glucocorticoid-sparing agents. Further details on the mechanism of action, adverse effects and monitoring requirements for these agents are provided on page 1004, although it is important to be aware that there may be different approaches to treatment regimens and doses between specialties for some drugs. For example, in dermatology, methotrexate is used in a once-weekly regimen, with doses of up to 25 mg per week, depending on the response (p. 1004). Hydroxycarbamide is an alternative immunosuppressant to methotrexate in psoriasis, but appears to be less effective and the risk of myelosuppression is greater. Ciclosporin (p. 1005) has a rapid onset of action and is effective in inducing clearance of psoriasis and eczema. Monitoring of blood pressure and renal function is required. Ciclosporin should be used only with caution after phototherapy, particularly PUVA, because of the

increased risk of skin cancer. Long-term use of ciclosporin is not advised. Dapsone is an immunomodulator and may be used in diseases in which neutrophils are implicated, such as dermatitis herpetiformis (p. 1256). Haemolysis, methaemoglobinaemia and hypersensitivity can occur, and monitoring is required (pp. 123 and 269). Hydroxychloroquine is of particular value in cutaneous lupus. More details on the mechanism of action, adverse effects and monitoring requirements are provided on page 1005.

Biological therapies

Biological inhibitors of pro-inflammatory cytokines, including tumour necrosis factor alpha (TNF-α) inhibitors, ustekinumab (an antibody to the p40 component of interleukin (IL)-12 and IL-23), guselkumab (an antibody to IL-23), secukinumab and ixekizumab (antibodies to IL-17A) and brodalumab (an antibody to the IL-17 receptor) are effective treatments for psoriasis. Rituximab, which causes depletion of B cells, may be used in pemphigus vulgaris. More details on the dosages, mechanism of action and adverse effects of these agents are provided on page 1006. Omalizumab, a monoclonal antibody directed against immunoglobulin E (IgE), was introduced for allergic asthma but may also have a role in non-allergic diseases, such as treatment-resistant urticaria (pp. 86 and 572). Intravenous immunoglobulin, pooled from donor plasma, may be used in the treatment of dermatomyositis (p. 1039) and occasionally may be indicated in other dermatological diseases.

Dermatological surgery

Most dermatological surgical procedures are performed under local anaesthetic. Knowledge of local anatomy is essential, particularly the locations of vessels and nerves. In certain sites, such as the fingers, soles of the feet and nose, local cutaneous nerve blocks are useful. Some sites are associated with particular risks, such as keloidal scarring on the upper trunk of young patients, unsightly scars over the scapulae, and poor healing and risk of ulceration following procedures on the lower legs.

Excision biopsy

This involves surgical removal of the lesion followed by histological examination. The most common indication is suspicion of malignancy. The lesion and line of excision should be marked out and the margin of excision decided before the procedure. It is important to excise down to the appropriate anatomical plane. Depending on body site, a range of procedures can minimise the resulting defect. Healing by secondary intention may also achieve good cosmetic results.

Curettage

Curettage involves using a small, spoon-shaped implement (curette), not only as a definitive treatment but also to obtain histology. Curettage does not preserve tissue architecture very well, however, and it may be difficult to distinguish between dysplasia and invasive malignancy. It can be an effective treatment for basal cell papillomas, actinic keratoses, intra-epidermal carcinoma and superficial basal cell carcinoma.

Shave excision

Shave excision using local anaesthetic may be used for simple and effective treatment of raised superficial benign skin lesions affecting epidermis and upper dermis, such as benign naevi and skin tags.

Mohs' micrographic surgery

Mohs' micrographic surgery is employed to ensure adequate tumour excision margins, while conserving unaffected tissue. It is most commonly used for basal cell carcinoma (p. 1229).

Non-surgical treatments

Cryotherapy

Cryotherapy is a destructive treatment using liquid nitrogen to cause cell-wall and membrane destruction and cell death. Liquid nitrogen can be applied either with a cotton bud or, more effectively, with a spray gun. A wide variety of conditions can be treated but it is essential for the correct diagnosis to be made first, if necessary by diagnostic biopsy. Cryotherapy should not be used to treat melanocytic naevi. Benign lesions, such as viral warts and basal cell papillomas, respond well, and cryotherapy can also be effective for actinic keratoses, Bowen's disease or superficial non-melanoma skin cancer. Malignant indications require more vigorous treatment, usually with two cycles, and this is normally carried out in secondary care. Considerable inflammation, blistering and pigmentary change, particularly hypopigmentation, can occur. Caution is required to avoid damage to tendons and nerves, especially when using cryotherapy on digits.

Laser therapy

Laser therapy involves treatment with monochromatic light. Skin components (chromophores), such as haemoglobin and melanin, absorb specific wavelengths of electromagnetic radiation, and these wavelengths can therefore be used to destroy these targets selectively and to treat certain skin disorders. Lasers targeting haemoglobin are employed for vascular abnormalities, such as spider naevi, telangiectasiae and port-wine stains, and lasers targeting melanin can treat benign pigmentary disorders or pigment in tattoos or drug-induced hyperpigmentation (for example, secondary to minocycline). Melanin lasers can also be used for hair removal if the hair is pigmented. Light delivery in short pulses restricts damage to the treated site.

The carbon dioxide laser emits infrared light that is absorbed by water in tissues and can therefore be used for destructive purposes. The depth of effect can be controlled, such that the carbon dioxide laser is widely employed for resurfacing in photorejuvenation or acne scarring. Significant morbidity is associated with this destructive laser, although this may be minimised with fractionated regimens, and general anaesthesia is usually required.

Photodynamic therapy

Photodynamic therapy (PDT) is widely used in dermatology, predominantly for actinic keratoses, Bowen's disease and superficial basal cell carcinoma (p. 1229).

Radiotherapy and grenz (Bucky) ray therapy

Radiotherapy can be employed for several skin conditions, including non-melanoma skin cancer or lentigo maligna that is not suitable for surgical treatment, but its use in dermatology has declined. Scarring and poikiloderma can occur at treated

sites, although these are minimised if fractionated regimens are chosen. Superficial radiotherapy is now rarely employed to treat benign dermatoses. Even more superficial ionising radiation (grenz, or Bucky, rays) can be useful for localised dermatoses that are having severe effects on quality of life, if conventional treatments have been inadequate; for example, it may avoid the need for systemic immunosuppression in a patient with severe recalcitrant localised scalp psoriasis.

Skin tumours

Pathogenesis

Skin cancer is the most common malignancy in fair-skinned populations. It is subdivided into non-melanoma skin cancer (NMSC) and melanoma. NMSC is further subdivided into the most common skin cancer, basal cell carcinoma (BCC), and squamous cell carcinoma (SCC). The latter has precursor non-invasive states of intra-epithelial carcinoma (Bowen's disease, BD) and dysplasia (actinic keratosis, AK). Melanoma is much less common than NMSC, but because of its metastatic risk it is the cause of most skin cancer deaths.

UVR is a complete carcinogen and is the main environmental risk factor for skin cancer, which is much more common in countries with high ambient sun exposure, such as Australia. Skin cancer risk also increases if an individual migrates to such a country when young, particularly if less than 10 years of age. Epidemiological evidence supports a close link between chronic UVR exposure and risk of SCC and AK, and a modest link between sun exposure and BCC risk. Melanoma usually arises on sites that are intermittently exposed to UVR, and episodes of sunburn have been implicated as a risk factor for melanoma. There is good evidence to show that sunbed exposure is also a risk for both melanoma and NMSC, particularly when exposure starts in adolescence and early adult life. Strategies to reduce sun exposure are therefore important for skin cancer prevention, with reliance mainly on behavioural modification, covering up and judicious sunscreen use. Indeed, there is evidence to show that sunscreen use reduces naevi development in children, and in adults regular sunscreen use reduces the risk of AK and SCC and is likely also to have preventative roles in melanoma and BCC development.

There are identifiable genetic predispositions for some skin cancers, such as in xeroderma pigmentosum, an autosomal recessive condition caused by an inherited defect in DNA excision repair (pp. 1221 and 1321), or basal cell naevus (Gorlin's) syndrome, an autosomal dominant disorder caused by loss-of-function mutations affecting the *PTCH1* tumour suppressor genes, with consequent activation of the Hedgehog pathway (p. 1321). Interestingly, the Hedgehog pathway is also almost invariably activated in sporadic BCC, which usually contain somatic mutations in *PTCH1* and less commonly in the *SMO* gene, which lies in the same signalling pathway. The genetics of SCC are heterogeneous and less clearly defined, with several mutations and pathways implicated, including *TP53*, *CDKN2A/p16*, NOTCH, EGFR and the MAPK signalling pathways. Interestingly, many of the mutations seen in SCC also occur in the pre-cancers AK and BD. The genetics of melanoma are discussed on page 1232.

Cutaneous immune surveillance is also critical and immunosuppressed organ transplant recipients have a greatly increased risk of skin cancer, particularly SCC. Interestingly, patients who have received high treatment numbers of PUVA (more than 150), which is immunosuppressive, are also at increased risk of skin cancer, particularly SCC.

Despite UVB being a complete carcinogen, there is no evidence at present that UVB phototherapy significantly increases skin cancer risk, although ongoing vigilance is required. Ionising radiation, notably radiotherapy, thermal radiation and chemical carcinogens, such as arsenic or coal tar, can increase NMSC risk, particularly SCC. A role for oncogenic human papillomaviruses in SCC development is also implicated, particularly in immunosuppressed patients, where viral DNA is detected in more than 80% of tumours. Chronic inflammation is a risk factor for SCC, which may arise in chronic skin ulcers (p. 1223), discoid lupus erythematosus or vulgaris, and the scarring genetic skin disease dystrophic epidermolysis bullosa (see Box 29.25, p. 1254), in which up to 50% of patients develop SCC.

Malignant tumours

Basal cell carcinoma

The incidence of NMSC has increased dramatically in recent decades and basal cell carcinoma (BCC) accounts for more than 70% of cases. In Europe, the ratio of BCC to SCC is 4–5 : 1 in immunocompetent patients. It is a malignant tumour that rarely metastasises; it is thought to derive from immature pluripotent epidermal cells and is composed of cells with similarities to basal layer epidermis and appendages. Lesions typically occur at sites of moderate sun exposure, particularly the face, and are slow-growing. The incidence increases with age and males are more commonly affected. Lesions may ulcerate and invade locally; hence the term 'rodent ulcer'.

Clinical features

Early BCCs usually present as pale, translucent papules or nodules, with overlying superficial telangiectatic vessels (nodular BCC). If untreated, they increase in size and ulcerate, to form a crater with a rolled, pearled edge and ectatic vessels (Fig. 29.11). There may be some pigmentation or a cystic component. A superficial multifocal type can occur, frequently on the trunk, and may be large (up to 10 cm in diameter); often there are multiple lesions. Superficial BCC usually presents as a red/brown plaque or patch with a raised, thread-like edge, which is

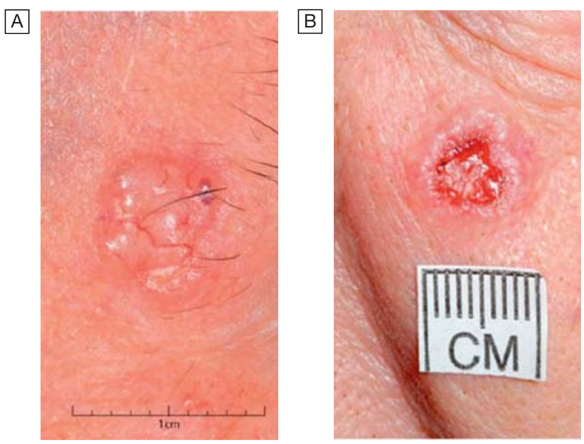

Fig. 29.11 Basal cell carcinoma. **A** A nodular BCC showing the translucent nature of the tumour and the abnormal arborising vessels. **B** An ulcerated BCC showing the raised, rolled edge.

often best seen by stretching the skin; this helps to distinguish it from Bowen's disease. Less commonly, a morphoeic, infiltrative BCC presents as a poorly defined, slowly enlarging, sclerotic yellow/grey plaque.

Diagnosis and management

The diagnosis is often obvious clinically, based on the features mentioned above, although a diagnostic confirmatory biopsy may be required prior to definitive treatment. Management depends on the characteristics of the tumour and on patient factors, including comorbidities and patient wishes. Essentially, treatment will be either surgical or, in some cases, medical (Box 29.14). Surgical excision, ideally with a 4–5 mm margin, is the treatment of choice, with a cure rate of approximately 95%. Curettage and cautery may also be effective for selected lesions. Management of infiltrative morphoeic BCC and/or lesions at difficult sites, such as around the eye, may require more complex techniques such as Mohs' micrographic surgery to ensure adequate tumour excision margins, while conserving unaffected tissue. This involves processing of frozen sections of all margins in stages (usually on the same day) until all the tumour is removed. The procedure is time-consuming (so can be difficult for elderly, frail patients) and requires particular surgical and pathology skills, but is associated with the highest long-term cure rates, with 98–99% clear at 5-year follow-up.

If a surgical approach is used for management of BCC and the primary tumour is not completely excised, re-excision may be required, although follow-up may be appropriate as not all tumours that are incompletely excised recur. However, this is not recommended for tumours at high-risk sites or for infiltrative morphoeic BCC, where complete excision is advisable. Cryotherapy may be effective for BCC but can cause blistering and scarring, so is best suited to small, superficial lesions at low-risk sites.

Radiotherapy can be invaluable for large BCC lesions in frail patients but is less commonly used because of the risk of scarring.

Medical therapies can be used to treat low-risk BCC, particularly when surgery is not appropriate for a patient. Topical immunomodulators, such as imiquimod, are effective for low-risk BCC and may be particularly useful for patients who are not able to attend a hospital clinic setting but are able to apply a topical preparation at home over a 6-week period. Imiquimod usually induces a prominent inflammatory reaction and patients should be advised that dose adjustments may be required. Topical 5-fluorouracil can also be effective for low-risk small lesions of superficial BCC, but is rarely used since it usually provokes an intense inflammatory reaction. Intralesional interferon-alpha2b has been used for BCC but multiple treatments and high cost preclude its regular use.

PDT is an effective treatment for low-risk, predominantly superficial BCC, as well as AK and BD. Usually, topical porphyrin PDT is employed, which involves application of a porphyrin prodrug to the lesion to be treated. The prodrug is taken up and converted by the cell's haem cycle to protoporphyrin IX, a photosensitiser. This is photochemically activated by visible (normally red) light, usually delivered by a light-emitting diode (LED), in the presence of oxygen, causing the production of reactive oxygen species, which cause destruction of treated tissue. The photosensitiser is taken up preferentially by diseased skin, and adverse effects in normal skin are minimised. PDT is at least as effective as cryotherapy and surgery for superficial BCC and may be preferred at sites of poor healing, such as the lower leg, or where cosmetic outcome is important. PDT is not as effective as surgery for long-term clearance of nodular BCC but can be considered if surgery is not appropriate. Pain during irradiation may occur during PDT, although adjustments to the irradiation regime can reduce discomfort. PDT is usually undertaken in the outpatient clinic setting and is well suited to frail elderly patients who are not able to undertake treatment with topical agents at home.

Rarely, advanced BCC may be locally invasive or even metastasise. Major advances have been made in targeted drug development, and Hedgehog pathway inhibitors, such as vismodegib and sonidegib, can be used effectively for disease control and palliation in this setting, although there may be significant associated drug-induced toxicity.

i 29.14 Management of non-melanoma skin cancer and pre-cancer

Basal cell carcinoma

- Excision results in the lowest recurrence rates
- Mohs' micrographic surgery is effective for high-risk BCC
- Medical treatments are often appropriate for low-risk superficial tumours in patients with comorbidities
- Cryotherapy and topical 5-fluorouracil can be used for superficial BCC
- Topical photodynamic therapy and topical imiquimod are both effective in superficial BCC
- BCC in patients with Gorlin's syndrome should not be treated with radiotherapy
- Hedgehog pathway inhibitors can induce clinical response in patients with advanced inoperable BCC

Squamous cell carcinoma

- Excision is the treatment of choice for invasive SCC
- Most recurrences or metastases occur within 5 years
- Medical management is not usually considered for invasive SCC

Carcinoma in situ (Bowen's disease)

- For single/few lesions on good healing sites, cryotherapy, curettage, photodynamic therapy, topical imiquimod and 5-fluorouracil are options
- For multiple lesions and/or poor healing sites such as the lower leg, photodynamic therapy, where feasible, is the treatment of choice, although topical 5-fluorouracil or imiquimod is an alternative

Actinic keratosis

- For single/few lesions on good healing sites, cryotherapy, curettage, 5-fluorouracil/salicylic acid and ingenol mebutate are options. especially if hyperkeratotic
- For multiple lesions/field change, conventional or daylight photodynamic therapy, topical 5-fluorouracil, imiquimod or diclofenac in hyaluronic acid gel may be effective

Squamous cell carcinoma

Squamous cell carcinoma (SCC) is a malignancy that arises from epidermal keratinocytes and is the second most common skin cancer, occurring most frequently in elderly males and smokers. There is a close association between cumulative UVR exposure and SCC risk, with most SCC lesions occurring on chronically sun-exposed sites in white populations and often arising at sites of field-change carcinogenesis, with coexistent precursors of AK and BD commonly evident. In the immunosuppressed patient population, such as organ transplant recipients, SCC is the most common skin cancer and its incidence is dramatically increased, particularly in association with the duration of immunosuppression

and the degree of sun exposure and damage accrued pre-transplant. The risk of SCC is also increased in HIV infection. Furthermore, SCC arising in the immunosuppressed is more likely to behave aggressively or to metastasise.

Clinical features

The tumours usually occur on chronically sun-exposed sites, such as bald scalp, tops of ears, face and back of hands. The clinical presentation may be diverse, ranging from rapid development of a painful keratotic nodule in a pre-existing area of dysplasia (Fig. 29.12) to the de novo presentation of an erythematous, infiltrated, often-warty nodule or plaque that may ulcerate. The clinical appearance depends on histological grading; well-differentiated tumours more often present as defined keratotic nodules (Fig. 29.12), whereas poorly differentiated tumours tend to be ill defined and infiltrative, and may ulcerate. SCC has metastatic potential; some tumours, such as those on lips and ears and in immunosuppressed patients, behave more aggressively and are more likely to metastasise to draining lymph nodes.

Management

Early diagnosis is important and complete surgical excision is the usual treatment of choice (see Box 29.14). Standard excision with a 4–6 mm margin is advised and the cure rate is approximately 90–95%. Mohs' surgery is an option but is used less frequently for SCC than for BCC. High-risk SCC should be treated aggressively, with a wider margin of excision of at least 6 mm where feasible. This may include larger, thicker lesions, tumours at sites where metastases are more likely, such as the ear, lip or non-sun-exposed sites, and those occurring in the immunosuppressed and/or with histology showing the tumour to be poorly differentiated, with evidence of lymphatic, vascular or perineural involvement or a high mitotic index. Such patients and those with metastatic disease require management via a multidisciplinary team. In patients who are at high risk for further SCC, systemic retinoids may have a role in reducing the rate of SCC development, but rapid appearance of tumours occurs on drug cessation. Occasionally, curettage and cautery may be appropriate if the tumour is small and low-risk and either surgical excision is contraindicated or the patient is unwilling to proceed. Radiotherapy may be indicated if surgical excision is not feasible. Cryotherapy and topical non-surgical therapies are not usually used in invasive SCC because of risk of recurrence and metastasis.

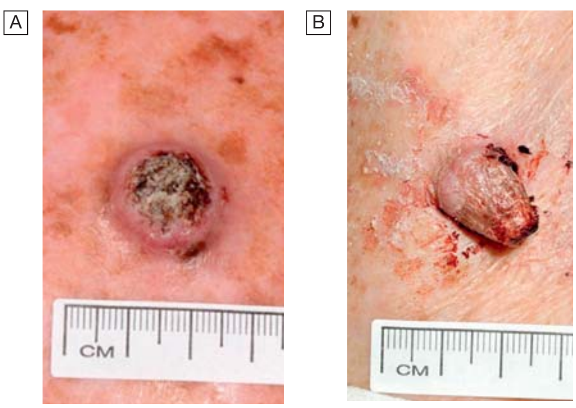

Fig. 29.12 Squamous cell carcinoma. A A centrally keratinous, symmetrical, well-differentiated SCC. Clinically, this could be confused with keratoacanthoma. B An SCC arising from an area of epidermal dysplasia.

Actinic keratosis

Actinic keratoses (AK) are scaly, erythematous lesions arising on chronically sun-exposed sites. Histology shows dysplasia, although the diagnosis of typical AK is usually made on clinical grounds (Fig. 29.13). They are common in fair-skinned people who have had significant sun exposure, are often multiple and increase with age. The prevalence is much higher in Australia than in the UK and some surveys have shown a prevalence of more than 50% in those over 40 years old. The rate of progression to SCC is less than 0.1% and spontaneous resolution is possible. However, SCC can also arise de novo and without progression from AK. Increase in size, ulceration, bleeding, pain or tenderness can be indicative of transformation into SCC.

Management

Several treatments are available for AK (see Box 29.14). Emollients and photoprotection, including high-factor sunscreens, may suffice for mild disease. Single or low numbers of lesions of AK can be effectively treated with cryotherapy. Hyperkeratotic lesions may be treated with the antimetabolite 5-fluorouracil, combined with salicylic acid, or may require curettage and cautery.

Multiple lesions require field-directed therapy; 5-fluorouracil is widely used in this setting and is effective but topical imiquimod is an alternative. Diclofenac in a hyaluronic acid gel base can also be used topically for low-grade maintenance control of AK, the rationale for its use being the over-expression of cyclo-oxygenase (COX)-2 in AK lesions. Topical ingenol mebutate can also be used and has the advantage of a short treatment regime, although severe inflammation may be induced. PDT is widely used for field-change multiple AK, with high efficacy rates; it is at least as effective as cryotherapy or 5-fluorouracil. The relative selectivity of treatment allows subclinical disease to be treated, while sparing normal skin. A regimen using daylight to activate the photosensitiser is increasingly used worldwide for extensive mild AK, with high efficacy rates, comparable to hospital-based PDT but without the need for specialised equipment and allowing patients to be treated at home.

Fig. 29.13 Actinic keratosis. Close-up of a hyperkeratotic AK on the ear.

Fig. 29.14 Intra-epidermal carcinoma (Bowen's disease). The lower leg is a common site and lesions are often treated non-surgically.

Bowen's disease

Clinical features

Bowen's disease (BD) is the name given to an intra-epidermal carcinoma that usually presents as a slowly enlarging, erythematous, scaly plaque on the lower legs of fair-skinned elderly women (Fig. 29.14) but other sites can also be involved. It can be confused with eczema or psoriasis, but is usually asymptomatic and does not respond to topical glucocorticoids. It may also be hard to distinguish from superficial BCC. Transformation into SCC occurs in 3% or less.

Diagnosis

Incisional biopsy is usually undertaken to confirm the diagnosis. This shows an intra-epidermal carcinoma with no invasion through the basement membrane. Histology may also be obtained by curettage but this does not allow distinction from invasive SCC to be made, due to loss of tissue orientation and architecture.

Management

While curettage or excision may be appropriate in some settings, non-surgical therapies are generally preferred (see Box 29.14), especially on the lower legs. PDT, in particular, may be advantageous for BD on the lower leg because of relative selectivity of treatment and sparing of normal tissue, thus reducing the risk of poor healing and ulceration at this vulnerable site. Given the low risk of malignant transformation, the option of no active treatment may also be appropriate for some elderly frail patients.

Cutaneous lymphomas

The most common form of cutaneous T-cell lymphoma is mycosis fungoides (MF). This can persist for years in patch and plaque stages, often resembling eczema or psoriasis. Only sometimes does it progress through to nodules and finally a systemic stage, Sézary's syndrome. B-cell lymphomas, on the other hand, usually present as nodules or plaque-like tumours. The diagnosis of cutaneous T-cell lymphoma requires a high index of suspicion, particularly in patients thought to have unusual recalcitrant forms of eczema or psoriasis.

Treatment is symptomatic and there is no evidence that it alters prognosis. In the early stages of cutaneous T-cell lymphoma, systemic or local glucocorticoids may be indicated; alternatively, narrowband UVB phototherapy (for patch-stage MF) or PUVA (for plaque-stage MF) may be used. Once lesions have moved beyond plaque stage, localised radiotherapy, electron beam radiation, the synthetic retinoid bexarotene, interferon-alpha, extracorporeal photopheresis and systemic anti-lymphoma chemotherapy regimens may be needed. Management of advanced disease invariably requires a multidisciplinary team approach, with collaboration between dermatologists, pathologists and haematological oncologists.

i 29.15 Classification of cutaneous malignant melanoma

Melanoma without metastatic potential	
• Melanoma in situ	• Lentigo maligna
Melanoma with metastatic potential	
• Superficial spreading melanoma	• Acral lentiginous melanoma
• Nodular melanoma	• Subungual melanoma
	• Lentigo maligna melanoma

Melanoma

Melanoma is a malignant tumour of epidermal melanocytes. While only 4% of skin cancers are melanomas, they account for 80% of skin cancer deaths. There has been a steady rise in the incidence of melanoma in fair-skinned populations over recent decades, with the highest figures in Australasia. Primary prevention and early detection are essential, as therapy for advanced and metastatic disease remains unsatisfactory.

Pathophysiology

Risk factors for melanoma include fair skin, freckles, red hair, number of naevi and sunlight exposure. The type of sunlight exposure is under debate but intermittent exposure, such as recreational time in the sun, sunburn and sunbed use, is implicated. Patients with multiple atypical naevi (dysplastic naevus syndrome) and fair-skinned people, often with variant alleles in the melanocortin-1 gene, are at increased risk of melanoma. A family history of melanoma increases the risk but a strong family history is unusual. Rarely, autosomal dominant inheritance of melanoma with incomplete penetrance can occur due to mutations in *CDKN2A*, which encodes the p16 tumour suppressor protein. In these patients, the lifetime risk of melanoma is more than 50%. Several other susceptibility genes and potential genetic targets for therapeutic intervention in advanced disease have also been identified.

Clinical features

Melanoma can occur at any age and site and in either sex, but typically affects the leg in females and back in males. It is rare before puberty. The classification of invasive malignant melanoma is shown in Box 29.15. Early lesions may be in situ and pre-invasive before becoming invasive melanoma with metastatic potential. Any change in naevi or development of new lesions should be assessed to exclude malignancy and, for this, the dermatoscope is invaluable (see Fig. 29.2, p. 1217). Real-time non-invasive imaging techniques are being investigated as tools to assist in diagnosis but are largely experimental. If there is any doubt, excision is advised.

Superficial spreading melanoma

Superficial spreading melanoma (SSM) is the most common type in Caucasians. It usually presents as a slowly enlarging, macular, pigmented lesion, with increasing irregularity in shape and pigment; this superficial, radial growth phase can last for

Fig. 29.15 Superficial spreading melanoma. A A superficial spreading malignant melanoma with a palpable area indicative of vertical growth phase (Breslow thickness 1.3 mm). B A nodular malignant melanoma arising de novo and with Breslow thickness of 3.5 mm.

approximately 2 years. Subsequently, the lesion may become palpable and this is indicative of a vertical growth phase, with dermal invasion; when this occurs, the tumour has the potential to invade lymphatics and vessels and to become metastatic (Fig. 29.15A). Approximately 50% of melanomas arise from a pre-existing naevus.

Nodular melanoma

Nodular melanoma is most common in the fifth and sixth decades, particularly in men and on the trunk (Fig. 29.15B). This may account in part for the increased mortality rates from melanoma in men, as these are tumours with greater metastatic risk. They often present as a rapidly growing nodule that may bleed and ulcerate. Nodular melanomas may be heavily pigmented, or relatively amelanotic and erythematous, and be confused with benign vascular lesions. A rim of pigmentation may, however, be seen under the dermatoscope. Lesions may develop de novo or from a pre-existing naevus or SSM.

Lentigo maligna melanoma

This arises from a prolonged pre-invasive phase termed lentigo maligna. It occurs as a very slowly expanding, pigmented, macular lesion, usually on photo-exposed head and neck sites of elderly patients; histology shows in situ changes only. This phase may last for several years before a nodule of invasive melanoma develops in a proportion of cases (lentigo maligna melanoma).

Acral lentiginous or palmoplantar melanoma

This accounts for only approximately 10% of melanomas in fair-skinned races and is more common in dark-skinned people, in whom it is responsible for 50% of cases. This indicates that UVR exposure may not be implicated in acral melanoma risk.

Subungual melanoma

This form of melanoma is rare. It may present as a painless, proximally expanding streak of pigmentation arising from the nail matrix, and progresses to nail dystrophy and involvement of the adjacent nail fold (Hutchinson's sign).

Diagnosis and management

The diagnosis is made by excision biopsy of a suspicious lesion. The initial biopsy should include a 2 mm margin, followed up where possible by wider excision if the diagnosis is confirmed. Occasionally, radiotherapy or imiquimod may be used for lentigo maligna, if surgery is not feasible. The Breslow thickness of the tumour (the maximal depth from epidermal granular cell layer to deepest tumour cells) is critical for management and prognosis. The presence of ulceration may lead to under-estimation of the Breslow thickness. The mitotic rate and the presence or absence of any evidence of lymphovascular or perineural involvement should also be ascertained. The clinical staging of melanoma extent is essential, in order to establish whether disease is primary and localised, or if there is nodal or metastatic spread.

Wide excision of melanoma with a low risk of metastasis (stage 1 disease, Breslow thickness < 1 mm) with a 1 cm clear margin is accepted practice. The margin of excision for more advanced disease is controversial, although a 2–3 cm margin for thicker tumours is generally advised as an attempt to reduce risk of local recurrence. There is no evidence that more radical surgery with 4–6 cm margins is beneficial. The majority of tumours can be excised without the need for grafting. For tumours with a Breslow thickness of 1 mm or more, a sentinel lymph node biopsy should be considered. This is usually performed at the time of wider excision and involves injection of radio-labelled blue dye at the site of the primary melanoma, allowing identification of the draining 'sentinel' node by radioscintigraphy; this sentinel node is then removed and examined in detail by histology, immunohistochemistry and/or PCR of melanocyte gene products to look for tumour deposits. If the biopsy is positive, local lymphadenectomy is usually offered. This procedure provides additional prognostic information but there is no evidence that it improves survival. Local recurrence of disease and palpable local node involvement should be treated surgically. Localised cutaneous metastases or in transit disease may be amenable to palliation with electrochemotherapy if there is no evidence of widespread metastatic disease.

Despite the major advances in treatment options for advanced melanoma, the prognosis for metastatic disease remains poor and treatment options are palliative. Genetic developments have facilitated the introduction of tumour-targeted treatments for advanced, unresectable and/or metastatic disease, such as the *B-Raf* and *c-Kit* kinase inhibitors for patients expressing these gene mutations, notably dabrafenib and vemurafenib, with demonstrable clinical responses. Immunotherapy with ipilimumab, which blocks T-cell activation by inhibiting CTLA-4, alone or in combination with the programmed cell death (PD1) pathway blockers nivolumab or pembrolizumab, provides clinically meaningful improvements in quality of life and survival to patients with advanced disease. Standard chemotherapy may also be used in some cases of metastatic disease, although outcomes are poor. Other biological and gene therapies and vaccines are also being investigated. It is important for patients with advanced melanoma to be managed through a multidisciplinary team in order to optimise care and facilitate their inclusion in clinical trials.

All patients should be advised regarding ongoing photoprotection, with sensible behaviour in the sun, covering up, wearing hats and high-factor sunscreen use. However, evidence has shown that despite patients with melanoma being advised to photoprotect, many follow this advice only for the first year following diagnosis, thus emphasising the need for ongoing reinforcement of guidance with regard to photoprotection. It is also prudent to advise patients who are photoprotecting to optimise oral vitamin D through diet and/or supplements.

Prognosis

Patients with a primary tumour of less than 1 mm Breslow thickness have more than a 95% chance of disease-free survival

at 10 years, but this figure drops to approximately 50% for a tumour of greater than 3.5 mm thickness. Survival rates fall to less than 10% for those with advanced nodal or metastatic disease.

Benign skin lesions

In practice, it is often difficult to distinguish between skin cancer and a benign lesion on clinical grounds; if there is any doubt, biopsy and histology are required. Benign melanocytic naevi and basal cell papillomas, in particular, can often be mistaken for melanoma, even by dermatologists. Keratoacanthoma, while benign, is also commonly considered to be invasive SCC on clinical grounds.

Keratoacanthoma

This benign tumour has a striking clinical presentation of rapid growth over weeks to months and subsequent spontaneous resolution. It is thought to be associated with chronic sun exposure and most commonly occurs on the central face. The classical appearance is of an isolated dome-shaped nodule often of 5 cm or more in diameter, with a central keratin plug (Fig. 29.16). Clinically and histologically, the lesion often resembles SCC (see Fig. 29.12A). Most are treated surgically, either by curettage and cautery or by excision, to rule out SCC and to avoid the unsightly scar after spontaneous resolution.

Freckle

Histologically, a freckle (ephelis) consists of normal numbers of melanocytes, but with focal increases in melanin in keratinocytes. They are most common on sun-exposed sites in fair-skinned individuals, particularly children and those with red hair, and on the face. There is a familial tendency. Clinically, freckles are brown macules that darken following UVR exposure.

Lentigo

A lentigo (plural lentigines) consists of increased numbers of melanocytes along the basement membrane, but without formation of the nests that occur in melanocytic naevi. These lesions usually occur at sites of chronic sun exposure (see the background skin changes in Fig. 29.12A), become more common with age, and are often referred to as 'liver spots' or 'age spots'. They can vary in colour from light to very dark brown. Distinction from melanoma is essential and histology may be required.

Haemangiomas

Benign vascular tumours or hamartomas are common and include Campbell de Morgan spots (Fig. 29.17), which present as pink/red papules on the upper half of the body. They can sometimes be difficult to distinguish from melanocytic lesions, particularly if they are thrombosed or occur on particular sites, such as the lip or genitalia. The dermatoscope is helpful for this (see Fig. 29.2, p. 1217).

Basal cell papilloma

Basal cell papillomas (also known as seborrhoeic warts or keratoses) are common, benign epidermal tumours (Fig. 29.17). They may be flat, raised, pedunculated or warty-surfaced, and can appear to be 'stuck on'. They occur in both sexes and with increasing age, and are most common on the face and trunk. The colour may vary from yellow to almost black and the surface may seem 'greasy', with pinpoint keratin plugs visible, particularly with a magnifying lens. If there is no doubt about the diagnosis, they can be left alone or treated by cryotherapy or curettage if they are cosmetically troublesome. If there is a suspicion of melanoma, excision or diagnostic biopsy should be undertaken.

Melanocytic naevi

Melanocytic naevi (moles) are localised benign clonal proliferations of melanocytes. It is thought that they may arise as the result of abnormalities in the normal migration of melanocytes during development. It is quite normal to have 20–50, although, interestingly, individuals with red hair have fewer. Genetic and environmental factors are implicated. Monozygotic twins have higher concordance in naevi numbers than dizygotic twins. Individuals who have had greater sun exposure have higher numbers of naevi. Most melanocytic naevi appear in childhood and early adult life, or during pregnancy or oestrogen therapy. The onset of a new mole is less common after the age of 25 years. Congenital melanocytic naevi occur at or shortly after birth.

Fig. 29.16 **Keratoacanthoma.**

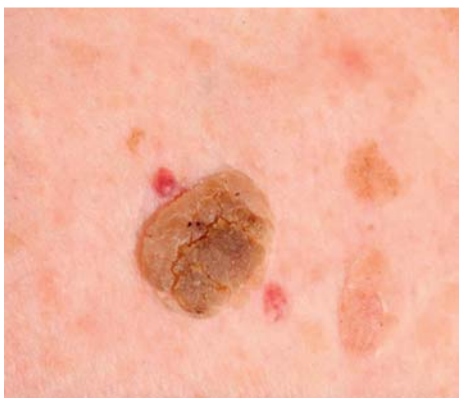

Fig. 29.17 **A typical basal cell papilloma.** Note the neighbouring basal cell papillomas and the coincidental benign angiomas (Campbell de Morgan spots).

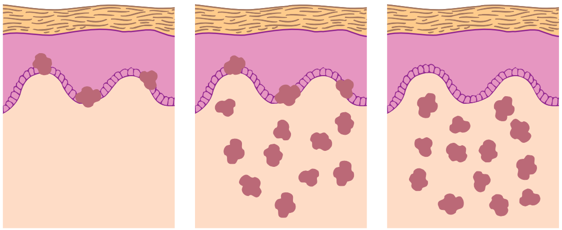

Fig. 29.18 Classification of melanocytic naevi. Classification is based on microscopic location of the nests of naevus cells.

Clinical features

Acquired melanocytic naevi are classified according to the microscopic location of the melanocyte nests (Fig. 29.18). Junctional naevi are usually macular, circular or oval, and mid- to dark brown. Compound and intradermal naevi are nodules because of the dermal component, and may be hair-bearing. Intradermal naevi are usually less pigmented than compound naevi. Their surface may be smooth, cerebriform, hyperkeratotic or papillomatous.

Some individuals have large numbers of naevi, often at unusual sites, such as the scalp, palms or soles, and these may frequently appear 'atypical' in terms of variability in pigmentation, size and shape. Some may be very dark or pink and may show a depigmented or inflamed halo. If these naevi are removed, then 'dysplastic changes' are often seen. Such naevi are known to occur in some rare families with an inherited melanoma predisposition. However, the significance of such changes in non-familial cases is unclear and there is no consensus on management and follow-up.

Although approximately 50% of melanomas arise in pre-existing naevi, most naevi do not become malignant; although a changing naevus must be taken seriously, most will not be melanomas. Malignant change is most likely in large congenital melanocytic naevi (risk may correlate with the size of the lesion) and possibly in families who have been diagnosed as showing large numbers of atypical naevi with a history of melanoma.

Diagnosis and management

Melanocytic naevi are normal and do not require excision, unless malignancy is suspected or they become repeatedly inflamed or traumatised. Advice on photoprotection is important for fair-skinned individuals with multiple naevi.

Blue naevi

These are melanocytic naevi in which there is a proliferation of spindled melanocytes relatively deep within the dermis. Light scattering means that the pigment appears blue rather than brown. They may be difficult to distinguish from nodular melanoma and are therefore often excised.

Dermatofibroma

A dermatofibroma is a characteristically firm, often pigmented, raised lesion, most commonly found on the lower legs. Its aetiology is unclear, although a reactive process secondary to insect bites or trauma is one hypothesis. There is frequently a ring of pigment around the lesion and dimpling when the skin is pinched, reflecting epidermal tethering.

Acrochordon

Acrochordons, or skin tags, are benign pedunculated lesions; they are most common in skin flexures and usually have a very characteristic clinical appearance. However, they may sometimes be confused with melanocytic naevi. Treatment is not required unless there is diagnostic doubt or they are causing symptoms, such as irritation, or for cosmetic reasons. Cryotherapy or snip or shave excision may be appropriate in that situation.

Lipoma

Lipomas are benign tumours of adipocytes that are characteristically soft and lie more deeply in the skin than epidermal tumours; they are usually diagnosed easily on clinical grounds. A variant, angiolipoma, is typically painful. Treatment is not required unless there is diagnostic doubt or they are symptomatic or cosmetically troublesome, in which case a diagnostic biopsy or surgical excision may be required.

Common skin infections and infestations

Bacterial infections

Impetigo

Impetigo is a common and highly contagious superficial bacterial skin infection. There are two main presentations: bullous impetigo, caused by a staphylococcal epidermolytic toxin, and non-bullous impetigo (Fig. 29.19), which can be caused by either *Staphylococcus aureus* or streptococci, or both together. *Staphylococcus* spp. are the most common agents in temperate climates, whereas streptococcal impetigo is more often seen in hot, humid areas. All ages can be affected but non-bullous disease particularly affects young children, often in late summer. Outbreaks can arise in conditions of overcrowding

Fig. 29.19 Non-bullous impetigo.

29

and poor hygiene or in institutions. A widespread form can occur in neonates. Predisposing factors are minor skin abrasions and the existence of other skin conditions, such as infestations or eczema.

In non-bullous impetigo, a thin-walled vesicle develops; it rapidly ruptures and is rarely seen intact. Dried exudate, forming golden crusting, arises on an erythematous base. In bullous disease, the toxins cleave desmoglein-1, causing a superficial epidermal split and the occurrence of intact blisters with clear to cloudy fluid, which last for 2–3 days. The face, scalp and limbs are commonly affected but other sites can also be involved, particularly if there are predisposing factors such as eczema. Lesions may be single or multiple and coalesce. Constitutional symptoms are uncommon. A bacterial swab should be taken from blister fluid or an active lesion before treatment commences. Around one-third of the population is a nasal carrier of *Staphylococcus*, so swabs from the nostrils should also be obtained.

In mild, localised disease, topical treatment with mupirocin or fusidic acid is usually effective and limits the spread of infection. The use of topical antiseptics and soap and water to remove infected crusts is also helpful. Staphylococcal carriage should be treated, with mupirocin topically to the nostrils, if swabs are positive. In severe cases, an oral antibiotic, such as flucloxacillin or clarithromycin, is indicated. If nephritogenic streptococci are isolated then systemic antibiotics should be considered to reduce the risk of streptococcal glomerulonephritis (p. 401). Underlying disease, such as infestations, must be treated and cross-infection minimised. Scarring does not occur but there may be temporary dyspigmentation.

Staphylococcal scalded skin syndrome

Staphylococcal scalded skin syndrome (SSSS) is a potentially serious exfoliating condition occurring predominantly in children, particularly neonates (Fig. 29.20). It is caused by systemic circulation of epidermolytic toxins from a *Staph. aureus* infection. The same toxins are implicated in bullous impetigo, which is a localised form of SSSS. The focus of infection may be minor skin trauma, the umbilicus, urinary tract or nasopharynx. The child presents with fever, irritability and skin tenderness. Erythema usually begins in the groin and axillae, and around the mouth. Blisters and superficial erosions develop over 1–2 days and can rapidly involve large areas, with severe systemic upset. Bacterial swabs should be obtained from possible primary sites of infection. A skin snip should also be taken for urgent histology. This is a sample of the superficial peeling skin removed by 'snipping with scissors', without the need for local anaesthetic. It shows a split beneath the stratum corneum, and differentiates SSSS from toxic epidermal necrolysis, in which the whole epidermis is affected (see Fig. 29.41, p. 1254). Systemic antibiotics and intensive supportive measures should be commenced immediately. Bacterial swabs from nostrils, axillae and groins should be taken from family members to exclude staphylococcal carriage. Although the acute presentation of SSSS is often severe, rapid recovery and absence of scarring are usual, as the epidermal split is superficial.

Toxic shock syndrome

This condition is characterised by fever, desquamating rash, circulatory collapse and multi-organ involvement (p. 252). It is caused by staphylococcal toxins and early cases were thought to arise with tampon use. Intensive supportive care and systemic antibiotics are required.

A

B

Fig. 29.20 Staphylococcal scalded skin syndrome. **A** Extensive erythema and superficial peeling of the skin. **B** The condition was rapidly diagnosed by examination of a frozen section of skin snip. *A, From Savin JA, Dahl M, Hunter JAA. Clinical dermatology, 3rd edn. Oxford: Blackwell; 2002.*

Ecthyma

Ecthyma is caused by either staphylococci or streptococci, or both together, and is characterised by adherent crusts overlying ulceration. It occurs worldwide but is more common in the tropics. In Europe, it occurs more frequently in children. Predisposing factors include poor hygiene, malnutrition and underlying skin disease, such as scabies. It is commonly seen in drug abusers, and minor trauma can predispose to lesion development.

Folliculitis, furuncles and carbuncles

Hair follicle inflammation can be superficial, involving just the ostium of the follicle (folliculitis), or deep (furuncles and carbuncles).

Superficial folliculitis

The primary lesions are follicular pustules and erythema. Superficial folliculitis is often infective, caused by *Staph. aureus*, but can also be sterile and caused by physical (for example, traumatic epilation) or chemical (for example, mineral oil) injury. Staphylococcal folliculitis is most common in children and often occurs on the scalp or limbs. Pustules usually resolve without scarring in 7–10 days but can become chronic. In older children and adults, they may progress to a deeper form of folliculitis. The condition

Fig. 29.21 **Staphylococcal carbuncle.**

Fig. 29.22 **Acute cellulitis of the leg.** Note the chronic lymphoedema and the haemorrhagic blistering. Blister fluid was positive for group G streptococci.

Fig. 29.23 **Erysipelas.** Note the blistering and the crusted rash with raised, erythematous edge. The yellow discoloration is due to topical iodine treatment.

is often self-limiting and may respond to irritant removal and antiseptics. More severe cases may require topical or systemic antibiotics and treatment of *Staph. aureus* carrier sites.

Deep folliculitis (furuncles and carbuncles)

A furuncle (boil) is an acute *Staph. aureus* infection of the hair follicle, usually with necrosis. It is most common in young adults and males. It is usually sporadic but epidemics occasionally occur. Malnutrition, diabetes and HIV predispose, although most cases arise in otherwise healthy people. Any body site can be involved but neck, buttocks and anogenital areas are common. Infection is often associated with chronic *Staph. aureus* carriage in the nostrils and perineum, and may be due to resistant strains, such as meticillin-resistant organisms (MRSA). Friction caused by tight clothing may be contributory. Initially, an inflammatory follicular nodule develops and becomes pustular, fluctuant and tender. Crops of lesions sometimes occur. There may be fever and mild constitutional upset. Lesions rupture over days to weeks, discharge pus, become necrotic and leave a scar.

If a deep *Staph. aureus* infection of a group of contiguous hair follicles occurs, this is termed a carbuncle and is associated with intense deep inflammation (Fig. 29.21). This usually occurs in middle-aged men, often with predisposing conditions such as diabetes or immunosuppression. A carbuncle is an exquisitely tender nodule, usually on the neck, shoulders or hips, associated with severe constitutional symptoms. Discharge, necrosis and scarring are usual. Bacterial swabs must be taken and treatment is with anti-staphylococcal antibiotics, e.g. flucloxacillin, and sometimes incision and drainage.

Other staphylococcal toxins may also be pathogenic. For example, Panton–Valentine leukocidin-producing *Staph. aureus* can cause recurrent abscesses (**definition**: localised collections of pus in cavities) and may be difficult to eradicate.

Cellulitis and erysipelas

Cellulitis is inflammation of subcutaneous tissue, due to bacterial infection (Fig. 29.22). In contrast, erysipelas is bacterial infection of the dermis and upper subcutaneous tissue (Fig. 29.23), although in practice it may be difficult to distinguish between them. These conditions are most commonly caused by group A streptococci but culture of swabs from affected sites is often negative. There is frequently a source of organism entry, such as an ear infection, varicose eczema/ulcer or tinea pedis, and swabs should also be taken from these sites. Diabetes and immunosuppression are predisposing factors. The patient usually has malaise, fever and leucocytosis, and streptococcal serology will often be positive. The face (erysipelas) and legs (cellulitis) are most often affected and the site is hot, painful, erythematous and oedematous. Blistering often occurs and may be haemorrhagic. Regional lymphadenopathy is common. Erysipelas typically has a well-defined edge due to its more superficial level of involvement, whereas cellulitis is typically ill defined. Treatment is usually with intravenous flucloxacillin, with clarithromycin, clindomycin and vancomycin as alternatives for penicillin-allergic patients. Milder cases may be treated with oral antibiotics. If cases are untreated, sequelae include lymphoedema, cavernous sinus thrombosis, sepsis and glomerulonephritis.

Mycobacterial infections

Mycobacterium leprae infection may involve the skin and its manifestations will be influenced by host immunity, patients with high levels of immunity presenting with paucibacillary

tuberculoid leprosy and those with low immune resistance developing multibacillary lepromatous leprosy. Hypopigmented or erythematous patches, with associated altered or lost sensation, or skin thickening, nodules and infiltration should raise suspicion of a diagnosis of leprosy (p. 267).

The skin may also be an extrapulmonary site of involvement in tuberculosis, usually due to infection with *Mycobacterium tuberculosis*. Skin manifestations depend on the route of infection, previous sensitisation and host immunity. There may be a variety of cutaneous features, including the red–brown scarring inflammatory plaques seen in lupus vulgaris due to direct skin inoculation; scrofuloderma, which describes the skin changes overlying lymph nodes or joints infected with tuberculosis; and the reactive nodular and ulcerated changes seen in patients with high levels of immune response, notably the tuberculids and erythema induratum (Bazin's disease). On diascopy, an 'apple jelly' appearance is typically seen, indicating the granulomatous nature of skin involvement. Granulomas evident on skin biopsy should certainly raise suspicion of a diagnosis of mycobacterial infection. Culture of organisms may be tricky but PCR can assist with diagnosis. Patients should be thoroughly investigated for signs of tuberculosis at pulmonary or other extrapulmonary sites (p. 588). Reactivation of latent tuberculosis is a particular concern for patients receiving treatment with immunosuppressants and biological agents, particularly TNF-α antagonists for conditions such as psoriasis. Vigilance is required in screening and workup of such patients prior to consideration of these therapeutic agents.

Other mycobacterial skin infections may occur, such as *Mycobacterium marinum*, typically seen in those who clean tropical fish tanks. Sporotrichoid spread of granulomatous nodules from the site of inoculation along lymphatics is typical; granulomatous changes are seen on histology and resolution usually occurs with a prolonged course of antibiotics such as doxycycline or minocycline. Resolution may also take place spontaneously or after destructive therapies, such as cryotherapy.

Leishmaniasis

This protozoan infection may be restricted to the skin or there may be may be systemic features depending on the species, which occur in different geographical areas (p. 281).

Necrotising soft tissue infections and anthrax

See pages 226 and 266, respectively.

Erythrasma

Erythrasma is a mild, chronic, localised, superficial skin infection caused by *Corynebacterium minutissimum*, which is part of the normal skin flora. Warmth and humidity predispose to this infection, which usually occurs in flexures and toe clefts. It is asymptomatic or mildly itchy and lesions are well defined, red–brown and scaly. *C. minutissimum* has characteristic coral-pink fluorescence under Wood's light. Microscopy and culture of skin scrapings can confirm the diagnosis but are not usually needed if Wood's light examination is positive. A topical azole (clotrimazole or miconazole) or fusidic acid is usually effective. Oral erythromycin can be used for extensive or resistant disease. Antiseptics can be used to prevent disease recurrence.

Pitted keratolysis

This is another superficial skin infection caused by *Corynebacterium* and *Streptomyces* spp., and possibly other organisms, producing characteristic circular erosions ('pits') on the soles. It is usually asymptomatic. The bacterium can be identified in skin scrapings and typically occurs in association with hyperhidrosis, which must be treated to prevent recurrence. Treatment is as for erythrasma.

Other bacterial skin infections

Syphilis and the non-venereal treponematoses are described on pages 337 and 253. There has been a marked increase in incidence of syphilis. Skin signs may be subtle; for example, secondary syphilis may be misdiagnosed as pityriasis rosea. Lesions on palms, soles and mucosae should raise suspicion. Microscopic identification of the spirochaete may be possible and syphilitic serology should be undertaken using enzyme immunoassay or PCR-based techniques, depending on availability. Lyme disease is described on page 255.

Viral infections

Herpesvirus infections

The cutaneous manifestations of the human herpesviruses are described on page 247. Topical antivirals may suffice for prophylaxis or treatment of mild viral disease, such as herpes simplex cold sore virus infection. Systemic antivirals are indicated for significant viral skin disease. For example, systemic aciclovir should be prescribed for eczema herpeticum (see Fig. 11.14, p. 247).

Papillomaviruses and viral warts

Viral warts are extremely common and are caused by the DNA human papillomavirus (HPV). There are over 90 subtypes, based on DNA sequence analysis, causing different clinical presentations. Transmission is by direct virus contact, in living or shed skin, and is encouraged by trauma and moisture such as in swimming pools. Genital warts are spread by sexual activity and show a clear relationship with cervical and intra-epithelial cancers of the genital area. HPV-16 and 18 appear to inactivate tumour suppressor gene pathways and lead to squamous cell carcinoma of the cervix or intra-epithelial carcinoma of the genital skin (p. 242). Vaccinations are available against HPV-16 and 18 and are recommended for adolescent females before they become sexually active. The relationship between skin HPV and skin cancer is unclear. Individuals who are systemically immunosuppressed – after organ transplantation, for example – have greatly increased risks of skin cancer and HPV infection but a causal link is not certain.

Clinical features

Common warts are initially smooth, skin-coloured papules, which become hyperkeratotic and 'warty'. They are most common on the hands (Fig. 29.24) but can occur on the face, genitalia and limbs, and are often multiple. Plantar warts (verrucae) have a slightly protruding rough surface and horny rim, and are often painful on walking. Paring reveals capillary loops that distinguish plantar warts from corns. Other varieties of wart include:

- *mosaic warts*: mosaic-like sheets of warts
- *plane warts*: smooth, flat-topped papules, usually on the face and backs of hands, which may be pigmented and therefore misdiagnosed
- *facial warts*: often filiform
- *genital warts*: may be papillomatous and exuberant.

Fig. 29.24 **Viral wart on the finger.** The capillary loops are evident within the warty hyperkeratosis. Periungual sites are common and more difficult to treat.

Management

Most viral warts resolve spontaneously, although this may take years and active treatment is therefore often sought. However, asymptomatic warts generally should not be treated. Viral warts are particularly problematic and more recalcitrant to treatment in immunosuppressed patients following organ transplantation.

Treatments are destructive. Salicylic acid or salicylic/lactic acid combinations and regular wart paring for several months are the most consistently effective treatments. For certain types of warts, such as filiform facial warts, cryotherapy is generally the treatment of choice, but for common hand and foot warts salicylic acid wart paint should be used first. Cryotherapy is usually the next step and is repeated 2–4-weekly. However, caution is required, particularly on the hands, as over-vigorous cryotherapy can lead to scarring, nail dystrophy and even tendon rupture. Periungual and subungual warts can be problematic and nail cutting and subsequent electrodessication may help. Several other therapies have been used for recalcitrant warts, including topical formaldehyde, podophyllotoxin, trichloroacetic acid, cantharidin, topical or systemic retinoids, intralesional bleomycin or interferon injections, and contact sensitisation with, for example, diphencyprone. Imiquimod and PDT may also be beneficial, particularly for multiple warts in immunosuppressed patients, and laser therapy can have a role in some cases.

Molluscum contagiosum

Molluscum contagiosum is caused by a DNA poxvirus skin infection. It is most common in children over the age of 1 year, particularly those with atopic dermatitis. It also occurs frequently in immunosuppressed patients, including those with HIV (p. 306). Lesions are dome-shaped, 'umbilicated', skin-coloured papules with central punctum (Fig. 29.25). They are often multiple and found at sites of apposition, such as the side of the chest and the inner arm. Spontaneous resolution occurs but can take months. Prior to resolution, they often become inflamed and may leave small, atrophic scars. Destructive therapies may be painful and risk scarring, and the decision not to treat is often sensible. Gentle squeezing with forceps after bathing can hasten resolution. Topical salicylic acid, podophyllin, cantharidin, trichloroacetic acid, cryotherapy and curettage are alternatives. Efficacy with imiquimod has also been reported.

Fig. 29.25 **Molluscum contagiosum.** Note the central umbilication.

Orf

Orf is a parapoxvirus skin infection and is an occupational risk for those who work with sheep and goats. Inoculation of virus, usually into finger skin, causes significant inflammation and necrosis, which typically resolves within 2–6 weeks. No specific treatment is required, unless there is secondary infection. Erythema multiforme (p. 1264) can be provoked by orf.

Other viral exanthems

See page 236.

Fungal infections

Fungal skin infections can be superficial (dermatophytes and yeasts) or, less commonly, deep (chromomycosis or sporotrichosis); the latter are seen more often in tropical climates or in the immunocompromised. Dermatophyte infections (ringworm) are extremely common and usually caused by fungi of the *Microsporum*, *Trichophyton* and *Epidermophyton* species. The fungi can originate from soil (geophilic) or animals (zoophilic), or be confined to human skin (anthropophilic). Dermatophyte infections usually present with skin (tinea corporis), scalp (tinea capitis), groin (tinea cruris), foot (tinea pedis) and/or nail (onychomycosis) involvement (Fig. 29.26).

Diagnosis

Skin scrapings, hair pluckings or nail clippings must be taken from areas of disease activity – typically, the advancing lesion edge for skin involvement, the crumbling dystrophic nail and subungual hyperkeratosis for nail involvement, and plucked hair from scalp or other affected hair-bearing sites – in order to confirm the diagnosis by microscopy and culture (p. 1215).

Management

The azoles (ketoconazole, miconazole), triazoles (itraconazole, fluconazole) and triallylamines (terbinafine) are used most widely in fungal skin disease. Topical antifungals such as terbinafine or miconazole may suffice, although systemic treatment (terbinafine, itraconazole or griseofulvin) may be required for stubborn or extensive disease and scalp or nail involvement. Indeed, prolonged courses of systemic treatment may be needed for nail involvement. The fungistatic agent griseofulvin, given orally, is usually used for fungal infection of scalp or nails in children in the UK, as it is the only drug licensed in children for this indication; outside the UK, and in adults, terbinafine is usually the treatment of

A

B

Fig. 29.26 Dermatophyte infections. A *Trichophyton rubrum* infection of the groin (tinea cruris). B *Microsporum canis* infection of the scalp (tinea capitis).

choice. In addition to systemic antifungals, short courses of systemic or topical glucocorticoid are often used in kerion on the basis of reducing inflammation and possible hair loss. However, glucocorticoid use is controversial, with no good evidence of benefit.

Tinea corporis

Tinea corporis should feature in the differential diagnosis of a red, scaly rash (p. 1217). Typically, lesions are erythematous, annular and scaly, with a well-defined edge and central clearing. There may also be pustules at the active edge. Lesions are usually asymmetrical and may be single or multiple. The degree of inflammation is dependent on the organism involved and the host immune response. *Microsporum canis* (from dogs) and *Trichophyton verrucosum* (from cats) are common culprits. Ill-advised use of topical glucocorticoids can modify the clinical presentation and increase disease extension (tinea incognito).

Tinea cruris

This is extremely common worldwide and is usually caused by *Trichophyton rubrum*. Itchy, erythematous plaques develop in the groins and extend on to the thighs, with a raised active edge (Fig. 29.26A).

Tinea pedis

Tinea pedis or 'athlete's foot' is the most common fungal infection in the UK and USA, and is usually caused by anthropophilic fungi, such as *T. rubrum*, *T. interdigitale* and *Epidermophyton floccosum.* It typically presents as an itchy rash between the toes, with peeling, fissuring and maceration. Involvement of one sole or palm (tinea manuum) with fine scaling is characteristic of *T. rubrum* infection. Vesiculation or blistering is more often seen with *T. mentagrophytes*.

Tinea capitis

This is a dermatophyte infection of scalp hair shafts and is most common in children. It typically presents as an area of scalp inflammation and scaling, often with pustules and partial hair loss (Fig. 29.26B). Infection may be within the shaft (endothrix, most commonly caused by *T. tonsurans*), causing patchy hair loss with broken hairs at the surface ('black dot'), little inflammation and no fluorescence with Wood's light. Infection outside the hair shaft (ectothrix, most commonly caused by *Microsporum audouinii* (anthropophilic)) shows minimal inflammation; *M. canis* (from dogs and cats) infections are more inflammatory and can be identified by green fluorescence with Wood's light. Kerion is a boggy, inflammatory area of tinea capitis, usually caused by zoophilic fungi such as cattle ringworm (*T. verrucosum*).

Onychomycosis

This is a fungal infection of the nail plate and the species involved are generally those that cause tinea capitis or tinea pedis. Onychomycosis usually presents with yellow/brown nail discoloration, crumbling, thickening and subungual hyperkeratosis. Usually, some nails are spared, there is asymmetry and toenails are more commonly involved.

Candidiasis

This is a superficial skin or mucosal infection caused by a yeast-like fungus, *Candida albicans* (p. 300). Infections are usually not serious, unless the patient is immunocompromised, in which case deeper tissues can be involved (p. 316). The organism has a predilection for warm, moist environments and typical presentations are napkin candidiasis in babies, genital and perineal candidiasis, intertrigo and oral candidiasis. The diagnosis can be confirmed by microscopy and culture of skin swabs, and treatment is with topical or systemic antifungals, such as azoles.

Pityriasis versicolor

Pityriasis versicolor is a persistent, superficial skin condition caused by various species of the commensal yeast *Malassezia*, most commonly *Malassezia globosa*, but sometimes *M. sympadialis* or *M. furfur*, It occurs in men and women and in different races. It is found more frequently in warmer, humid climates, and is usually more severe and persistent in the immunocompromised. It is characterised by scaly, oval macules on the upper trunk, usually hypopigmented but occasionally hyperpigmented. Hypopigmentation is more obvious after sun exposure and tanning. The diagnosis can be confirmed by microscopy of skin scrapings, showing 'spaghetti and meatballs' hyphae. Treatment with selenium sulphide or ketoconazole shampoos and topical or systemic azole antifungal agents is usually effective, although recurrence is common because these yeasts are skin commensals, and maintenance topical therapy may be required. Altered pigmentation can persist for months after treatment.

Infestations

Scabies

Scabies is caused by the mite *Sarcoptes scabiei*. It spreads in households and environments where there is intimate personal contact. The diagnosis is made by identifying the scabietic burrow (**definition**: a linear or curvilinear papule, caused by a burrowing scabies mite; p. 234 and Fig. 29.27) and visualising the mite (by extracting with a needle or using a dermatoscope). In small children, the palms and soles can be involved, with pustules. Pruritus is prominent. The clinical features include secondary eczematisation elsewhere on the body; the face and scalp are rarely affected, except in infants. Involvement of the genitals in males and of the nipples commonly occurs. Even after successful treatment, itch can continue and occasionally nodular lesions persist.

Topical treatment of the affected individual and all asymptomatic family members/physical contacts is required to ensure eradication. Two applications 1 week apart of an aqueous solution of permethrin or malathion to the whole body, excluding the head, are usually successful. If there is poor adherence, immunosuppression or heavy infestation (crusted 'Norwegian' scabies), systemic treatment with a single oral dose of ivermectin is sometimes appropriate.

Head lice

Infestation with the head louse, *Pediculus humanus capitis*, is common. It is highly contagious and spread by direct head-to-head contact. Scalp itch leads to scratching, secondary infection and cervical lymphadenopathy. The diagnosis is confirmed by identifying the living louse or nymph on the scalp or on a black sheet of paper after careful fine-toothed combing of wet hair following conditioner application. The empty egg cases ('nits') are easily seen on the hair shaft (p. 1210) and are hard to dislodge.

Treatment is recommended for the affected individual and any infected household/school contacts. Eradication in school populations is difficult because of poor adherence and treatment resistance. Topical treatment with dimeticone, permethrin, carbaryl or, less often, malathion in lotion or aqueous formulations may be effective and should be applied twice at an interval of 7–10 days. Rotational treatments within a community may avoid resistance. 'Wet-combing' (physical removal of live lice by regular combing of conditioned wet hair – 'bug busting') can suffice but may be less effective than pharmacological treatments. Vaseline should be applied to eyelashes/brows twice daily for at least a fortnight. High-temperature washing of clothing and bedding is required. Treatment resistance and recurrence can be problematic.

Body lice

These are similar to head lice but live on clothing, particularly in seams, and feed on the skin. Poor hygiene and overcrowded conditions predispose. Itch, excoriation (**definition**: a linear ulcer or erosion resulting from scratching) and secondary infection occur. Dry-cleaning and high-temperature washing or insecticide treatment of clothes are required. Treatment options are as for head lice. For heavy infestation, oral ivermectin may be indicated.

Pubic (crab) lice

Usually, these are sexually acquired and very itchy. Management is as for head and body lice and whole-body treatment should be undertaken. Pubic hair may need to be shaved. Sexual and other close contacts should also be treated and patients should also be screened for sexually transmitted diseases.

A

B

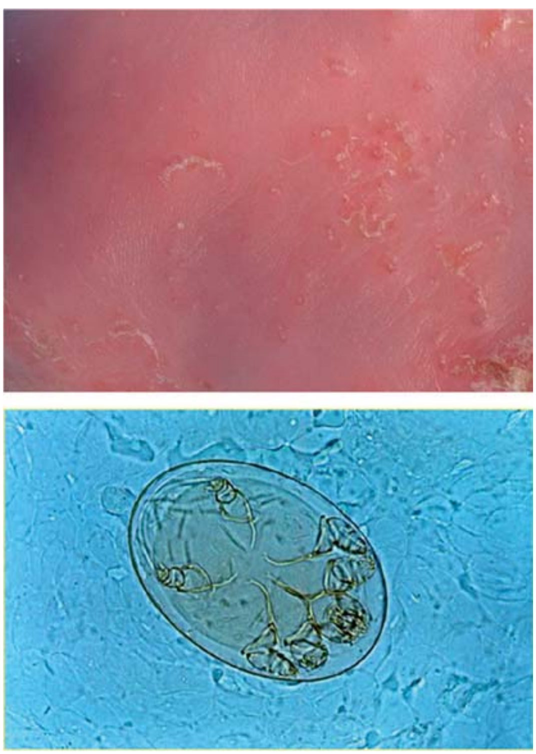

Fig. 29.27 Scabies. A Burrows evident on the palm of the hand. B A mite still in its egg, seen on light microscopy of scrapings over a burrow. Note that the mite has only six legs, unlike adult mites, which have eight.

Acne and rosacea

Acne vulgaris

Acne is chronic inflammation of the pilosebaceous units. It is extremely common, generally starts during puberty and has been estimated to affect over 90% of adolescents. It is usually most severe in the late teenage years but can persist into the thirties and forties, particularly in females (Box 29.16).

29.16 Acne in adolescence

- **Epidemiology**: acne vulgaris is most common between the ages of 12 and 20. It often begins around 10–13 years of age, lasts 5–10 years and usually resolves by age 20–25.
- **Emotional effects**: at all ages acne can have negative effects on self-esteem, but it is especially important to assess how it affects an adolescent. Depression and suicideal ideation may occur. The consequences (whether acne is objectively severe or not) can be devastating, leading to embarrassment, school avoidance, and life-long effects on ability to form friendships, attract partners, and acquire and keep employment.
- **Treatment**: effective treatments aim to improve the condition, prevent worsening (including later scarring) and restore emotional well-being and self-esteem.

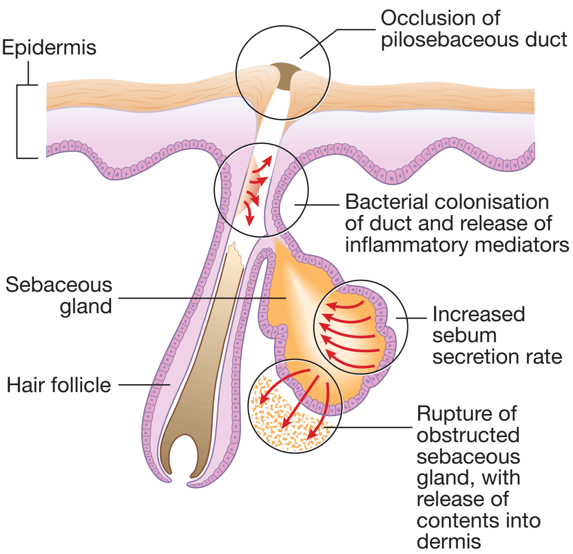

Fig. 29.28 **Pathogenesis of acne.**

Pathogenesis

The key components are increased sebum production; colonisation of pilosebaceous ducts by *Propionibacterium acnes*, which in turn causes inflammation; and hypercornification and occlusion of pilosebaceous ducts (Fig. 29.28). Severity of acne is associated with sebum excretion rate, which increases at puberty. Both androgens and progestogens increase sebum excretion and oestrogens reduce it, but most patients with acne have normal hormone profiles. There may be a positive family history and there is high concordance in monozygotic twins, indicating that genetic factors are important, but the candidate genes are poorly defined.

Clinical features

Acne usually affects the face and often the trunk. Greasiness of the skin may be obvious (seborrhoea). The hallmark is the comedone (**definition**: open comedones (blackheads) are dilated keratin-filled follicles, which appear as black papules due to the keratin debris; closed comedones (whiteheads) usually have no visible follicular opening and are caused by accumulation of sebum and keratin deeper in the pilosebaceous ducts – Fig. 29.28). Inflammatory papules, nodules and cysts occur and may arise from comedones (Fig. 29.29). Scarring may follow deep-seated or superficial acne and may be keloidal.

There are also distinct clinical variants:

- *Acne conglobata*: characterised by comedones, nodules, abscesses, sinuses (**definition**: cavities or channels that permit the escape of pus or fluid) and cysts, usually with marked scarring. It is rare, usually affecting adult males, and most commonly occurs on trunk and upper limbs. It may be associated with hidradenitis suppurativa (a chronic, inflammatory disorder of apocrine glands, predominantly affecting axillae and groins), scalp folliculitis and pilonidal sinus.
- *Acne fulminans*: a rare but severe presentation of acne, associated with fever, arthralgias and systemic inflammation, with raised neutrophil count and plasma viscosity. It is usually found on the trunk in adolescent males. Costochondritis can occur.

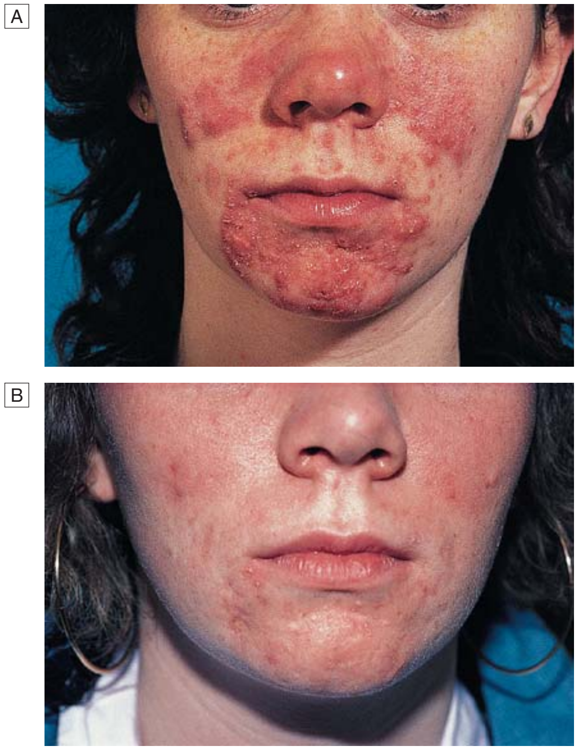

Fig. 29.29 **Cystic acne in a teenager.** A Before treatment. B After prolonged systemic antibiotic treatment.

- *Acne excoriée*: self-inflicted excoriations due to compulsive picking of pre-existing or imagined acne lesions. It usually affects teenage girls, and underlying psychological problems are common.
- *Secondary acne*: comedonal acne can be caused by greasy cosmetics or occupational exposure to oils, tars or chlorinated aromatic hydrocarbons. Predominantly pustular acne can occur in patients using systemic or topical glucocorticoids, oral contraceptives, anticonvulsants, lithium or antineoplastic drugs, such as the epidermal growth factor receptor (EGFR) inhibitors. Most patients with acne do not have an underlying endocrine disorder but acne is a common feature of polycystic ovary syndrome (p. 658), which should be suspected if acne is moderate to severe and associated with hirsutism and menstrual irregularities. Virilisation should also raise suspicion of an androgen-secreting tumour.

Investigations

Investigations are not required in typical acne vulgaris. Secondary causes and suspected underlying endocrine disease or virilisation should be investigated (p. 657).

Management

Mild to moderate disease

Mild disease is usually managed with topical therapy (p. 1225). If comedones predominate, then topical benzoyl peroxide or retinoids should be used. Benzoyl peroxide has both anti-comedogenic and antiseptic effects. It is an irritant, which may contribute to the therapeutic response, but this can be minimised by adjusting treatment regimes. Azelaic acid may

also be used for mild acne and has both antimicrobial and anti-comedogenic action. Topical retinoids, in particular *all-trans* retinoic acid and adapalene, are widely employed for mild to moderate comedonal acne vulgaris. Treatment should be initially applied at low concentrations for short duration and increased as tolerated. Patients with mild inflammatory acne should respond to topical antibiotics, such as erythromycin or clindamycin, which can be used in combination with other treatments.

For moderate inflammatory acne, a systemic tetracycline should be used at adequate dose for 3–6 months in the first instance (p. 1227; Fig. 29.29B). Oxytetracycline must be taken on an empty stomach, in a dose of up to 1.5 g a day. It has a good safety profile, even with long-term use, but adherence may be a challenge. Lymecycline is an alternative and is taken once daily, with or without food, thereby improving adherence. Doxycycline is another option but commonly causes photosensitivity. Minocycline is used less frequently, as it can cause hyperpigmentation, autoimmune hepatitis and drug-induced lupus, and monitoring is required. If the patient fails to respond, then alternatives include erythromycin or trimethoprim.

In women with acne, oestrogen-containing oral contraceptives can be a useful adjunct, as they are associated with a small reduction in sebum production. Combined oestrogen and anti-androgen (such as cyproterone acetate) contraceptives may provide additional efficacy, particularly in women with acne and hirsutism, as seen in polycystic ovary syndrome (p. 658).

Patients should be referred for consideration of isotretinoin (13-*cis*-retinoic acid) if there is a failure to respond adequately to 6 months of therapy with these combined systemic and topical approaches (p. 1227).

Moderate to severe disease

Isotretinoin (13-*cis*-retinoic acid) has revolutionised the treatment of moderate to severe acne that has not responded adequately to other therapies. It has multifactorial mechanisms of action, with reduction in sebum excretion by over 90%, follicular hypercornification, *P. acnes* colonisation and inflammation. Oral isotretinoin is usually used at a dose of 0.5–1 mg/kg over 4 months. Sebum excretion typically returns to baseline within a year after treatment cessation, although clinical benefit is usually longer-lasting. Many patients will not require further treatment, although a second or third course of isotretinoin may be needed. A low-dose continuous or intermittent-dose regimen may occasionally be considered for a longer duration in patients who relapse after a higher-dose regimen, and may also be beneficial for older females with persistent acne. Combination with systemic glucocorticoid may be required in the short term for severe acne, in order to minimise the risk of disease flare early in the treatment course. Thorough screening and monitoring are required, given the side-effect profile of isotretinoin, particularly with respect to teratogenicity and possible mood disturbance (p. 1227). Pregnancy must be avoided during treatment and for a minimum of 2 months after drug cessation, and a strict pregnancy prevention programme and regular pregnancy testing are required. Depression and suicide have been reported in association with isotretinoin, although a causal role has not been established. However, pre-drug screening for depressive symptoms should be undertaken and mood monitored during therapy.

Other treatments and physical measures

Intralesional injections of triamcinolone acetonide may be required for inflamed acne nodules or cysts, which can also be incised and drained, or excised under local anaesthetic. Scarring may be prevented by adequate treatment of active acne. Keloid scars may respond to intralesional glucocorticoid and/or silicone dressings. Carbon dioxide laser, microdermabrasion, chemical peeling or localised excision can also be considered for scarring. UVB phototherapy or PDT can occasionally be used in patients with inflammatory acne who are unable to use conventional therapy, such as isotretinoin. There is no convincing evidence to support a causal association between diet and acne. The psychological impact of acne must not be under-estimated and should be considered in management decisions (Box 29.16).

Rosacea

This chronic inflammatory condition affects the central face and consists of flushing, erythema, papules, pustules and telangiectasiae. The cause is unknown. Rosacea is distinct from acne vulgaris; sebum excretion is normal and comedones are absent. The relative contribution of *Demodex* mite and cutaneous vasomotor instability to the pathogenesis of rosacea remains poorly defined.

Clinical features

Rosacea most commonly affects fair-skinned, middle-aged females and can be exacerbated by heat, sunlight and alcohol. The convexities of nose, forehead, cheeks and chin are typically involved (Fig. 29.30). The condition is heterogeneous and intermittent flushing, followed by fixed erythema and telangiectasiae, predominates in some; in others, papules and pustules are prominent. Sebaceous gland hyperplasia and soft tissue overgrowth of the nose (rhinophyma) can occur, particularly in males. Conjunctivitis and blepharitis may also occur. Facial lymphoedema can be an added complication.

Investigations

Usually, no investigations are required and the diagnosis is obvious clinically. However, rosacea must be distinguished from acne vulgaris, systemic lupus erythematosus, photosensitivity disorders and seborrhoeic dermatitis (the latter may coexist with rosacea).

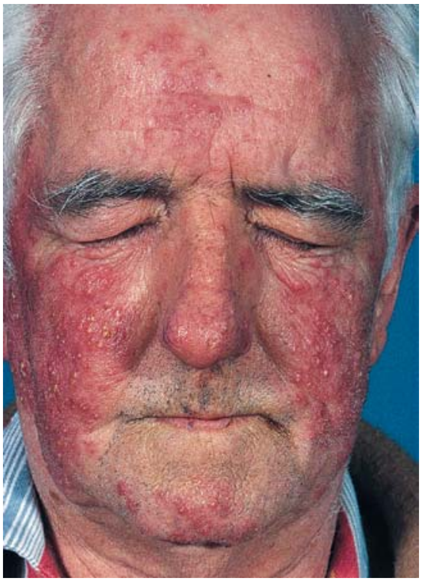

Fig. 29.30 Rosacea. Typical erythematous papulopustular rosacea affecting the mid-face.

29

Management

Mild disease may respond to topical antimicrobials, such as metronidazole or azelaic acid. Topical ivermectin may be beneficial in some cases, supporting a contributory role of *Demodex* in pathogenesis. Tetracycline or erythromycin for 3–6 months is usually effective in inflammatory pustular disease resistant to topical therapy (p. 1227). Relapse may require intermittent or chronic antibiotic use. Erythema and telangiectasiae do not usually respond well to antibiotics but vascular laser therapy may be effective. Topical vasoconstrictors, such as the α_2-adrenoceptor agonist brimonidine, may be of benefit in some cases where erythema and telangiectasiae predominate. Systemic isotretinoin may be helpful in severe resistant disease and rhinophyma may require laser therapy or surgery.

Eczemas

The term 'eczema' derives from the Greek word 'to boil' and is synonymous with the other descriptive term, 'dermatitis'. Eczema describes a clinical and histological pattern, which can be acute or chronic and has several causes. Acutely, epidermal oedema (spongiosis) and intra-epidermal vesiculation (producing multilocular blisters) predominate, whereas with chronicity there is more epidermal thickening (acanthosis). Vasodilatation and T-cell lymphocytic infiltration of the upper dermis also occur.

Clinical features

There are several patterns of eczema (Box 29.17) but the clinical features are similar, irrespective of the cause (Box 29.18). Some subtypes of eczema have specific distinguishing features and these are discussed in more detail below.

Investigations

Bacterial and viral swabs for microscopy and culture are important in suspected secondary infection. Bacterial swabs are commonly positive, particularly for staphylococci, although clinical assessment is required in order to ascertain whether swab results are of clinical significance and whether antibiotic treatment is required. Individuals with atopic eczema have an increased susceptibility to herpes simplex virus (HSV) and are at risk of developing a widespread infection, eczema herpeticum. The presence of small, punched-out lesions on a background of worsening eczema suggests the possibility of secondary HSV infection. Skin scrapings to rule out secondary fungal infection should also be considered. Total IgE and specific IgE tests and skin prick tests are not routinely undertaken in atopic eczema as they are not usually helpful, although they may occasionally be indicated in some cases as directed by the history. Patch tests should be performed if contact allergic dermatitis is suspected (see Box 29.22 below). Skin biopsy is not usually required unless there is diagnostic doubt.

29.17 Classification of eczema

Endogenous
- Atopic, seborrhoeic

Exogenous
- Irritant, allergic, photo-allergic, chronic actinic dermatitis

Characteristic patterns and morphology
- Asteatotic, discoid, gravitational, lichen simplex, pompholyx

29.18 The clinical morphology of eczema

Acute
- Erythema, oedema, usually typically ill defined
- Papules, vesicles and occasionally bullae
- Exudation, fissuring
- Scaling

Chronic
- May be as above but less oedema, vesiculation and exudate
- Lichenification: skin thickening with pronounced skin markings, secondary to chronic rubbing and scratching
- Fissures (**definition**: slit-shaped deep ulcers), excoriations
- Dyspigmentation: hyper- and hypopigmentation can occur

Management

A general approach to the management of eczema includes advice, education and support, required for patients with eczema of any type (Fig. 29.31). Input from patient support groups, such as the National Eczema Society in the UK, can be very helpful. Intensive and prolonged treatments are often required and chronic eczema can have a major and devastating adverse impact on personal and family lives. Emollients and topical glucocorticoids are mainstays of treatment for all eczema types, in order to improve skin barrier function, limit transepidermal water loss and reduce inflammation. Emollients can be used as bath additives and soap substitutes, and applied directly to the skin, often combined with antiseptics. Sedative antihistamines are useful if sleep is interrupted but non-sedating antihistamines are ineffective, as the itch of eczema is not primarily mediated by histamine.

Ointments are preferred for chronic eczema, whereas cream- or lotion-based treatment may be more appropriate for acute eczema (see Box 29.11). Treatment is once to twice daily (p. 1225). Hydrocortisone (1%) or clobetasone butyrate is generally used on the face, with more potent glucocorticoids restricted to trunk and limbs (see Box 29.12). A good strategy is to employ an intensive regimen with more potent glucocorticoids initially and then taper use according to response. A key principle is to use the least potent glucocorticoid that is effective for the shortest possible time. The patient should be given instructions on how much to apply, using the fingertip unit for guidance (a strip of glucocorticoid cream on distal phalanx pulp should cover two palm-size areas). It is also important to monitor glucocorticoid use and the easiest way to do this is ask how long it takes to use a specific size of glucocorticoid tube. The side-effects of topical glucocorticoid therapy need to be considered but glucocorticoid phobia and under-treatment of eczema are often more of a problem than over-treatment. Particular care should be taken on certain sites, such as the face and flexures, and in children and the elderly (see Box 29.2 and Fig. 29.10, p. 1226).

The clinical features of eczema influence the choice of topical treatment. For example, appropriate treatment of acute exudative eczema could be with potassium permanganate soaks, emollients and topical glucocorticoids under wet wraps. Chronic eczema may be best treated with a potent topical glucocorticoid in an ointment formulation and occlusion with a paste bandage to ease itching and scratching.

The topical calcineurin inhibitors tacrolimus and pimecrolimus may be useful glucocorticoid-sparing agents for eczema, particularly on the face; they cause local cutaneous immunosuppression.

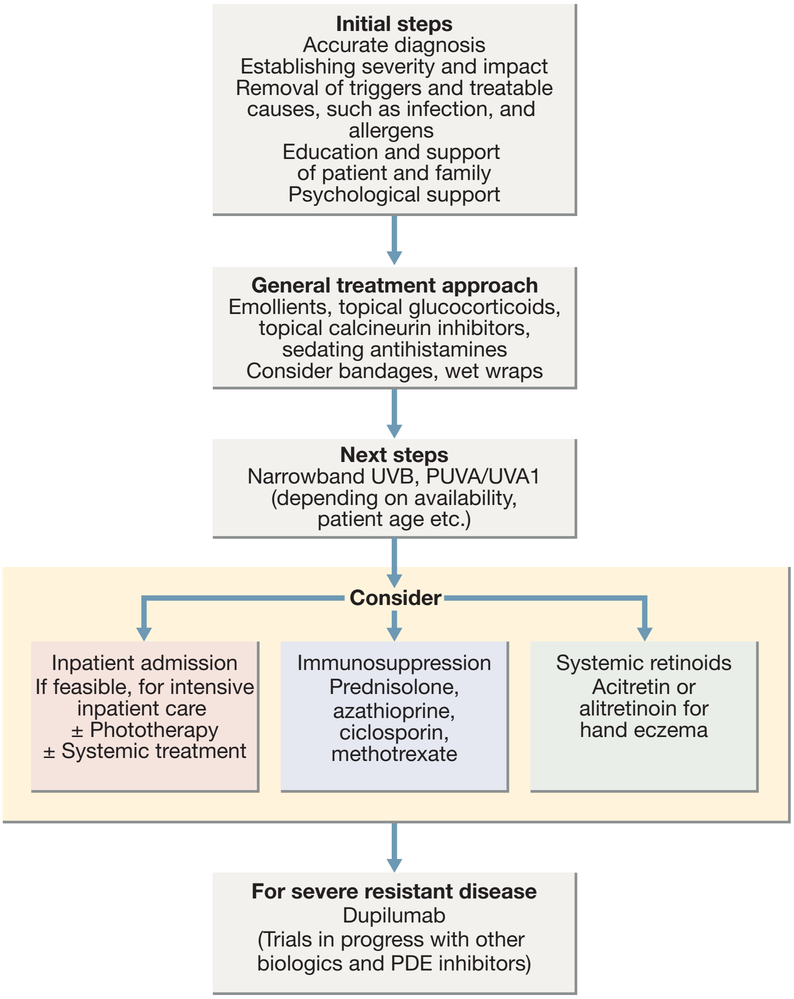

Fig. 29.31 General management approaches: atopic eczema. (PDE = phosphodiesterase; PUVA = psoralen-ultraviolet A; UVA1 = ultraviolet A1; UVB = narrowband ultraviolet B)

Initial burning and stinging may limit use but are usually transient side-effects. Bacterial and viral skin infection risk may be increased due to immunosuppression. Caution should be employed with sun exposure and these agents should not be used in combination with phototherapy because of their immunosuppressive effects.

Atopic eczema

This is the most common subtype of eczema. The prevalence has increased dramatically since the early 1980s, and the disease now affects at least 20% of schoolchildren and 5–10% of adults in the UK.

Pathogenesis

Generalised prolonged hypersensitivity to common environmental antigens, such as pollen and house-dust mite, is the hallmark of atopy, in which there is a genetic predisposition to produce excess IgE. Atopic individuals manifest one or more of a group of diseases that includes asthma, hay fever, food and other allergies, and atopic eczema. Genetic factors play an important role in all of these conditions, supported by higher concordance of atopic disease in monozygotic twins compared with dizygotic twins. Filaggrin gene mutations increase the risk of developing atopic eczema by more than threefold, emphasising the importance of epidermal barrier impairment in this disease. Other genes are also likely to be implicated, with many other susceptibility loci identified, although these studies require further replication. Decreased skin barrier function may also allow greater penetration of allergens through the epidermis, and thus cause immune stimulation and subsequent inflammation. The interaction between genes and environment is important; it has been estimated that 60–80% of individuals are genetically susceptible to the induction of IgE-mediated sensitisation to environmental allergens such as food and animal hair. Eczema is characterised by infiltration of Th2 cells, which are known to play a role in activating mast cells and eosinophils, as well as stimulating IgE production by IgE-producing B cells. The contributing roles of the microbiome are also being explored. Thus, the pathogenesis of atopic eczema is complex and multifactorial, involving an interplay of contributing factors.

Clinical features

Atopic eczema is extremely itchy and scratching accounts for many of the signs (Fig. 29.32). Widespread cutaneous dryness (also known as xeroderma or xerosis) is another feature. The distribution and character of the rash vary with age (Box 29.19). Complications are listed in Box 29.20.

Investigations

The diagnosis of atopic eczema is made using clinical criteria (Box 29.21). Interestingly, while most patients with atopic eczema have raised total IgE levels and IgE-specific antibodies, this is not a prerequisite for the diagnosis, as a significant minority have normal levels of IgE.

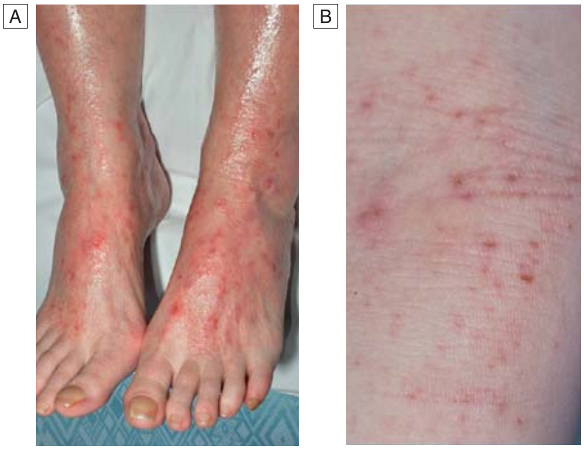

Fig. 29.32 Atopic eczema. A This patient had life-long chronic atopic eczema and experienced a generalised flare of disease triggered by infection. B Lichenification of chronic flexural eczema secondary to rubbing and scratching.

29.19 Atopic eczema: distribution and character of rash

Babies and infants

- Often acute and facial involvement prominent
- Trunk involved but nappy area usually spared

Children

- Flexures: behind knees, antecubital fossae, wrists and ankles

Adults

- Face and trunk usually involved, limb involvement not restricted to flexures
- Lichenification common

29.20 Complications of atopic eczema

Secondary infection

Bacterial

- *Staphylococcus aureus* most common

Viral

- Herpes simplex virus can cause a widespread severe eruption – eczema herpeticum
- Papillomavirus and molluscum contagiosum are more common in atopic eczema, especially if treated with topical glucocorticoids

Increased susceptibility to irritants

- Defective barrier function

Increased susceptibility to allergy

- Food allergy – mainly relevant in infants; eggs, cow's milk protein, nuts, fish, wheat and soya may cause an immediate reaction with angioedema and/or urticaria rather than exacerbation of eczema
- Anaphylaxis in severe allergy
- Increased risk of sensitisation to type IV allergens because of impaired barrier function

Impact on life and health

- Poor sleep, loss of schooling, behavioural difficulties, failure to thrive in children
- Impact on sleep, work, relationships, hobbies, psychology and quality of life in adults

29.21 Diagnostic criteria for atopic eczema

Itchy skin rash (or history of itch or rubbing from parent) and at least three of the following:

- History of involvement of skin creases (or cheeks if <4 years)
- History of atopic disease (asthma, hay fever) (or in a first-degree relative if <4 years)
- Dry skin (xeroderma)
- Visible flexural eczema (cheeks, forehead, outer limbs if <4 years)
- Onset in first 2 years of life

Management

The general principles of management are as described in Figure 29.31. Emollients and topical glucocorticoids, tar and ichthammol paste bandages, or wet wraps in children, are often required. Topical calcineurin inhibitors may be used as glucocorticoid-sparing agents but should not be used in infected eczema. Secondary infection should be treated but positive skin swabs in isolation, without clinical evidence of infection, do not necessarily require treatment with antibiotics, although antiseptics would be appropriate. Sedating antihistamines may help to break the itch/scratch cycle. Identification and avoidance of allergens are important.

Phototherapy is generally the next step, if topical therapies are insufficient (see Fig. 29.31). Narrowband UVB is usually the initial phototherapy of choice and can also be used in children. PUVA or UVA1 can also be chosen if UVB is ineffective, although mainly in adults as PUVA is generally avoided in children. Localised phototherapy may be used for eczema on hands and feet and PUVA may be more effective in that situation. Systemic immunosuppression with, for example, oral glucocorticoids, intermittent ciclosporin, azathioprine or methotrexate may be needed if the response to topical therapies and phototherapy is inadequate. Systemic retinoids, such as acitretin or alitretinoin, may be indicated: for example, in hand and foot eczema.

Encouraging early trial data are emerging to support the use of dupilumab, which blocks IL-4Rα, and the anti-IL-13 agents lebrikizumab and tralokinumab in atopic eczema. Phosphodiesterase 4 inhibitors are also being investigated.

Seborrhoeic eczema

This is an erythematous scaly rash affecting the scalp (dandruff), central face, nasolabial folds, eyebrows, central chest and upper back. It is associated with, and may be due to, overgrowth of *Malassezia* yeasts. When severe, it may resemble psoriasis. Severe or recalcitrant seborrhoeic eczema can be a marker of immunodeficiency, including HIV infection (p. 314). Topical azoles, such as ketoconazole shampoo and cream, often combined with mild glucocorticoid, are mainstays. Treatment often needs to be repeated due to disease recurrence.

Discoid eczema

Discoid eczema, which is also known as nummular eczema, is common and characteristically consists of discrete, coin-shaped eczematous lesions, which are often impetiginised and most commonly occur on the limbs of men. It is an eczema type that can be due to any chronic itchy condition, whether primarily of the skin or secondary to an underlying disease. Initial management should include topical antiseptics, in addition to emollients and topical glucocorticoids. Judicious antibiotic use may also be required for acute flares.

i 29.22 Common type IV delayed hypersensitivity allergens

Allergen	Source
Nickel	Jewellery, jean studs, bra clips, watches
Dichromate	Cement, leather, matches
Rubber chemicals	Clothing, shoes, rubber gloves, tyres
Colophony	Sticking plaster, collodion, nail varnish
Paraphenylenediamine	Hair dye, clothing, tattoos
Balsam of Peru	Perfumes, citrus fruits, shower/bath products
Neomycin, benzocaine	Topical medications
Parabens	Preservative in cosmetics and creams
Wool alcohols	Lanolin, cosmetics, creams
Epoxy resin	Resin adhesives, glues
Methyl- and chloromethyl-isothiazolinone	Preservatives, with increasing numbers of cases of allergy reported

Irritant eczema

Detergents, alkalis, acids, solvents and abrasives are common irritants. Strong irritants have acute effects, whereas weaker irritants commonly cause chronic eczema, especially of the hands, after prolonged exposure. Individual susceptibility varies and the elderly, atopic and fair-skinned are predisposed. Irritant eczema accounts for most occupational cases of eczema and is a significant cause of time off work. Irritant avoidance, including protective clothing (such as gloves), is essential. Emollients and topical glucocorticoids are indicated.

Allergic contact eczema

This occurs due to a delayed hypersensitivity reaction following contact with antigens or haptens. Previous allergen exposure is required for sensitisation and the reaction is specific to the allergen or closely related chemicals. Common allergens are listed in Box 29.22.

Allergy persists indefinitely and eczema occurs at sites of allergen contact and can secondarily spread beyond this. The distribution of eczema can be very informative with regard to possible culprits. There are many recognisable patterns of sites of eczema involvement, such as earlobes, wrists and umbilicus due to contact with nickel in earrings, watches and jeans studs; hands and wrists due to rubber gloves; and upper eyelids due to colophony from rubbing of the eyes in nail varnish wearers. Oedema may also be a feature (Fig. 29.33). Allergen avoidance is key and may involve a change of occupation, recreational activities or hobbies. It is important to ensure that patients are fully informed as to the nature and likely occurrence of allergens and good detective work is required to scrutinise lifestyle and daily activities. Treatment with emollients and topical glucocorticoids helps but will not suffice if there is continued allergen exposure.

Asteatotic eczema

This occurs in dry skin and is common in the elderly. Low humidity caused by central heating, over-washing, diuretics and cholesterol-lowering drugs predispose. The most common site is the lower legs, and a 'crazy paving' pattern of fine fissuring on an erythematous background is seen. Emollients are a mainstay, in combination with topical glucocorticoids. Patients must be advised to use caution with flammable emollients and to avoid bathroom slippages related to emollients on floor and feet, and this is particularly relevant for the elderly.

Fig. 29.33 Allergic contact eczema. This was caused by the application of an antihistamine cream. The acute eczematous reaction and bilateral periorbital oedema are typical.

Gravitational eczema

Gravitational or stasis eczema occurs on the lower legs and is often associated with signs of venous insufficiency: oedema, loss of hair, induration, lipodermatosclerosis and ulceration. Emollients should be used and topical glucocorticoids should be applied to eczematous areas but not to ulcers. There is a high risk of sensitisation to topical preservatives (such as chlorocresol), antibiotics (such as neomycin) and bandages (such as rubber additives). Oedema and ulceration are treated by leg elevation and compression bandages (p. 1224).

Lichen simplex

Lichenification of eczema occurs secondary to chronic rubbing and scratching, and lichen simplex is a localised form. Common sites include the neck, lower legs and anogenital region. Treatment with emollients and very potent topical glucocorticoids may be required, often impregnated in tape or with occlusion.

Pompholyx

Intensely itchy vesicles and bullae occur on the palms, palmar surface and sides of the fingers and soles. Pompholyx may have several causes, which include atopic eczema, irritant and contact allergic dermatitis and fungal infection. The underlying cause must be treated or removed.

Psoriasis and other erythematous scaly eruptions

Psoriasis

Psoriasis is a chronic inflammatory, hyperproliferative skin disease. It is characterised by well-defined, erythematous scaly plaques,

particularly affecting extensor surfaces, scalp and nails, and usually follows a relapsing and remitting course. Psoriasis affects approximately 1.5–3% of Caucasians but is less common in Asian, South American and African populations. It occurs equally in both sexes and at any age; although it is uncommon under the age of 5 years, more than 50% of patients present before the age of 30 years. The age of onset follows a bimodal distribution, with an early-onset type in the teenage or early adult years, often with a family history of psoriasis, a more severe disease course and strong HLA association. The later-onset type is typically seen between 50 and 60 years, usually without a family history and with a less severe disease course.

Pathogenesis

Both genetic and environmental factors are important. Twin studies show concordance rates of 60–75% and 15–20% for psoriasis arising in monozygotic and dizygotic twins, respectively. The age at onset and severity of disease are often similar in familial cases. If one parent has psoriasis, the chance of a child being affected is about 15–20%; if both parents have the disease, this rises to 50% and the risk is increased further if a sibling also has the disease.

Variants of the HLA-C region within the major histocompatibility complex (MHC) on chromosome 6 account for almost half of the heritability of psoriasis. However, at least 70 other loci are implicated, with susceptibility variants that lie within or close to genes involved in regulating epidermal barrier function, antigen presentation, cytokine production, notably IL-13 and IL-23, T-cell differentiation (especially Th-1 and Th-17 subsets) and nuclear factor kappa B (NFκB) signalling. Some of the loci that predispose to psoriasis overlap with those implicated in Crohn's disease, ankylosing spondylitis and psoriatic arthritis.

Environmental triggers for psoriasis are shown in (Box 29.23). Although the theory is controversial, stress may exacerbate psoriasis in susceptible individuals and psoriasis is itself a cause of psychological stress. Likewise, there is a higher incidence of smoking and heavy alcohol consumption in patients with psoriasis but it is unclear whether this is cause or effect. There is also an association between psoriasis and metabolic syndrome (p. 730).

The histological changes of psoriasis are shown in Figure 29.34. The main features are:

- keratinocyte hyperproliferation and abnormal differentiation, leading to retention of nuclei in the stratum corneum
- inflammation, with a T-cell (mainly activated Th-1 and Th-17) lymphocytic infiltrate and release of cytokines and adhesion molecules, such as interleukins (including IL-17 and IL-23), TNF-α, IFN-γ and intercellular adhesion molecule (ICAM)-1
- vascular changes, with tortuosity of dermal capillary loop vessels and release of mediators, such as vascular endothelial growth factor (VEGF).

The initiating event for psoriasis is unknown. Disordered cell proliferation is a key feature; this was previously thought to be the primary event but is now considered to be secondary to inflammatory change. The transit time for keratinocyte migration, from basal layer to shedding from stratum corneum, is shortened from approximately 28 to 5 days, so that immature cells reach the stratum corneum prematurely. Proliferation rate is also increased in non-lesional skin but to a lesser extent. Similarly, even the clinically unaffected nails of patients with psoriasis grow more quickly than those of controls.

While immunological factors clearly play a key role in psoriasis, the precise mechanisms of disease initiation and the sequence of events that lead to psoriasis are not fully defined.

i 29.23 Exacerbating factors in psoriasis

Trauma

- Lesions can appear at sites of skin trauma, such as scratches or surgical wounds (Köbner isomorphic phenomenon)

Infection

- β-haemolytic streptococcal throat infections often precede guttate psoriasis (see Fig. 29.35C)
- Severe psoriasis may be the initial presentation of HIV infection

Sunlight

- Psoriasis may occur or worsen after sun exposure, mainly due to Köbnerisation at sites of sunburn or polymorphic light eruption

Drugs

- Antimalarials, β-adrenoceptor antagonists (β-blockers), lithium, NSAIDs and TNF-α inhibitors can exacerbate psoriasis
- 'Rebound' flare of psoriasis may occur after withdrawal of systemic glucocorticoids or potent topical glucocorticoids. Rebound psoriasis is often unstable and may be pustular

Psychological factors

- Anxiety and stress may exacerbate psoriasis in predisposed individuals

(NSAID = non-steroidal anti-inflammatory drug; TNF-α = tumour necrosis factor alpha)

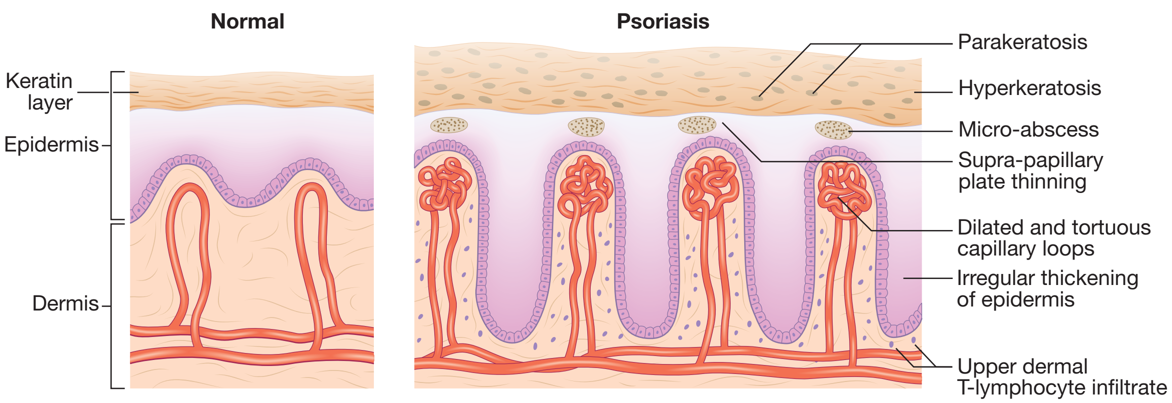

Fig. 29.34 The histology of psoriasis.

Fig. 29.35 **Psoriasis.** **A** Chronic plaque psoriasis, most prominent on extensor surfaces. **B** Nail involvement, with coarse pitting and separation from the nail plate (onycholysis). **C** Guttate psoriasis following a streptococcal throat infection. **D** Erythrodermic psoriasis.

Clinical features

Psoriasis has several different presentations (Fig. 29.35).

Plaque psoriasis

This is the most common presentation and usually represents more stable disease. The typical lesion is a raised, well-demarcated erythematous plaque of variable size (Fig. 29.35A). In untreated disease, silver/white scale is evident and more obvious on scraping the surface, which reveals bleeding points (Auspitz sign). The most common sites are the extensor surfaces, notably elbows and knees, and the lower back. Others include:

- *Scalp*: involvement is seen in approximately 60% of patients. Typically, easily palpable, erythematous scaly plaques are evident within hair-bearing scalp and there is clear demarcation at or beyond the hair margin. Occipital involvement is common and difficult to treat. Less often, fine diffuse scaling may be present and difficult to distinguish from seborrhoeic dermatitis. Involvement of other 'seborrhoeic sites', such as eyebrows, nasolabial folds and the pre-sternal area, is not uncommon and again may be confused with seborrhoeic dermatitis. Temporary hair loss can occur but permanent loss is unusual.
- *Nails*: involvement is common, with 'thimble pitting', onycholysis (separation of the nail from the nail bed, Fig. 29.35B), subungual hyperkeratosis and periungual involvement (p. 1210).
- *Flexures*: psoriasis of the natal cleft and submammary and axillary folds is usually symmetrical, erythematous and smooth, without scale.
- *Palms*: psoriasis of the palms can be difficult to distinguish from eczema.

Guttate psoriasis

This is most common in children and adolescents and is often the initial presentation (Fig. 29.35C). It may present shortly after a streptococcal throat infection and evolves rapidly. Individual lesions are droplet-shaped, small (usually less than 1 cm in diameter), erythematous, scaly and numerous. An episode of guttate psoriasis may clear spontaneously or with topical treatment within a few months, but UVB phototherapy is often required and is highly effective. Guttate psoriasis often heralds the onset of plaque psoriasis in adulthood.

Erythrodermic psoriasis

Generalised erythrodermic psoriasis is a medical emergency (Fig. 29.35D).

Pustular psoriasis

Pustular psoriasis may be generalised or localised. Generalised pustular psoriasis is uncommon, unstable and life-threatening. It will often emerge in the context of plaque disease and the onset is usually sudden, with large numbers of small, sterile pustules on an erythematous background, often merging into sheets, with waves of new pustules in subsequent days. The patient is usually febrile and systemically unwell, and this must be dealt with as a medical emergency (p. 1224). Unstable pustular psoriasis may be precipitated as a rebound phenomenon following either topical or systemic glucocorticoid use in a patient with psoriasis. Localised pustular psoriasis of the palms and soles (palmoplantar pustulosis) is more common, chronic and closely associated with smoking; small, sterile pustules and erythema develop and resolve with pigmentation and scaling (p. 1210). A localised form of sterile pustulosis of a few digits (acropustulosis) can also occur. It is unclear whether these localised forms of pustulosis are truly psoriatic.

Arthropathy

Between 5% and 10% of individuals with psoriasis develop an inflammatory arthropathy, which can take on a number of patterns (p. 1035). Joint involvement is more likely in patients with psoriatic nail disease.

Investigations

Skin biopsy is not usually required but may be performed if there is diagnostic doubt. An infection screen, particularly throat swab and/or serology for recent streptococcal infection, may be informative in guttate psoriasis. Assessment of impact on life using the DLQI and disease extent using PASI (Psoriasis Area and Severity Index, p. 1211) is essential. Due to the association of psoriasis with metabolic syndrome, comorbidities and cardiovascular risk factors should be assessed and managed (p. 730). HIV testing should be considered in severe or recalcitrant psoriasis.

Management

Counselling about diagnosis and management of skin involvement and other comorbidities is paramount. Information and services must be available for patients. Psoriasis can have a major impact on all aspects of life and this must not be under-estimated. Reassurance is also needed, as the condition is generally not life-threatening. Advice regarding reduction in risk factors for cardiovascular disease should be given (smoking cessation, reduction of alcohol intake, adequate exercise and a normal body mass index). Associated diseases, such as hypertension and diabetes, should be treated.

Patients need to be involved in their own management, as the disease is usually chronic and the benefit/risk profile of treatments must be discussed and tailored to individuals. The endpoint for treatment also needs to be discussed because complete disease clearance may not be practical or appropriate and patients vary considerably in their treatment requirements. Extent of disease and impact on quality of life must be taken into account. Patient adherence to topical and systemic therapies is essential and dependent on the treatment practicalities.

The treatment approach generally follows a stepwise progression, with treatment categories broadly summarised (Fig. 29.36).

Topical treatments, including emollients, are the first-line approach. Vitamin D receptor agonists, such as calcipotriol, calcitriol and tacalcitol, are often used as first-line topical treatment. The mechanism of action includes increased differentiation and reduction of proliferation, reducing plaque scale and thickness. Calcipotriol is most widely used and can be applied once to twice daily; if less than 100 g of ointment is used each week, there is no risk of hypercalcaemia. Vitamin D analogues can cause irritation but this is often temporary. Topical glucocorticoids may be required in the management of psoriasis, particularly at flexural or facial sites, and may be alternated or combined with vitamin D analogues. However, safe, appropriately supervised and judicious use is necessary, with awareness of the potential risk of rebound unstable or pustular psoriasis with glucocorticoid over-use or sudden cessation. Dithranol and coal tar are effective and, like vitamin D analogues, work by increasing differentiation and inhibiting proliferation. Although often effective, they are messy and time-consuming. Modified versions of Goeckerman's regimen (the combination of coal tar and UVB) are still used, but coal tar has a characteristic odour and can be irritant. Short-contact dithranol therapy at relatively high concentrations applied for 15–30 minutes can be used but causes brown staining of skin and purple discoloration of light hair. In recent years, efforts have been made to improve the tolerance of tar and dithranol preparations, but at reduced efficacy. Overall, the use of tar and dithranol has reduced in recent years but they can be highly effective in selected patients.

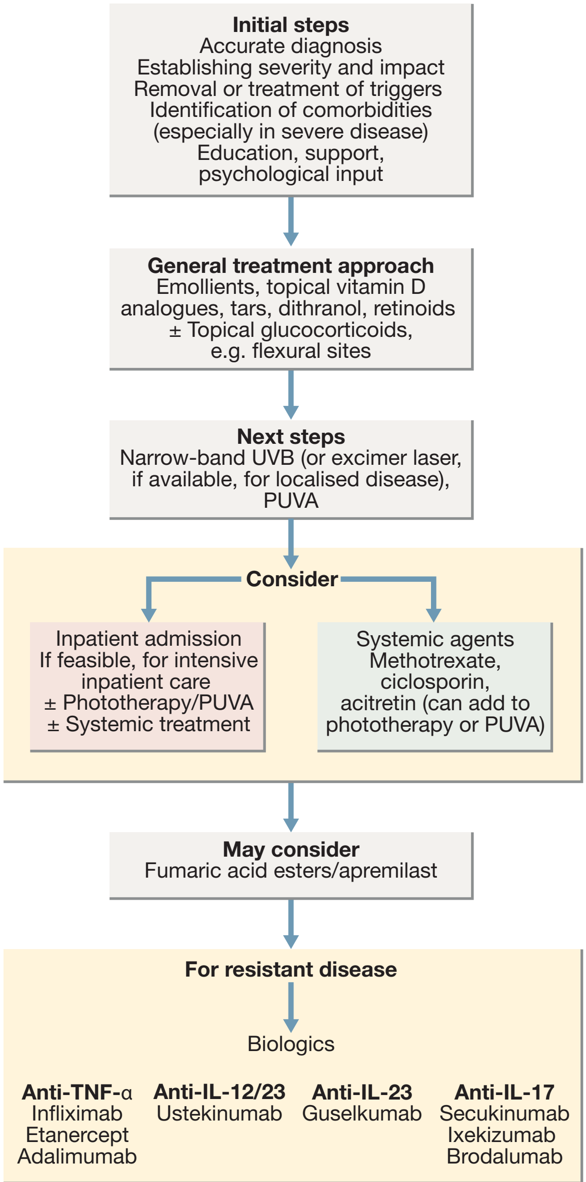

Fig. 29.36 General management approaches: psoriasis. (IL = interleukin; PUVA = psoralen–ultraviolet A; TNF-α = tumour necrosis factor alpha; UVB = ultraviolet B)

If topical treatment is insufficient, then UVB phototherapy or PUVA should usually be the next step. If the patient continues to have active disease or early recurrence, then the addition of systemic retinoid such as acitretin to UVB or PUVA can be effective. Alternatively, immunosuppressants, such as methotrexate or ciclosporin, may be required. For difficult treatment-resistant disease, fumaric acid esters, apremilast and biologics should be considered (p. 1005 and Fig. 29.37).

The active component of fumaric acid ester therapy is dimethyl fumarate and efficacy in psoriasis has been confirmed. Common adverse effects are flushing and diarrhoea. Lymphopenia is also expected at effective doses. Apremilast is indicated for moderate to severe psoriasis resistant to standard measures. Of the biological agents, the anti-TNF-α agents (etanercept, infliximab, adalimumab or golimumab), ustekinumab (an inhibitor

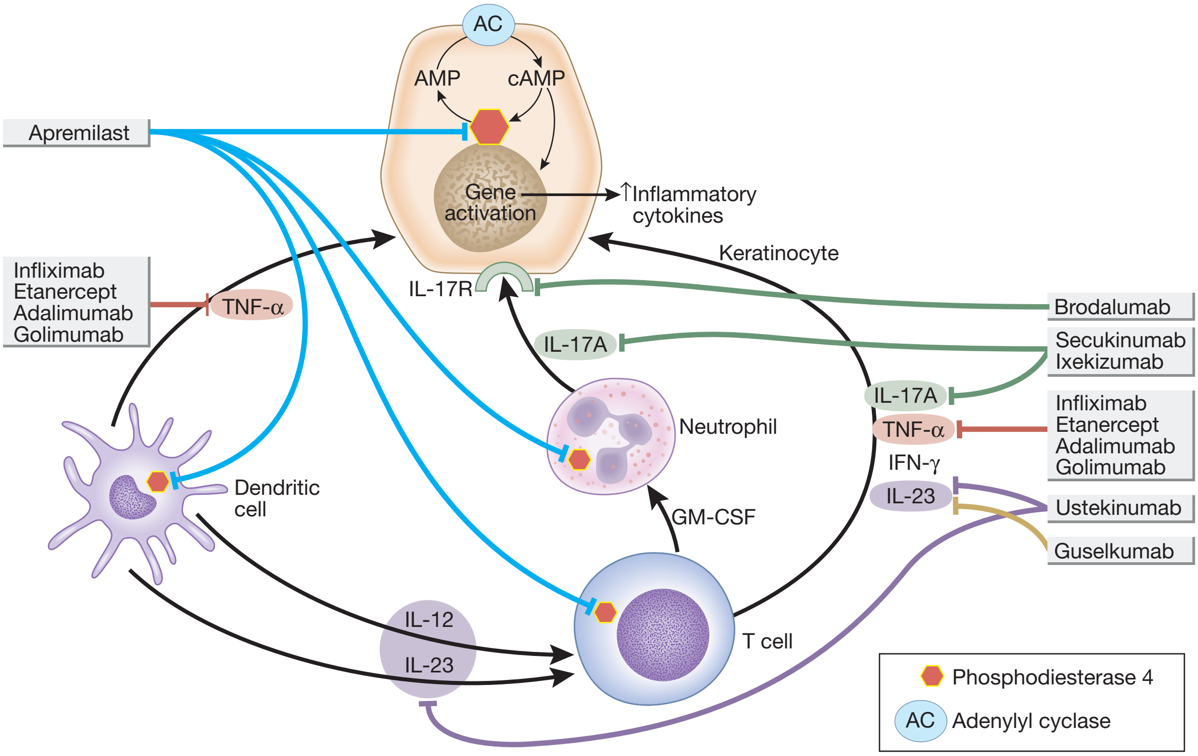

Fig. 29.37 Developments in understanding of key pathways and drug targets in psoriasis. Other drug targets are also under development, such as Janus kinase (JAK) inhibitors (tofacitinib and baricitinib) and sphingosine-1-phosphate receptor (S1PR1) antagonists (ponesimod). This diagrammatic image is illustrative of key pathways and drug targets but is not comprehensive. (AMP = adenosine monophosphate; cAMP = cyclic adenosine monophosphate; GM-CSF = granulocyte macrophage colony-stimulating factor; IL = interleukin; TNF-α = tumour necrosis factor alpha)

of IL-12 and IL-23), guselkumab (an IL-23 inhibitor) and secukinumab or ixekizumab (an IL-17 inhibitor) may all be effective and this is a rapidly evolving field. More details of the mechanisms of action and adverse effects of these agents are provided on page 1006.

Individualised management is essential. For example, a patient with localised plaque psoriasis on elbows, knees and sacrum should respond to topical treatment only, whereas someone with guttate psoriasis is likely to need phototherapy as a first-line approach because of difficulties in topical drug application in extensive disease. A patient with extensive chronic plaque psoriasis and significant arthropathy would be better suited to a systemic drug, such as methotrexate, than phototherapy, which would be unlikely to improve joint symptoms. Thus, whilst a stepwise general approach to management (see Fig. 29.36) may offer guidance, the correct choice for any given patient must be determined on an individual basis.

Pityriasis rosea

This is an acute, self-limiting exanthem that particularly affects young adults and occurs worldwide, with a slight female predominance. It usually presents in spring and summer, although no infective agent has been identified and its aetiology is unknown. It is characterised by the appearance of a ‘herald patch’, an oval lesion (1–2 cm) with a central pinkish (salmon-coloured) centre, a darker periphery and a characteristic collarette of scale. It is followed 1–2 weeks later by a widespread papulosquamous eruption, which is typically arranged in a symmetrical ‘fir tree’ pattern on the trunk. Individual lesions also have a collarette of scale. An inverse variant with flexural involvement can occur. Mucosal involvement is rare. There is a small risk of recurrence. Symptomatic relief can be achieved with emollients and mild topical glucocorticoids. Post-inflammatory hyperpigmentation can supervene, particularly in darker skin types.

Pityriasis lichenoides chronica

This is rare but typically presents within the first three decades of life. The aetiology is unclear but the condition is part of a spectrum and remits spontaneously. The more acute variety (pityriasis lichenoides et varioliformis acuta, PLEVA) presents as crops of papules that rapidly evolve with central necrosis, each attack lasting up to 3 months. The more chronic variety presents as a persistent, widespread, scaly eruption. Characteristically, lesions are brown papules with a mica-like scale (‘cornflake’). The condition fluctuates but can persist for months or years. Emollients, topical glucocorticoids and long-term oral erythromycin can occasionally be helpful. UVB phototherapy or PUVA is usually effective, although recurrences are high.

Drug eruptions

It is essential to consider a drug cause in anyone presenting with an erythematous maculopapular or papulosquamous eruption, and a careful drug history is critical (p. 1265). Exfoliation (‘peeling’) and post-inflammatory hyper- or, less commonly, hypopigmentation can occur.

Other causes

Secondary syphilis (p. 337), pityriasis versicolor (p. 1240) and fungal infection with *Tinea corporis* (p. 1240) can all cause an

erythematous papulosquamous rash and must be considered in the differential diagnosis of erythematous papulosquamous rashes.

Lichenoid eruptions

Lichen planus

Lichen planus occurs worldwide. It typically presents as a pruritic rash; the mucosae, hair and nails may also be involved.

Pathogenesis

The disease probably has an autoimmune basis since there is an association with inflammatory bowel disease, primary biliary cirrhosis, autoimmune hepatitis, hepatitis B and C, alopecia areata, myasthenia gravis (p. 1141) and thymoma. There are also similarities with graft-versus-host disease (GVHD, p. 937). Lichen planus can occasionally occur in families and possible HLA associations have been reported but there is no clear inheritance pattern. On skin biopsy, characteristic histological changes include hyperkeratosis, basal cell degeneration and a heavy, band-like T-lymphocyte infiltrate in the papillary dermis, with affinity for the epidermis (epidermotropism). The dermo-epidermal junction has a 'sawtooth' appearance.

Clinical features

Lichen planus occurs in both sexes and at any age, although usually between 30 and 60 years. It generally presents on the distal limbs, most commonly on the flexural aspects of the wrists and forearms (Fig. 29.38), and on the lower back. It is intensely itchy and lesions are violaceous, shiny, flat-topped, polygonal papules, with a characteristic fine lacy, white network on the surface (Wickham's striae). New lesions may appear at sites of skin trauma (Köbner phenomenon) and the rash may become generalised. Individual lesions may last for many months and can become hypertrophic and modified by scratching, particularly on the lower legs. The eruption usually remits over months but can become chronic, particularly with hypertrophic disease. Post-inflammatory pigmentary change is common, particularly in darker skin types. Mucous membrane involvement occurs in 30–70% of patients, usually as a network of white, lacy striae on the buccal mucosae (p. 1210) and tongue. These oral changes are often asymptomatic and should be sought on examination. Genital and other mucosal surfaces can also be affected (pp. 334 and 336). Nail involvement occurs in about 10% and can range from longitudinal ridging to a destructive nail dystrophy, scarring (pterygium) and nail loss (p. 1261). Scalp involvement usually presents as an inflammatory scarring alopecia, often with tufting of residual hairs. The classical presentation of lichen planus is unmistakable, but less common atypical variants, which include annular, atrophic, actinic, linear, bullous, follicular, pigmented and ulcerative types, can be a diagnostic challenge.

Fig. 29.38 Lichen planus. Violaceous papules on the flexural aspect of forearm, arising at a site of minor linear trauma (Köbner phenomenon).

Investigations

A skin biopsy should be performed if there is diagnostic doubt. A careful drug history must be taken, as, although the classical presentation of lichen planus is usually 'idiopathic', the main differential is a drug-induced lichenoid reaction (see below). Other differential diagnoses include psoriasis, pityriasis rosea, pityriasis lichenoides chronica and secondary syphilis. Screening for underlying disease, such as hepatitis, must be considered.

Management

The condition is usually self-limiting, although rarely it may persist for years, particularly oral lichen planus. Treatment is symptomatic and potent local glucocorticoids (topical, with occlusion or by injection for hypertrophic disease, or as oral rinse for oral involvement) may help the intense itch; short courses of systemic glucocorticoids are sometimes required for extensive disease. UVB, PUVA or UVA1 can be beneficial and, for recalcitrant disease, retinoids or immunosuppressants, such as ciclosporin or methotrexate, may be needed. A low but significant risk of malignant transformation exists with persistent oral and genital disease, so active treatment, surveillance and smoking cessation are important.

Drug-induced lichenoid eruptions

Drug-induced lichenoid reactions that are clinically and histologically difficult to distinguish from idiopathic lichen planus are important to identify. The likely culprits are gold, quinine, proton pump inhibitors, sulphonamides, penicillamine, antimalarials, antituberculous drugs, thiazide diuretics, β-blockers, angiotensin-converting enzyme (ACE) inhibitors, NSAIDs, sulphonylureas, lithium and dyes in colour developers (see Box 29.35, p. 1266).

Graft-versus-host disease

In the acute stage of graft-versus-host disease (GVHD, p. 937), there is a distinctive dermatitis associated with hepatitis. After about 3 months, chronic GVHD can present with a lichenoid eruption on the palms, soles, face and upper trunk. Progressive sclerodermatous skin thickening, associated with pigmentary changes, may lead to contractures and limited mobility.

Urticaria

Urticaria ('hives') is caused by localised dermal oedema secondary to a temporary increase in capillary permeability. If oedema involves subcutaneous or submucosal layers, the term angioedema is used.

Clinical features

Acute urticaria may be associated with angioedema of the lips, face, tongue, throat and, rarely, wheezing, abdominal pain, headaches and even anaphylaxis (p. 75). Urticaria present for less than 6 weeks is considered to be acute, and chronic if it continues for more than 6 weeks. Individual weals (**definition**: evanescent discrete areas of dermal oedema, often centrally white due to masking of local blood supply by fluid; weals can

be papules, macules, patches and plaques – Fig. 29.39) last for less than 24 hours; if they persist, urticarial vasculitis needs to be considered. Clarification of the duration of urticaria can be achieved by drawing around the weal and re-assessing 24 hours later. History-taking should probe for possible causes, including medications (Box 29.24). Physical triggers can also be assessed in challenge testing, such as eliciting dermographism or pressure testing. Enquiry about family history and medication, particularly ACE inhibitors, is important in angioedema. Examination may be unremarkable or weals may be evident (Fig. 29.39). The skin should be stroked firmly with an orange stick in order to ascertain whether dermographism is present or not.

Mast cell degranulation and release of histamine and other vasoactive mediators is the basis of urticaria (Fig. 29.40). Chronic spontaneous urticaria (previously called 'chronic idiopathic' or 'chronic ordinary' urticaria) is the most common chronic urticaria and has an autoimmune pathogenesis in some cases.

Fig. 29.39 Urticaria. Erythema, reflecting dilated dermal vessels, and oedema (with upper dermal oedema obscuring the erythema centrally) are evident. Note the absence of epidermal changes.

Investigations

Investigations should be guided by the history and possible causes but are often negative, particularly in acute urticaria. Some or all of the following may be appropriate:

- *Full blood count*: eosinophilia in parasitic infection or drug cause.
- *Erythrocyte sedimentation rate (ESR) or plasma viscosity*: elevated in vasculitis.
- *Urea and electrolytes, thyroid and liver function tests, iron studies*: may reveal an underlying systemic disorder.
- *Total IgE and specific IgE to possible allergens*: shellfish, peanut, house-dust mite. Particularly relevant if there is angioedema.
- *Autoantibodies, particularly antinuclear factor*: positive in systemic lupus erythematosus (SLE) and often positive in urticarial vasculitis. Other autoimmune diseases, such as

i 29.24 Causes of urticaria

Acute and chronic urticaria

- Autoimmune: due to antibodies that cross-link the IgE receptor on mast cells
- Allergens in foods and inhalants
- Contact allergens: latex, animal saliva
- Drugs: see Box 29.35 (p. 1266)
- Physical stimuli: heat, cold, pressure, sun, sweat, water
- Infections: intestinal parasites, hepatitis
- Others: SLE, pregnancy, thyroid disease
- Idiopathic: chronic spontaneous urticaria and angioedema

Urticarial vasculitis

- Hepatitis B, SLE, idiopathic

(IgE = immunoglobulin E; SLE = systemic lupus erythematosus)

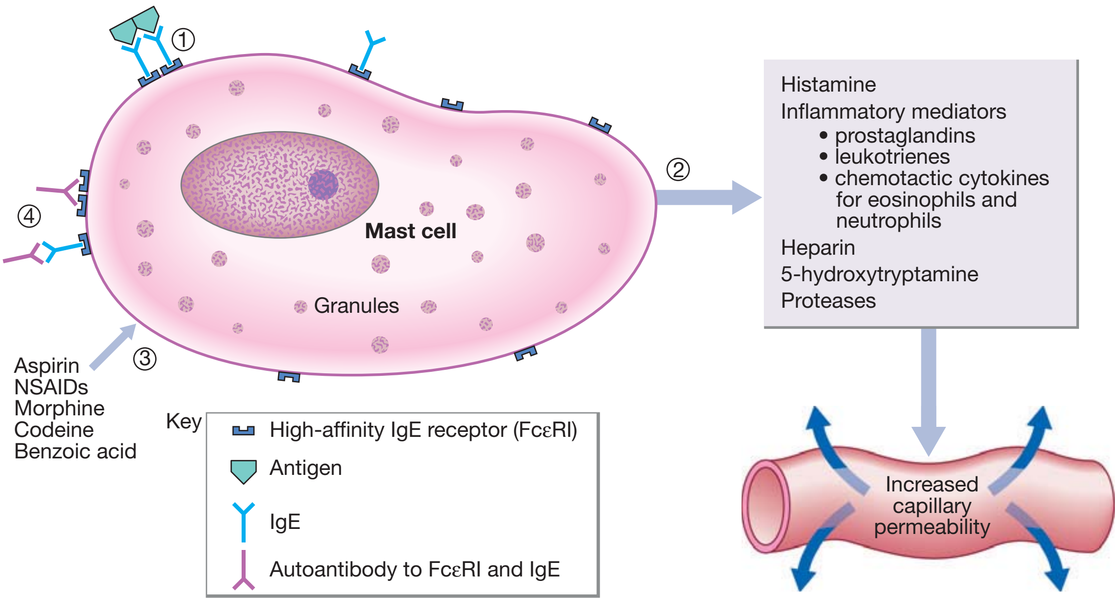

Fig. 29.40 Pathogenesis of urticaria. Mast cell degranulation occurs in a variety of ways. (1) Type I hypersensitivity causes degranulation. (2) Spontaneous mast cell degranulation in chronic urticaria. (3) Chemical mast cell degranulation. (4) Autoimmunity, with IgE antibodies directed against IgE receptors or IgE itself. Histamine and the leukotrienes are especially relevant mediators in urticaria. Heparin release is probably not a major factor in urticaria but plays a role in the osteoporosis that can occur in systemic mastocytosis. (IgE = immunoglobulin E; NSAID = non-steroidal anti-inflammatory drug)

rheumatoid arthritis and autoimmune hepatitis or thyroid disease, may be associated.

- *Complement C_3 and C_4 levels*: if these are low due to complement consumption, *C_1 esterase inhibitor* activity should be measured.
- *Infection screen*: hepatitis screen and HIV may be indicated.
- *Skin biopsy*: if urticarial vasculitis is suspected.
- *Challenge tests*: to confirm physical urticarias, such as dermographism, pressure, heat, cold.

Management

Removal or treatment of any trigger is essential, although this may not be identified in the majority of cases. Urticaria may be precipitated by aspirin, NSAIDs, codeine and opioids, and it is advisable to suggest alternatives such as paracetamol. In chronic urticaria, non-sedating antihistamines, such as fexofenadine, loratadine or cetirizine, are usually beneficial. If there is lack of response after 2 weeks, an alternative non-sedating antihistamine should be used and an H_2-blocker, such as cimetidine or ranitidine, can be added. Mast cell stabilisers or leukotriene receptor antagonists, such as montelukast, can be used for more recalcitrant disease. For chronic urticaria, narrowband UVB phototherapy is valuable and has proven efficacy. Systemic glucocorticoids are widely prescribed for urticaria but are not indicated in the majority of cases. If systemic glucocorticoids are used, efficacy may be seen only at relatively high doses and they are appropriate only for occasional short courses in the acute setting, usually in association with angioedema. Patients with a history of life-threatening anaphylaxis, as in peanut or wasp sting allergy, should carry a self-administered adrenaline (epinephrine) injection kit. The management of anaphylaxis and hereditary angioedema is discussed on pages 76 and 87. The IgE monoclonal antibody omalizumab may be effective in patients with severe recalcitrant urticaria.

Bullous diseases

Blistering can occur at any level in the skin and there are a variety of different presentations, depending on the underlying defect and level of involvement. Knowledge of the molecular basis of many blistering disorders has advanced considerably through understanding of the basic processes of cell adhesion and studies of rare genetic blistering disorders, particularly epidermolysis bullosa (Box 29.25). This section concentrates on primary blistering skin diseases.

29.25 Classification of epidermolysis bullosa

Type	Mode of inheritance	Level of blister*	Abnormality
Simple	Autosomal dominant	Epidermal basal cell	Keratins 5 and 14
Junctional	Autosomal recessive	Lamina lucida	Laminin-5 and $\alpha_6\beta_4$ integrin
Dystrophic	Autosomal dominant and recessive	Dermis below lamina densa	Collagen VII

*See Figure 29.1 (p. 1213).

Toxic epidermal necrolysis

Toxic epidermal necrolysis (TEN) is a medical emergency, as the extensive mucocutaneous blistering is associated with a high mortality rate. It is usually drug-induced (see Box 29.35, p. 1266), with anticonvulsants, sulphonamides, sulphonylureas, NSAIDs, allopurinol and antiretroviral therapy often implicated. Usually 1–4 weeks after drug commencement, the patient becomes systemically unwell and often pyrexial. Erythema and blistering develop, initially on the trunk but rapidly involving all skin; an early warning sign is cutaneous pain. Sheets of blisters coalesce and denude, and the underlying skin is painful and erythematous (Fig. 29.41). Gentle lateral pressure on stroking the skin results in epidermal detachment (Nikolsky sign), demonstrating the severity of skin fragility. Mucous membrane involvement and blistering are usual. Blistering of skin and mucosae may be haemorrhagic. A disease severity score (Box 29.26) is used to predict outcome. The main differential diagnosis is staphylococcal scalded skin syndrome (p. 1236), although the diagnosis is usually obvious in an adult patient with a culprit drug. There is often overlap with Stevens–Johnson syndrome and targetoid lesions, especially on palms and soles, may be evident. Skin

Fig. 29.41 Toxic epidermal necrolysis. Note the extensive erythema, oedema and epidermal loss secondary to carbamazepine.

29.26 Disease severity score for toxic epidermal necrolysis: SCORTEN

Factor

- Age >40 years
- Heart rate >120 beats/min
- Cancer or haematological malignancy
- Involved body surface area >10%
- Blood urea >10 mmol/L (28 mg/dL)
- Serum bicarbonate <20 mmol/L
- Blood glucose ≥14 mmol/L (252 mg/dL)

Mortality rates

- 0–1 factor present = 3%
- 2 factors = 12%
- 3 factors = 35%
- 4 factors = 58%
- ≥5 factors = 90%

From Bastuji-Garin S, Fouchard N, Bertocchi M, et al. SCORTEN: a severity-of-illness score for toxic epidermal necrolysis. J Invest Dermatol 2000; 115:149–153.

snip may allow early diagnosis. If there is diagnostic doubt, then full-thickness skin biopsy should be undertaken for histology and direct immunofluorescence in order to exclude immunobullous or other diagnoses.

Identification and discontinuation of the causative drug are essential. Sepsis and multi-organ failure are major risks. Intensive care in a dedicated dermatology ward or intensive care or burns unit is of paramount importance. Treatment is supportive, with regular sterile dressings and emollients, careful attention to fluid balance and treatment of infection if it develops. Urethral and ocular involvement is common and must be looked for and treated symptomatically. Ocular and urethral scarring can be problematic in survivors. There is no conclusive evidence that intravenous immunoglobulins, systemic glucocorticoids or ciclosporin improve outcomes and survival.

Immunobullous diseases

There are various subtypes of immunobullous disease that affect patients of different ages and have clinical characteristics (Box 29.27). The key investigation is an elliptical biopsy taken from the edge of a recent blister (Box 29.28). The sample is halved: one half is put in formalin for subsequent histology, while the other is sent fresh for direct immunofluorescence. Serum should also be sent for indirect immunofluorescence in suspected immunobullous disease (p. 1215).

Bullous pemphigoid

Bullous pemphigoid (BP) is the most common immunobullous disease and occurs worldwide. It is a disease of the elderly, with an average age of onset of 65 years; males and females are equally affected.

Pathogenesis

The disease is caused by autoantibodies (BP-230 and BP-180) directed against the hemi-desmosomal BP antigens, BPAg-1 (intracellular) and BPAg-2 (transmembranous type XVII collagen), respectively. Antibody–antigen binding initiates complement activation and inflammation, with hemi-desmosomal damage and subepidermal blistering.

Clinical features

There is often a lengthy prodrome of an itchy, urticated, erythematous rash prior to the development of tense bullae (Fig. 29.42A). Milia (**definition**: small epidermal keratin cysts) may develop due to basement membrane disruption. Mucosal involvement is uncommon.

i 29.27 Age of onset in immunobullous skin disorders

Disease	Age
Pemphigus vulgaris	40–60 years
Pemphigus foliaceus	Any age (endemic form in parts of Brazil and South Africa, from teenage years on)
Bullous pemphigoid	Sixties and over
Dermatitis herpetiformis	Young, associated with coeliac disease
Linear IgA disease	Any age
Pemphigoid gestationis	Pregnant females
Epidermolysis bullosa acquisita	Any age
Bullous lupus erythematosus	Young black females

i 29.28 Clinical and investigation findings in the immunobullous disorders

Disease	Site of blisters	Nature of blisters	Mucous membrane involvement	Antigen	Circulating antibody (indirect IF)	Fixed antibody (direct IF)
Pemphigus vulgaris	Trunk, head	Flaccid, fragile, many erosions	100%	Desmoglein-1 and 3 (120 kD)	IgG	IgG, C_3 intercellular (epidermal)
Pemphigus foliaceus	Trunk	Often not present, multiple erosions, may mimic dermatitis	No	Desmoglein-1	IgG	IgG, C_3 intercellular (epidermal)
Bullous pemphigoid	Trunk, flexures and limbs	Tense, milia as blisters resolve	Occasional	BP-230 and 180	IgG (70%)	IgG, C_3 at BMZ
Dermatitis herpetiformis	Elbows, lower back, buttocks	Excoriated and often not present	No	Unknown	Anti-endomysial and tissue transglutaminase	Granular IgA in papillary dermis
Linear IgA disease	Widespread	Tense, often annular configuration, 'string of beads'	Frequent	Unknown	50% have low titres of circulating antibody	Linear IgA at BMZ
Pemphigoid gestationis	Periumbilical and limbs	Tense, milia as blisters resolve	Rare	Collagen XVII (part of hemi-desmosome, BP-180)	Circulating antibodies to BP-180 (type XVII collagen) (and BP-230)	C_3 at BMZ
Epidermolysis bullosa acquisita	Widespread	Tense, scarring, milia	Common (50%)	Type VII collagen	IgG (anti-type VII collagen)	IgG at BMZ
Bullous lupus erythematosus	Widespread	Tense	Rare	Type VII collagen	Anti-type VII collagen	IgG, IgA, IgM at BMZ

(BMZ = basement membrane zone; IF = immunofluorescence; Ig = immunoglobulin)

A

B

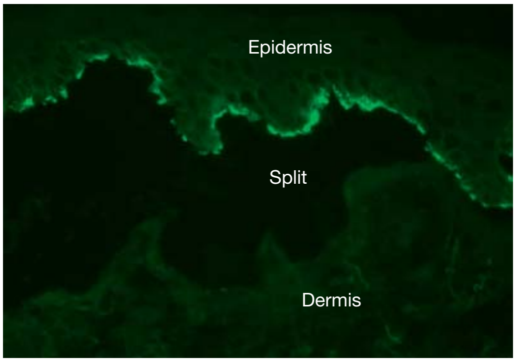

Fig. 29.42 Bullous pemphigoid. A Large, tense, unilocular blisters. B Immunofluorescence on salt-split skin, showing a subepidermal blister and linear IgG and C3 deposition at the basement membrane zone.

Investigations

The diagnosis can be made by skin biopsy, which shows subepidermal blistering with an eosinophil-rich inflammatory infiltrate. Direct immunofluorescence demonstrates the presence of IgG and C3 at the basement membrane (Fig. 29.42B). Indirect immunofluorescence may show positive titres of circulating anti-epidermal antibodies. Distinction from epidermolysis bullosa acquisita requires immunofluorescence studies using the patient's serum on salt-split skin. In BP, the immunoreactants localise to the epidermal side (hemi-desmosome) of split skin, whereas in epidermolysis bullosa acquisita they localise to the base of the split (type VII collagen/anchoring fibrils).

Management

Very potent topical glucocorticoids are effective and may be sufficient in frail elderly patients; they need to be applied to all sites, however, and not just lesional skin. Tetracyclines, such as doxycycline, have an important role and may limit the use of systemic glucocorticoids. However, most patients with extensive disease require systemic glucocorticoids (0.75 mg/kg/day or less), often combined with immunosuppressants as glucocorticoid-sparing agents. In severe refractory disease, other therapies, such as intravenous immunoglobulin or rituximab, are sometimes used but are of unproven efficacy. The condition often burns out over a few years.

Pemphigus

Pemphigus is less common than BP and patients tend to be younger.

Pathogenesis

The cause is IgG1 and IgG4 autoantibodies, directed against desmogleins-1 and 3, resulting in intra-epidermal blistering. The syndrome may occur spontaneously or be secondary to drugs such as penicillamine or captopril and underlying malignancy (paraneoplastic pemphigus). Pemphigus foliaceus is a very superficial form, in which antibodies are directed against desmoglein-1 only and affect just the most superficial epidermis.

Clinical features

Skin and mucosae are usually involved, although disease may be restricted to mucosae only, which may be severely affected. Due to the higher level of split within the epidermis, the blisters are flaccid, easily ruptured and often not seen intact. Erosions are common and the Nikolsky sign is positive. The trunk is usually affected. The condition is associated with significant morbidity and mortality.

Investigations

The diagnosis can be made by skin biopsy, which shows intra-epidermal blistering and acantholysis, with positive direct immunofluorescence for IgG (usually IgG1 or IgG4) and C3 at the periphery of keratinocytes, giving a 'chicken wire' appearance within the epidermis. The titres of circulating epidermal autoantibodies can also be used to monitor disease activity. Investigations should screen for associated autoimmune disease or malignancy if paraneoplastic pemphigus is suspected.

Management

Pemphigus is more difficult to treat than BP and high-dose systemic glucocorticoids such as prednisolone (0.5–1.0 mg/kg/day) are usually required. Azathioprine and cyclophosphamide are most often used as glucocorticoid-sparing agents but a range of other immunosuppressants may be considered for severe recalcitrant disease, including methotrexate, ciclosporin, mycophenolate mofetil, intravenous immunoglobulins, plasma exchange, extracorporeal photopheresis and rituximab. Often, long-term treatment is required to prevent relapse.

Dermatitis herpetiformis

Dermatitis herpetiformis (DH) is an autoimmune blistering disorder that is strongly associated with coeliac disease (CD). While fewer than 10% of individuals with CD develop DH, almost all patients with DH have evidence of partial villous atrophy on intestinal biopsy, even if they have no gastrointestinal symptoms (p. 806). It is unclear why some CD patients develop DH and others do not. Although DH is a bullous disease, intact vesicles and blisters are seldom seen, as the condition is so pruritic that excoriations on extensor surfaces of arms, knees, buttocks, shoulders and scalp may be the only signs.

The diagnosis can be made by skin biopsy, which shows subepidermal vesiculation in the dermal papillae and a neutrophil- and eosinophil-rich infiltrate. Direct immunofluorescence shows granular IgA in the papillary dermis. Anti-endomysial antibodies and tissue transglutaminase should be assessed and jejunal biopsy undertaken if indicated. The condition usually responds to a gluten-free diet but, if not, dapsone can also be used.

Linear IgA disease

This occurs in children (chronic bullous disease of childhood) and adults, and is usually self-limiting, although it can be active for a few years. Drugs, notably vancomycin, can be a secondary cause. Blisters

can arise on erythematous, urticated or otherwise normal-looking skin and often form an annular configuration at the edge of the lesion: 'clusters of jewels' (herpetiform) and 'string of beads' (annular/polycyclic). Mucosal involvement is common and ophthalmology input important, as corneal scarring is a risk with longstanding disease. Linear IgA is seen at the basement membrane on direct immunofluorescence and localises to either roof or floor of salt-split skin. Dapsone, sulfapyridine, prednisolone, colchicine or intravenous immunoglobulin may be effective.

Epidermolysis bullosa acquisita

This chronic blistering disease affects skin and mucosae, and scarring, hair loss and nail dystrophy may be problematic. Blisters often follow trauma and milia develop. It can be very difficult to distinguish from other immunobullous diseases, such as bullous pemphigoid. It is caused by an IgG antibody to type VII collagen, which provokes subepidermal blistering and a mixed inflammatory infiltrate, although the latter may not be prominent. Direct immunofluorescence on perilesional skin shows IgG and C3 at the dermo-epidermal junction and pattern analysis may be helpful in distinction from bullous pemphigoid. Indirect immunofluorescence microscopy on salt-split normal human skin typically shows IgG and IgA in the floor of the artificially induced blister, whereas in BP antibody localisation would be to the roof of the blister. Epidermolysis bullosa acquisita is very difficult to treat, as it often does not respond well to immunosuppressants. Mainstays of treatment include systemic glucocorticoids in combination with dapsone or colchicine. Other immunosuppressive approaches may be required and include ciclosporin, azathioprine, immunoglobulins, plasmapheresis and rituximab. The condition may be associated with inflammatory bowel disease, rheumatoid arthritis, multiple myeloma and lymphoma, and thus associated comorbidities should be sought.

Porphyria cutanea tarda and pseudoporphyria

These conditions may also cause blistering (see Boxes 29.9 and 29.35, pp. 1221 and 1266). Porphyria is discussed in more detail on page 378.

Pigmentation disorders

Decreased pigmentation

Disorders causing hypopigmentation and/or depigmentation include:

- vitiligo
- albinism
- pityriasis alba: depigmented areas on the face, particularly in children, with or without scale and usually considered to be eczematous
- pityriasis versicolor (p. 1240): hypopigmentation or, less commonly, hyperpigmentation can occur
- idiopathic guttate hypomelanosis: multiple small areas of depigmentation arising in chronically sun-exposed skin
- rarely, phenylketonuria (p. 369) and hypopituitarism.

Vitiligo

Vitiligo is an acquired condition affecting 1% of the population worldwide. Focal loss of melanocytes results in the development of patches of hypopigmentation. A positive family history of vitiligo is relatively common in those with extensive disease, and this type is also associated with other autoimmune diseases. Trauma and sunburn may (through the Köbner phenomenon) precipitate the appearance of vitiligo. It is thought to be the result of cell-mediated autoimmune destruction of melanocytes but why some areas are targeted and others are spared is unclear.

Clinical features

Generalised vitiligo is often symmetrical and involves hands, wrists, feet, knees and neck, as well as areas around body orifices (Fig. 29.43). The hair of the scalp, beard, eyebrows and lashes may also depigment. Segmental vitiligo is restricted to one part of the body but not necessarily a dermatome. The patches of depigmentation are sharply defined, and in Caucasians may be surrounded by hyperpigmentation. Spotty perifollicular pigment may be seen within the depigmentation and is often the first sign of repigmentation. There is no history or evidence of inflammation within the patches, which may be helpful in distinguishing vitiligo from post-inflammatory hypopigmentation. Sensation in the depigmented patches is normal (unlike in tuberculoid leprosy, p. 267). Wood's light examination enhances the contrast between pigmented and non-pigmented skin. The course is unpredictable but most patches remain static or enlarge; a few repigment spontaneously.

Management

Protecting the patches from excessive sun exposure with clothing or sunscreen may be helpful to avoid sunburn. Camouflage cosmetics may be beneficial, particularly in those with dark skin. In fair skin, photoprotection and cosmetic cover may be all that is required. Very potent or potent topical glucocorticoids have limited efficacy with respect to repigmentation. Topical pimecrolimus or tacrolimus may also have a role as a glucocorticoid-sparing agent. Phototherapy with narrowband UVB or PUVA can also be used. Narrowband UVB is the most effective repigmentary treatment available for generalised vitiligo, but even very prolonged courses often do not produce a satisfactory outcome. The absence of leucotrichia (white hairs in the area of vitiligo) and the presence of a trichrome pattern (three colours – normal skin colour, hypopigmentation and depigmentation) are good prognostic features. Vitiligo on the face, trunk and proximal limbs is more likely to respond than that on hands and feet.

Fig. 29.43 Vitiligo. Symmetrical localised patches of depigmented skin.

29

Exceptionally, depigmentation of normal non-lesional skin or a surgical approach with autologous melanocyte transfer, using a range of techniques including split-skin grafts and blister roof grafts, is sometimes used on dermabraded recipient skin in specific severe cases.

The impact of vitiligo differs markedly between populations. In the Indian subcontinent, the effects are more readily discernible than in pale-skinned individuals in northern Europe. Depigmentation is also seen in leprosy, which means that individuals with vitiligo are often stigmatised. The emotional impact of vitiligo may be immense; psychological support is essential and is important in conveying realistic expectations of possible treatment approaches.

Oculocutaneous albinism

Albinism results from a range of genetic abnormalities that lead to reduced melanin biosynthesis in the skin and eyes; the number of melanocytes is normal (in contrast to vitiligo). Albinism is usually inherited as an autosomal recessive trait and there are several different types and presentations.

Type 1 albinism is due to a defect in the tyrosinase gene, whose product is rate-limiting in the production of melanin. Affected individuals have an almost complete absence of pigment in the skin and hair at birth, with consequent pale skin and white hair, and failure of melanin production in the iris and retina. Patients have photophobia, poor vision not correctable with refraction, rotatory nystagmus, and an alternating strabismus associated with abnormalities in the decussation of nerve fibres in the optic tract.

A second form of albinism is due to a defect in the *P* gene, which encodes an ion channel protein in the melanosome. Patients may have gross reduction of melanin in the skin and in the eyes, but may be more mildly affected than type 1 albinos. Establishing the subtype of albinism requires genetic analysis, as there is considerable phenotypic heterogeneity.

Oculocutaneous albinos are at grossly increased risk of sunburn and skin cancer. In equatorial regions, many die from squamous cell carcinoma or, more rarely, melanoma in early adult life. Interestingly, they may develop pigmented melanocytic naevi and freckle in response to sun exposure.

Management

Strict photoprotection (p. 1221), with sun avoidance (including occupational exposure), clothing, hats and sunscreens, is important. Early diagnosis and treatment of skin tumours is essential.

Increased pigmentation

- *Diffuse hyperpigmentation*: most commonly due to hypermelanosis but other pigments may be deposited in the skin, such as orange discoloration with carotenaemia and bronze with haemochromatosis (p. 895).
- *Endocrine pigmentation*: may occur in several conditions. Melasma (chloasma) describes discrete patches of facial pigmentation that occur in pregnancy and in some women taking oral contraceptives. The mechanism for this localised increased hormonal sensitivity is unknown. Diffuse pigmentation, sometimes worse in the skin creases and mucosae, may be a feature of Addison's disease (p. 671), Cushing's syndrome (p. 666), Nelson's syndrome (p. 669) and chronic renal failure due to increased levels of pituitary melanotrophic peptides, including adrenocorticotrophic hormone (ACTH; p. 669).

i 29.29 Drug-induced pigmentation

Drug	Appearance
Amiodarone	Photo-exposed sites, slate-grey
Arsenic	Diffuse bronze pigmentation Raindrop depigmentation
Bleomycin	Usually flexural, brown
Busulfan	Diffuse brown
Chloroquine	Photo-exposed sites, blue-grey
Clofazimine	Red
Mepacrine	Yellow
Minocycline	Temples, shins, gingiva, sclera, scar sites, slate-grey
Phenothiazines	Photo-exposed sites, slate-grey
Psoralens	Photo-exposed sites, brown

- *Photo-exposed site hyperpigmentation*: occurs in some of the porphyrias but can also be drug-induced.
- *Drug-induced pigmentation* (Box 29.29): may be diffuse or localised. It is not always due to hypermelanosis but sometimes is caused by deposition of the drug or a metabolite.
- *Focal hypermelanosis*: seen in lesions such as freckles and lentigines, characterised by focal areas of increased pigmentation.

Establishing the cause is important. Photoprotection may minimise the risk of increasing pigmentation. Topical hydroquinone preparations can be used for skin lightening in some types of hyperpigmentation, although caution is required, particularly in darker skin types.

Hair disorders

These can be subdivided into disorders that cause loss of hair (alopecia) or excessive hair growth (hypertrichosis and hirsutism).

Alopecia

Alopecia is characterised by loss of hair. It can be further subdivided into localised and diffuse, and into scarring and non-scarring subtypes (Box 29.30).

Pathogenesis

Alopecia can be observed in association with inflammatory disorders that cause scarring (lichen planus, discoid lupus) and others that do not cause scarring (tinea capitis, psoriasis, seborrhoeic eczema). These conditions are discussed elsewhere. Alopecia areata has an autoimmune basis and there is a strong genetic component, with a family history in approximately 20% of cases. In addition to atopy, it is associated with other autoimmune diseases, particularly thyroid disease, and with Down's syndrome. The cause of androgenetic alopecia is unclear but likely to be multifactorial, with genetic, hormonal and end-organ receptor sensitivity to the factors implicated.

Clinical features

Alopecia areata

This usually presents with well-defined, localised, non-inflammatory, non-scarring patches of alopecia, usually on the

29.30 Classification and causes of alopecia

Localised	Diffuse
Non-scarring	
Tinea capitis	Androgenetic alopecia
Alopecia areata	Telogen effluvium
Androgenetic alopecia	Hypothyroidism
Traumatic (trichotillomania, traction, cosmetic)	Hyperthyroidism
Syphilis	Hypopituitarism
	Diabetes mellitus
	HIV disease
	Nutritional (especially iron) deficiency
	Liver disease
	Post-partum
	Alopecia areata
	Syphilis
	Drug-induced: chemotherapy, retinoids
Scarring	
Discoid lupus erythematosus	Discoid lupus erythematosus
Lichen planopilaris	Radiotherapy
Herpes zoster	Folliculitis decalvans
Pseudopelade	Lichen planopilaris
Tinea capitis/kerion	
Morphoea (en coup de sabre)	
Idiopathic	
Developmental defects	

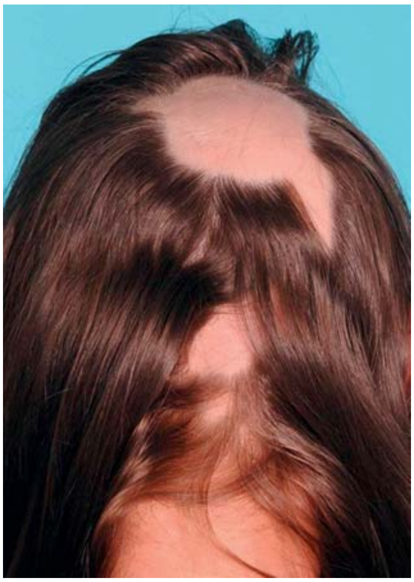

Fig. 29.44 Alopecia areata. The relatively extensive involvement and encroachment on posterior hairline are poor prognostic features.

scalp (Fig. 29.44). Pathognomonic 'exclamation mark' hairs are seen (broken hairs, tapering towards the scalp) during active hair loss. A diffuse pattern can uncommonly occur on the scalp. Eyebrows, eyelashes, beard and body hair can be affected. Alopecia totalis describes complete loss of scalp hair, and alopecia universalis is complete loss of all hair. Nail pitting may occur (p. 1261). Spontaneous regrowth is usual for small patches of alopecia but the prognosis is less good for larger patches, more extensive involvement, early onset and an association with atopy.

Androgenetic alopecia

Male-pattern baldness is physiological in men over 20 years old, although it can also occur in teenagers. It is also found in women, particularly post-menopausal ones. Characteristically, this involves bitemporal recession initially and subsequent involvement of the crown ('male pattern'), although it is often diffuse in women.

Investigations

Important investigations include full blood count, renal and liver function tests, iron studies, thyroid function, autoantibody screen and syphilis serology, as several systemic diseases, particularly iron deficiency and hypothyroidism, can cause diffuse non-scarring alopecia. Hair pull tests may help to establish the ratio of anagen to telogen hairs but require expertise for interpretation. Scrapings and pluckings should be sent for mycology if there is localised inflammation. Scalp biopsy and direct immunofluorescence of scarring alopecia may confirm a diagnosis of lichen planus or discoid lupus erythematosus but expert interpretation is needed.

Management

Any underlying condition, such as iron deficiency, should be treated and may result in clinical improvement. Alopecia can have a major impact on quality of life and psychological support is usually required. It is particularly important to establish realistic expectations.

Hair may spontaneously regrow in alopecia areata and it may be appropriate to offer no active intervention as, while some treatments may induce some hair regrowth, there is no evidence that any treatment fundamentally alters the course of the disease. There may be some response to topical or intralesional glucocorticoids. PUVA or immunotherapy with diphencyprone may be effective, with evidence of hair regrowth, but there is a risk of relapse on discontinuation of treatment. Short courses of systemic glucocorticoids are occasionally used in an attempt to limit acutely progressive extensive alopecia areata but should not be used in the long term; the risk of relapse on discontinuation is high. Ongoing trials of Janus kinase (JAK) inhibitors may provide future hope for patients with this difficult disease.

Some males with androgenetic alopecia may be helped by systemic finasteride. Topical minoxidil can be used in males and females with androgenetic alopecia but, if an effect is obtained, treatment must be continued and is expensive. In females, anti-androgen therapy, such as cyproterone acetate, can be used. Wigs are often appropriate for extensive alopecia. Scalp surgery and autologous hair transplants are expensive but can be used for androgenetic alopecia.

Hypertrichosis

Hypertrichosis is a generalised or localised increase in hair and may be congenital or acquired. It can be primary or secondary: for example, to drugs such as ciclosporin, minoxidil or diazoxide, malignancy or eating disorders. Laser therapy or eflornithine, which inhibits ornithine decarboxylase and arrests hair growth while it is being used, may be helpful. When the hypertrichosis follows a male pattern, it is called hirsutism.

Hirsutism

Hirsutism is the growth of terminal hair in a male pattern in a female (p. 657). The cause of most cases is unknown and, while it may occur in hyperandrogenism, Cushing's syndrome and polycystic ovary syndrome, only a small minority of patients have

a demonstrable hormonal abnormality. Psychological distress is often significant and oral contraceptives containing an anti-androgen such as cyproterone acetate, laser therapy or topical eflornithine may be beneficial.

Nail disorders

The nails can be affected by both local and systemic disease. The nail apparatus consists of the nail matrix and the nail plate, which arises from the matrix and lies on the nail bed (Fig. 29.45). The cells of the matrix and, to a lesser extent the bed, produce the keratinous plate.

Important information may be obtained from nail-fold examination, including dilated capillaries and ragged cuticles in connective tissue disease (Fig. 29.46) and the boggy inflammation of paronychia. The latter commonly occurs chronically in individuals undertaking wet work, in those with diabetes or poor peripheral circulation, and subsequent to increased cosmetic nail procedures and vigorous manicuring.

Normal variants

Longitudinal ridging and beading of the nail plate occur with age. White transverse patches (striate leuconychia) are often caused by airspaces within the plate.

Nail trauma

- *Nail biting/picking* is a very common habit. Repetitive proximal nail-fold trauma (often involving the thumb nail) results in transverse ridging and central furrowing of the nail.
- *Chronic trauma* from poorly-fitting shoes and sport can cause thickening and disordered growth of the nail (onychogryphosis) and subsequent ingrowing toenails.
- *Splinter haemorrhages* are fine, linear, dark brown longitudinal streaks in the plate (see Fig. 16.89, p. 529). They are usually caused by trauma, especially if distal. Uncommonly, they can occur in nail psoriasis and are also a hallmark of infective endocarditis.
- *Subungual haematoma* is red, purple or grey–brown discoloration of the nail plate, usually of the big toe (Fig. 29.47). These haematomas are usually due to trauma, although a history of this may not be clear. The main differential is subungual melanoma, although rapid onset, lack of nail-fold involvement and proximal clearing as the nail grows are clues to the diagnosis of haematoma. If there is diagnostic doubt, a biopsy may be needed.

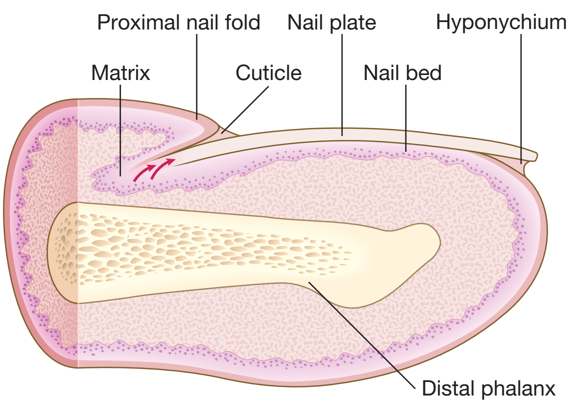

Fig. 29.45 The nail plate and bed. Arrows indicate the direction of nail growth.

Nail involvement in skin diseases

- *Dermatophyte infection/onychomycosis*: this is described on page 1240.
- *Psoriasis*: nail involvement is common (see Fig. 29.35B, p. 1249).

A

B

Fig. 29.46 Dermatomyositis. **A** Photo-aggravation. **B** Note the prominent periungual involvement. Erythema, dilated and tortuous capillaries in the proximal nail fold, and ragged cuticles are features of connective tissue disease.

Fig. 29.47 Subungual haematoma.

- *Eczema*: nails may be shiny due to rubbing skin. Fine pitting can occur. If there is periungual eczema, the nail may become dystrophic, with thickening and transverse ridging. Paronychia is common.
- *Lichen planus*: there may be longitudinal ridging and thinning of the nail, giving a sandpaper texture (trachyonychia), erythematous streaks (erythronychia), subungual hyperkeratosis, pigmentation and, in severe cases, pterygium (splitting of nail due to central fibrosis and scarring, giving a winged appearance) and a destructive nail dystrophy.
- *Alopecia areata*: nail-plate pitting and trachyonychia can occur.

Nail involvement in systemic disease

The nails may be affected in many systemic diseases and important examples are detailed below:

- *Beau's lines*: horizontal ridges/indentations in nail plate occur simultaneously in all nails (Fig. 29.48B). They typically follow a systemic illness and are thought to be due to temporary growth arrest of cells in the nail matrix; they subsequently migrate out as the nail grows. Normal nail growth is approximately 0.1 mm/day for fingers and 0.05 mm/day for toes, so the timing of the systemic upset can usually be estimated by the position of the Beau's lines.
- *Koilonychia*: this concave or spoon-shaped nail-plate deformity is caused by iron deficiency (Fig. 29.48C).
- *Clubbing*: in the early stages, the angle between the proximal nail and nail fold is lost. In its more established form, there may be swelling of the distal digits (Figs 29.48D and E) or toes. Causes include bronchogenic carcinoma, asbestosis (especially with mesothelioma), suppurative or fibrosing lung disease, cyanotic congenital heart disease, infective endocarditis, inflammatory bowel disease, biliary cirrhosis and thyrotoxicosis; rarely, clubbing can be familial or idiopathic.
- *Nail discoloration*: whitening may occur in hypoalbuminaemia. 'Half-and-half' nails (white proximally and red/brown distally) may be found in renal failure. Antimalarials and some other drugs occasionally discolour nails.

Nail involvement in congenital disease

Nails can be affected in congenital diseases, such as pachyonychia congenita, a rare, usually autosomal dominant, condition caused by mutations in differentiation-specific keratin genes 6A, 6B, 16 and 17. This results in palmoplantar keratoderma and gross nail discoloration and thickening, due to subungual hyperkeratosis, from birth.

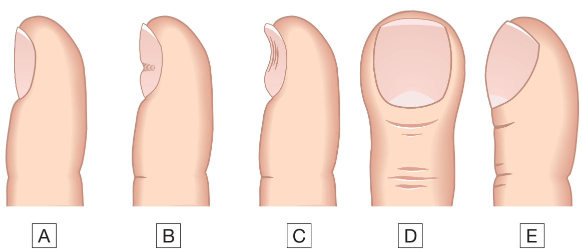

Fig. 29.48 The nail in systemic disease. **A** Normal nail. **B** Beau's line. **C** Koilonychia. **D** and **E** Digital clubbing.

Skin disease in general medicine

Many skin conditions present to other medical specialties. These are listed in Box 29.31 and the most common ones that are not discussed elsewhere are detailed below.

Conditions involving cutaneous vasculature

Vasculitis

Vasculitic involvement of the skin usually presents as palpable purpura (see Fig. 24.53, p. 1042). The diagnosis is confirmed by skin biopsy, along with histology and immunofluorescence examination. Underlying causes and their treatment are discussed on page 1040.

Pyoderma gangrenosum

The initial lesion of pyoderma gangrenosum (PG) is usually a painful, tender, inflamed nodule or pustule, which breaks down centrally and rapidly progresses to an ulcer with an indurated, undermined purplish or pustular edge (Fig. 29.49). Lesions may be single or multiple and are classified as ulcerative, pustular, bullous or vegetative. PG usually occurs in adults and, although it may occur in isolation, is usually associated with underlying disease, particularly inflammatory bowel disease, inflammatory arthritis, blood dyscrasias, immunodeficiencies and HIV infection. Investigation should be made with these associations in mind. The diagnosis is largely clinical, as histology is not specific. Analgesia, treatment of secondary bacterial infection and supportive

i 29.31 Skin problems in general medicine

Primary skin problems	
• Cellulitis • Vasculitis	• Leg ulcers • Pressure sores
Skin involvement in multisystem disease	
• Genetic: neurofibromatosis, tuberous sclerosis • Xanthomas • Amyloidosis	• Porphyria • Sarcoidosis • Systemic lupus erythematosus • Systemic sclerosis
Non-specific and variable skin reactions to systemic disease	
• Urticaria • Erythema multiforme • Annular erythemas • Erythema nodosum	• Pyoderma gangrenosum • Sweet's syndrome • Generalised pruritus
Skin conditions associated with malignancy	
• Dermatomyositis • Generalised pruritus	• Acanthosis nigricans • Superficial thrombophlebitis
Skin problems associated with specific medical disorders	
• Liver: generalised pruritus, pigmentation, spider naevi, palmar erythema, nail clubbing • Kidney: generalised pruritus, uraemic frost, pigmentation • Diabetes mellitus: necrobiosis lipoidica, diabetic dermopathy • Cutaneous Crohn's disease	
Skin problems secondary to treatment of systemic disease	
• Drug eruptions	
Miscellaneous	
• Granuloma annulare	• Morphoea

Fig. 29.49 Pyoderma gangrenosum. This young patient had Crohn's disease. Note the cribriform pattern of re-epithelialisation, which is characteristic of this condition.

dressings are important. Systemic treatment with glucocorticoids, dapsone, ciclosporin or other immunosuppressants is often required. Tetracyclines may be added for their anti-inflammatory effects. Treatment with TNF-α inhibitors and ustekinumab may be effective in severe recalcitrant PG. Once healing has taken place, recurrences are typically only intermittent.

Other neutrophilic dermatoses

These include Sweet's acute febrile neutrophilic dermatosis and the neutrophilic dermatosis of rheumatoid disease, which are characterised by intense inflammation, mainly consisting of neutrophils, around dermal blood vessels. There can be damage to vessels ('vasculopathy') but usually no frank vasculitis.

Pressure sores

Localised, prolonged, pressure-induced ischaemia can lead to the development of pressure sores, which can occur in up to 30% of the hospitalised elderly. They are associated with considerable morbidity, mortality and expense to health services. The main risk factors are immobility, poor nutrition, local tissue hypoxia – for example, with anaemia, peripheral vascular disease, diabetes, sepsis and skin atrophy – or barrier impairment, such as in eczema.

A localised area of erythema develops at sites of bony prominences (particularly sacrum, greater trochanter, ischial and calcaneal tuberosities, and lateral malleolus). This progresses to a blister and then erosion, which will develop into a deep necrotic ulcer, usually colonised by *Pseudomonas aeruginosa* if pressure is not alleviated.

Prevention is key and involves identification of at-risk patients and regular repositioning and use of pressure-relieving mattresses. Predisposing factors, such as anaemia and poor nutrition, should be corrected. Once established, significant infection must be treated and necrotic tissue debrided. Dressings encourage granulation, although surgical intervention may sometimes be needed.

Fig. 29.50 Scarring inflammatory alopecia. This patient had systemic lupus erythematosus and additional cutaneous features of scarring inflammatory discoid lupus erythematosus.

Connective tissue disease

Lupus erythematosus

This autoimmune disorder can be subdivided into systemic lupus erythematosus (SLE) and cutaneous lupus, which includes discoid lupus erythematosus (DLE) and subacute cutaneous lupus erythematosus (SCLE). The features of SLE are discussed on page 1035. Drug-induced DLE and SCLE should always be considered (see Box 24.78, p. 1057, and Boxes 29.34 and 29.35 below). DLE typically presents as scaly red plaques with follicular plugging, usually on photo-exposed sites of the face, head and neck, which resolve with scarring and pigmentary change. If the scalp is involved, scarring alopecia usually occurs (Fig. 29.50). Most patients with DLE do not develop SLE. Patients with SCLE may have extensive cutaneous involvement, usually aggravated by sun exposure, with an annular, polycyclic or papulosquamous eruption. Systemic involvement is uncommon and the prognosis usually good. There is a strong association with antibodies to Ro/SS-A antigen. A diagnosis of cutaneous lupus is confirmed by histopathology and direct immunofluorescence. Cutaneous lupus may respond to topical glucocorticoids, antimalarials or immunosuppressants. Antimalarials and photoprotection are important mainstays in the management of cutaneous lupus, and systemic immunosuppression may be required for resistant disease. Paradoxically, low-dose UVA1 phototherapy can be effective for lupus.

Systemic sclerosis

This autoimmune multisystem disease presents with severe Raynaud's syndrome, digital ulcers and skin fibrosis. Dilated nail-fold capillaries and ragged cuticles are frequent. The clinical features and management are described on page 1037.

Morphoea

Morphoea is a localised cutaneous form of scleroderma that can affect any site at any age. It usually presents as a thickened

violaceous plaque, which may become hyper- or hypopigmented. Plaques can become generalised. Linear forms exist and, if in the scalp, are associated with scarring hair loss (en coup de sabre). There is usually no systemic involvement. Topical glucocorticoids or immunosuppressants or phototherapy, particularly PUVA or UVA1, can be effective, and systemic immunosuppression may be used for resistant extensive disease.

Dermatomyositis

Dermatomyositis is a multisystem disease, predominantly affecting skin, muscles and blood vessels. Typical cutaneous features include a violaceous 'heliotrope' erythema periorbitally and involving the upper eyelids, but this can sometimes affect the upper trunk, shoulders ('shawl sign') and limbs. Linear erythematous streaks may also be observed on the back of hands and fingers, and papules over the knuckles (Gottron's papules). Tortuous dilated nail-fold capillaries, often best seen with a dermatoscope, and ragged cuticles are usually evident. Photo-aggravation of the cutaneous features is often prominent (see Fig. 29.46A, p. 1260). The clinical features and management are described on page 1039.

Granulomatous disease

Granuloma annulare

This is common and may be reactive, although a trigger is usually not apparent. The hallmark is the presence of dermal granulomas, which are usually palisading and associated with alteration of dermal collagen (necrobiosis). The condition is generally asymptomatic and may present as an isolated dermal lesion with a raised papular annular edge, or may be more generalised. An association between generalised disease and diabetes has been proposed but not confirmed. Lesions often resolve spontaneously. Intralesional glucocorticoids or cryotherapy can be used for localised disease, and UVB or UVA1 phototherapy or PUVA for generalised disease.

Necrobiosis lipoidica

This condition has some histological features in common with granuloma annulare, although necrobiosis predominates. The lesion has a characteristic yellow, waxy, atrophic appearance, often with violaceous edge (Fig. 29.51). Underlying blood vessels are easily seen because of tissue atrophy. Necrobiosis lipoidica typically appears on the shins and is prone to ulceration after trauma. There is a strong association with diabetes: most patients with necrobiosis lipoidica have or develop diabetes, although less than 1% of diabetic patients develop necrobiosis lipoidica. Treatment is difficult and includes very potent topical or intralesional glucocorticoids, topical calcineurin inhibitors, PUVA or UVA1 phototherapy and systemic immunosuppression.

Fig. 29.51 Necrobiosis lipoidica. Atrophic yellow plaques with violaceous edges, on the shins of a patient with diabetes mellitus.

Sarcoidosis

This condition is characterised by the presence of non-caseating granulomas. The cause is unknown, although infectious and genetic factors have been proposed. It is usually a multisystem disease (p. 608), with skin lesions in about one-third of patients. Cutaneous features can occur in isolation and include violaceous infiltrated dermal plaques and nodules, which can affect any site but particularly digits and nose (lupus pernio), more generalised hyper- or hypopigmented or annular papules and plaques, infiltrative changes in scars and erythema nodosum (see Fig. 17.59, p. 609). It has been reported more commonly and may be more severe in those of African, African American or Indian ancestry. Investigation is described on page 609. Cutaneous disease may respond to topical or intralesional glucocorticoids, cryotherapy, UVA1, laser or PDT (pp. 1226–1228). Clinical features and management of systemic disease are discussed on pages 608 and 610.

Cutaneous Crohn's disease

Cutaneous Crohn's disease (p. 813) is rare but may present as perianal and peristomal infiltrative plaques, lymphoedema, sinuses or fistulae, and oral granulomatous disease. These changes are termed 'metastatic' Crohn's and histology shows non-caseating granulomas. Reactive skin changes can also occur in the form of erythema nodosum and pyoderma gangrenosum (pp. 1265 and 1261). Treatment is of the underlying disease (p. 820).

Porphyrias

The porphyrias (described on p. 378) are a diverse group of diseases, caused by reduced or absent activity of specific enzymes in the porphyrin–haem biosynthetic pathway. Due to this loss of enzyme activity, porphyrin precursors proximal to the implicated enzyme step accumulate. If the accumulated porphyrins absorb visible light, then there will be skin features and photosensitivity, which explains why some porphyrias have skin features (porphyria cutanea tarda) and others do not (acute intermittent porphyria; p. 379). The most common skin presentations are photo-exposed site blistering, skin fragility and pain on daylight exposure.

Cutaneous porphyrias: fragility and blisters

Although porphyria cutanea tarda (PCT) may be genetically inherited, this is uncommon and acquired PCT is the most common porphyria worldwide. It is caused by an underlying chronic liver disease, in association with hepatic iron overload. The liver disease is often only diagnosed through investigation of the

Fig. 29.52 Porphyria cutanea tarda. Skin fragility, blistering, scarring, milia and hypertrichosis on the back of hands and fingers in hepatitis C.

skin presentation and it is thus an important diagnosis not to miss. Typical features are increased skin fragility, blistering, erosions, hypertrichosis, scarring and milia occurring on light-exposed areas, particularly the backs of the hands (Fig. 29.52). Less common features include facial hypertrichosis, hyperpigmentation and morphoea-like changes. Variegate porphyria (VP) and hereditary coproporphyria (HCP) may be indistinguishable on skin features and it is important to make the correct diagnosis, as acute neurovisceral attacks, which may be drug-induced (p. 1265), can occur in VP and HCP but not in PCT. Pseudoporphyria may also be impossible to distinguish from PCT on clinical grounds but is most frequently caused by a drug (commonly naproxen; see Box 29.35) or by sunbed use; on investigation, porphyrins are normal. A PCT-like presentation may also be seen in uraemia due to renal failure, but is caused by raised porphyrins due to impaired elimination rather than an enzyme defect.

Management of PCT requires removal or treatment of any underlying cause, which may involve venesection, iron chelation, very low-dose hydroxychloroquine once or twice per week and photoprotection.

Cutaneous porphyria: pain on sun exposure

Erythropoietic protoporphyria is caused by a genetic defect in the ferrochelatase gene that leads to ferrochelatase enzyme deficiency. It is an important diagnosis to consider. The presentation is usually in early childhood, although the diagnosis is often delayed. In part this is because, although the baby or child cries due to immediate pain on sunlight exposure, physical signs are often absent or minimal and thus a link with sunlight may not always be considered. The deficient ferrochelatase activity leads to accumulation of lipid-soluble protoporphyrins in the skin, explaining the photosensitivity manifest as pain on daylight exposure. Multiple pigment gallstones, anaemia (usually only problematic if considered to be due to iron deficiency) and, rarely, severe liver disease can occur, which may be fatal and requires liver transplantation. In addition to photoprotection, UVB phototherapy may be effective for the symptoms of photosensitivity and, more recently, the use of alpha-melanocyte-stimulating hormone (α-MSH) analogues has been explored.

Abnormal deposition disorders

Xanthomas

Deposits of fatty material in the skin, subcutaneous fat and tendons may be the first clue to primary or secondary hyperlipidaemia (pp. 346 and p. 373).

Amyloidosis

Cutaneous amyloid may present as periocular plaques in primary systemic amyloidosis (p. 81) and amyloid associated with multiple myeloma, but is uncommon in systemic amyloidosis secondary to rheumatoid arthritis or other chronic inflammatory diseases. Amyloid infiltration of blood vessels may manifest as 'pinch purpura' following skin trauma. Macular amyloid is more common in darker skin types and appears as pruritic grey/brown macules or patches, usually on the back. Potent topical glucocorticoids can be beneficial, although it is often treatment-resistant.

Genetic disorders

Neurofibromatosis

This is described in detail on page 1131.

Tuberous sclerosis

This is an autosomal dominant condition and two genetic loci have been identified: *TSC-1* (chromosome 9) encoding hamartin, and *TSC-2* (chromosome 16) encoding tuberin. The hallmark is hamartomas in many systems. The classic triad of clinical features comprises learning disability, epilepsy and skin lesions but there is marked heterogeneity in clinical features. Skin changes include pale oval (ash leaf) macules that occur in early childhood; yellowish/pink papules in the mid-face (angiofibromas, 'adenoma sebaceum'), occurring in adolescence; periungual and subungual fibromas; and connective tissue naevi (shagreen patches, often on lower back). Gum hyperplasia, retinal phakomas (fibrous overgrowths), renal, lung and heart tumours, cerebral gliomas and calcified basal ganglia may also occur.

Reactive disorders

Erythema multiforme

Erythema multiforme has characteristic clinical and histological features and can be triggered by a variety of factors (Box 29.32) but a cause is not always identified. The disease is likely to have an immunological basis. Lesions are multiple, erythematous, annular, targetoid 'bull's eyes' (Fig. 29.53) and may blister. Stevens–Johnson syndrome (pp. 1224 and 1254) is a severe form of erythema multiforme with marked blistering, mucosal involvement (mouth, eyes and genitals) and systemic upset.

Identification and removal/treatment of any trigger are essential. Analgesia and topical glucocorticoids may provide symptomatic relief. Supportive care is required in Stevens–Johnson syndrome, including ophthalmology input.

i 29.32 Provoking factors in erythema multiforme

Infections

- Viral: herpes simplex, orf, infectious mononucleosis, hepatitis B, HIV
- *Mycoplasma* and other bacterial infections

Drugs

- Sulphonamides, penicillins, barbiturates and carbamazepine

Systemic disease

- Sarcoidosis, malignancy, systemic lupus erythematosus

Other

- Radiotherapy, pregnancy

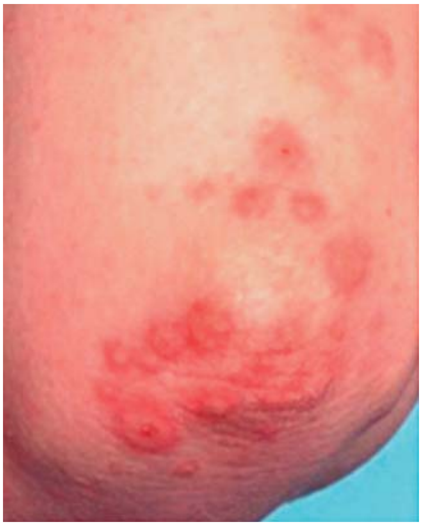

Fig. 29.53 Erythema multiforme in a young woman. Herpes simplex virus infection was the trigger.

29.33 Provoking factors in erythema nodosum

Infections
- Bacteria: streptococci, mycobacteria, *Brucella*, *Mycoplasma*, *Rickettsia*, *Chlamydia*
- Viruses: hepatitis B and infectious mononucleosis
- Fungi

Drugs
- Sulphonamides, sulphonylureas, oral contraceptives

Systemic disease
- Sarcoidosis, inflammatory bowel disease, malignancy

Other
- Pregnancy

Erythema nodosum

This is characterised histologically by a septal panniculitis of subcutaneous fat (see Fig. 17.59, p. 609). An identified trigger is often present (Box 29.33). Lesions are typically painful, indurated violaceous nodules on the shins and lower legs. Systemic upset, arthralgias and fever are common. Spontaneous resolution occurs over a month or so, leaving bruise-like marks. Any underlying cause should be identified and removed or treated. Bed rest, leg elevation and an oral NSAID frequently offer symptomatic relief. Systemic glucocorticoids are effective but seldom required, and must be avoided when there is a possibility of infection. Potassium iodide, dapsone or hydroxychloroquine may be effective for resistant disease but these are rarely required.

Acquired reactive perforating dermatosis

The hallmark of this condition is transepidermal elimination of dermal material, particularly collagen and elastic tissue. It presents as keratotic papules, particularly in patients with diabetes and chronic renal disease. Treatment with topical glucocorticoids, retinoids, PUVA or UVA1 therapy may help. There are other related perforating dermopathies, with characteristic histology.

Annular erythemas

This group of chronic, poorly defined, annular, erythematous and often scaly eruptions can be further subdivided and may be secondary to an identifiable cause. Erythema chronicum migrans can be associated with Lyme disease (*Borrelia burgdorferi*, p. 255). Erythema marginatum can occur in rheumatic fever (p. 515) or Still's disease (p. 1040). Erythema gyratum repens typically presents as concentric circles of erythema and scale with an advancing edge and is usually associated with underlying malignancy. Erythema annulare centrifugum presents with expanding, scaly, erythematous rings, with central fading. A trigger may not be apparent but possible associations include fungal infection, drugs, autoimmune or endocrine diseases, such as lupus or thyroid disease, and malignancy, particularly haematological. An underlying trigger must be sought and removed or treated. Topical glucocorticoids or phototherapy may be helpful for chronic disease.

Acanthosis nigricans

Hyperkeratosis and pigmentation are typical and affected sites have a velvety texture. The flexures, especially axillae and, in dark-skinned people, sides of neck, are involved (pp. 1325, 1326 and 720). There are several types, mainly associated with insulin resistance. Most often, acanthosis nigricans is found in conjunction with obesity and regresses with weight loss. It can be associated with malignancy, usually adenocarcinoma (particularly gastric), when it is usually more extensive and pruritic, and can involve mucous membranes.

Drug eruptions

Virtually all drugs may have cutaneous adverse effects (Fig. 29.54) and this should be considered in the differential diagnosis of most presentations of skin disease. Drugs can exert their adverse effects via several mechanisms, which can be broadly subdivided into non-immunological and immunological (Box 29.34).

29.34 Types of drug eruption

Non-immunological

Predictable
- Striae due to glucocorticoids (see Fig. 29.10, p. 1226)
- Asteatosis with statins
- Candidal infections with antibiotics
- Worsening of psoriasis with lithium, β-blockers, antimalarials, NSAIDs
- Urticaria with aspirin due to mast cell degranulation
- Bradykinin-mediated angioedema due to ACE inhibitors
- Doxycycline photosensitivity
- Dapsone haemolysis

Immunological

Unpredictable
- Immediate IgE-mediated hypersensitivity (type I): penicillin-induced urticaria and anaphylaxis
- Antibody-mediated (type II): penicillin-induced haemolysis
- Immune complex-mediated (type III): drug-induced serum sickness or vasculitis
- Delayed hypersensitivity (type IV): drug-induced erythema multiforme, lichenoid or pemphigus-like reaction; drug-induced lupus

(ACE = angiotensin-converting enzyme; IgE = immunoglobulin E; NSAIDs = non-steroidal anti-inflammatory drugs)

29.35 Clinical patterns of drug eruptions

Reaction pattern	Clinical features	Examples of causative drugs
Exanthematous	Erythema, maculopapular	Antibiotics (especially ampicillin), anticonvulsants, gold, penicillamine, NSAIDs, carbimazole, anti-TNF drugs and other biological therapies
Urticaria and angioedema	Sometimes accompanied by angioedema Angioedema alone	Salicylates, opiates, NSAIDs, antibiotics, dextran, ACE inhibitors
Lichenoid	Violaceous, lichen planus-like, dyspigmentation	Gold, penicillamine, antimalarials, thiazides, NSAIDs, β-blockers, ACE inhibitors, sulphonamides, lithium, sulphonylureas, proton pump inhibitors, quinine, antituberculous, dyes in colour developers
Purpura and vasculitis	Palpable purpura and necrosis	Allopurinol, antibiotics, ACE inhibitors, NSAIDs, aspirin, anticonvulsants, diuretics, oral contraceptives
Erythema multiforme	Target-like lesions and bullae on extensor aspects of limbs	See Box 29.32, p. 1264
Erythema nodosum	Tender, painful, dusky, erythematous nodules on shins	See Box 29.33, p. 1265
Exfoliative dermatitis	There may be erythroderma	Allopurinol, carbamazepine, barbiturates, penicillins, PAS, isoniazid, gold, lithium, penicillamine, ACE inhibitors
Toxic epidermal necrolysis	Rapid evolution, extensive blistering, erythema, necrolysis, mucosal involvement	Anticonvulsants, antibiotics, especially sulphonamides, NSAIDs, terbinafine, sulphonylureas, antiretrovirals, allopurinol
Photosensitivity (p. 1220)	Photo-exposed site rash, may be sunburn-like, exfoliation, lichenoid	Thiazides, amiodarone, quinine, NSAIDs, tetracyclines, fluoroquinolones, phenothiazines, sulphonamides, retinoids, psoralens
Drug-induced lupus	Photosensitivity, discoid lesions, urticarial or erythema multiforme-like. May have positive lupus serology and anti-histone antibodies	Allopurinol, thiazides, ACE inhibitors, PAS, anticonvulsants, β-blockers, gold, hydralazine, minocycline, penicillamine, lithium, proton pump inhibitors
Psoriasiform rash	Rash resembles psoriasis	See Box 29.23 (p. 1248)
DRESS	Facial oedema, fever, extensive rash, lymphadenopathy, eosinophilia and systemic involvement	Anticonvulsants, trimethoprim, minocycline, allopurinol, dapsone, terbinafine
AGEP/toxic pustuloderma	Rapid onset of sterile, non-follicular pustules on erythematous base	Ampicillin/amoxicillin, erythromycin, quinolones, sulphonamides, terbinafine, diltiazem, hydroxychloroquine
Acneiform eruptions	Rash resembles acne	Lithium, anticonvulsants, oral contraceptives, androgens, glucocorticoids, antituberculous drugs, EGFR antagonists (cetuximab and erlotinib)
Pigmentation		See Box 29.29 (p. 1258)
Bullous eruptions	Often at pressure sites and there may be other features, such as purpura, milia	Barbiturates, penicillamine, furosemide
Pseudoporphyria	May be indistinguishable from porphyria cutanea tarda clinically	NSAIDs, tetracyclines, retinoids, furosemide, nalidixic acid
Exacerbation of acute hepatic porphyrias		See page 1263 Always check all drugs for safety of use in porphyrias against standard guidelines
Drug-induced immunobullous disease	May resemble pemphigoid, pemphigus, dermatomyositis, scleroderma, epidermolysis bullosa acquisita	Penicillamine, ACE inhibitors, vancomycin
Fixed drug eruptions	Round/oval, erythema, oedema ± bullae Same site every time drug is given Pigmentation on resolution	Tetracyclines, sulphonamides, penicillins, quinine, NSAIDs, barbiturates, anticonvulsants
Hair loss	Diffuse	Cytotoxic agents, oral retinoids, anticoagulants, anticonvulsants, antithyroid drugs, lithium, oral contraceptives, infliximab
Hypertrichosis	Excessive hair growth in non-androgenic distribution	Diazoxide, minoxidil, ciclosporin

(ACE = angiotensin-converting enzyme; AGEP = acute generalised exanthematous pustulosis; DRESS = drug rash with eosinophilia and systemic symptoms; EGFR = epidermal growth factor receptor; NSAIDs = non-steroidal anti-inflammatory drugs; PAS = para-aminosalicylic acid; TNF = tumour necrosis factor)

Fig. 29.54 Drug eruption. Possible drug causes of rash should always be considered. This was doxycycline-induced photosensitivity in a farmer.

Clinical features

Cutaneous drug reactions typically present in specific patterns (Box 29.35). Non-immunologically mediated reactions can theoretically occur in anyone, given sufficient exposure to the drug, although idiosyncratic factors, such as genetic predisposition, may render some more susceptible. There is limited information on genetic determinants of drug responses and adverse effects, although advances have been made, e.g. with azathioprine (p. 1227), and provide exciting opportunities for therapeutic personalised medicine. Immunologically mediated cutaneous drug eruptions typically commence within days to weeks of starting the drug. Detailed history-taking relating to prescribed and non-prescribed medications is essential and there may be other clues (Box 29.36).

Investigations and management

The suspected drug must be stopped. If drug-induced photosensitivity is considered, the patient should be phototested while on the drug to confirm the diagnosis, and again after drug withdrawal to confirm resolution of photosensitivity (p. 1215). An eosinophilia and abnormalities in liver function tests may occur in adverse drug reactions and, for example, specific IgE to penicillin may be raised in penicillin-induced rash but, otherwise, specific investigations are not available. Rechallenge with drug is not usually undertaken unless the reaction is mild, as this can be risky. Drug withdrawal may not be straightforward and substitute drugs may be required. Antihistamines and/or topical or systemic glucocorticoids may provide supportive management, depending on the type of cutaneous reaction. The management of anaphylaxis is described on page 76.

i 29.36 Diagnostic clues to drug eruptions

- Past history of reaction to suspected drug
- Introduction of suspected drug a few days to weeks before onset of rash
- Recent prescription of a drug commonly associated with rashes (penicillin, sulphonamide, thiazide, allopurinol)
- Symmetrical eruption that fits with a well-recognised pattern, caused by a current drug
- Resolution of rash following drug cessation

Major physiological changes occur during pregnancy, which impact on several organ systems. These are necessary to support the growing fetus, to prepare for delivery and to support lactation. These changes can adversely affect the activity and progression of many pre-existing medical conditions. Emphasising this fact, information from the UK Confidential Enquiry into Maternal Deaths has revealed that over recent years, two-thirds of maternal deaths occur as the result of pre-existing medical conditions, rather than from obstetric causes. The most common causes of death were cardiac conditions (23%), pneumonia and influenza (14%), and venous thromboembolism (11%). Although some diseases can undergo remission during pregnancy, others can worsen, potentially jeopardising the health and well-being of the mother and fetus. In this chapter, we review the physiological changes that occur during pregnancy and the impact of pregnancy on the diagnosis, clinical course and management of common medical conditions. In addition, we review the pathogenesis and management of several medical conditions specific to pregnancy.

Planning pregnancy in patients with medical conditions

Patients with pre-existing medical conditions require careful counselling when planning a pregnancy to make them aware of the risks that pregnancy might pose, as well as the changes in symptoms that might be expected to occur during pregnancy. Although each disease is different, as is discussed later in this chapter, the general principles are to ensure that drugs that may be fetotoxic are stopped before pregnancy is attempted; that high-risk patients are kept under close surveillance during their pregnancy; and that new symptoms that emerge during pregnancy are treated seriously and fully investigated where appropriate.

Functional anatomy and physiology

The most important changes that occur in the anatomy and physiology of major organ systems during pregnancy are discussed below.

Bone metabolism

Major changes in bone metabolism take place to meet the demands of the growing fetus. Intestinal calcium absorption increases, due in part to increased production of 1,25-dihydroxyvitamin D ($1,25(OH)_2D$). Calcium is also released from the maternal skeleton due to increased bone resorption, stimulated by production of parathyroid hormone-related protein (PTHrP) by breast and placenta. This results in loss of bone from the maternal skeleton during pregnancy that continues until lactation ceases and then recovers. Serum concentrations of alkaline phosphatase (ALP) can increase by up to fourfold but this is due to release of ALP from the placenta rather than bone.

Cardiovascular system

Heart rate and stroke volume increase during pregnancy; when combined with peripheral vasodilatation and a reduction in systemic blood pressure, this causes a hyperdynamic circulatory state and an increase in cardiac output. Diaphragmatic elevation may affect the electrocardiogram (ECG), causing left axis deviation of up to 15°. Other changes include T-wave inversion in leads III and aVF, ST depression, small Q waves and a sinus tachycardia. Supraventricular and ventricular beats are common. Echocardiography shows a modest increase in the dimensions of the cardiac chambers.

Endocrine system

During early pregnancy there is secretion of human chorionic gonadotrophin (hCG) by trophoblast cells, which act on the corpus luteum in the ovary to stimulate oestradiol and progesterone production (Fig. 30.1). Levels of hCG rise rapidly during early pregnancy to reach a peak around 8 weeks, and then fall before stabilising at a lower level from 20 weeks until term. There is a progressive rise in oestradiol and progesterone levels; initially, these hormones are produced by the corpus luteum but placental production takes over after about 12 weeks. The high levels of gonadal hormones suppress pituitary gonadotrophin production but prolactin levels rise about 10-fold and there is an increase in volume of the anterior pituitary. Serum levels of free T_4 increase during the first trimester but, paradoxically, thyroid-stimulating hormone (TSH) levels fall by almost 50%. This is because hCG is homologous to TSH and mimics the effect of TSH on the thyroid, stimulating both T_3 and T_4 production. The raised levels of T_3 and T_4 feed back to the pituitary and reduce TSH secretion. Later in pregnancy, there is increased degradation of thyroxine by the placenta and levels of thyroxine-binding globulin (TBG) rise, causing the normal range for free T_4 and T_3 to fall progressively during the course of pregnancy. Although TSH levels are difficult to interpret early in pregnancy, they provide the best measure of thyroid function after about 16 weeks' gestation.

Gastrointestinal system

The high levels of progesterone during pregnancy lead to relaxation of smooth muscle in the gastrointestinal tract. This causes the lower oesophageal sphincter to relax, predisposing to gastro-oesophageal reflux and reduced gastrointestinal transit; this in turn leads to delayed gastric emptying and constipation.

Genitourinary system

Glomerular filtration rate (GFR) increases during pregnancy due to an increased cardiac output. By the second trimester, renal perfusion increases by up to 80% and GFR by 50%, leading to a fall in serum urea and creatinine. Mild glycosuria may be observed during normal pregnancy due mainly to an increase in filtered load of glucose. The ureters and renal pelvis are slightly dilated, most prominently on the left side, leading to the physiological hydronephrosis of pregnancy.

Glucose metabolism

Maternal glucose metabolism changes during pregnancy to optimise delivery of glucose and other nutrients to the fetus. During the second half of pregnancy in particular, there is maternal insulin resistance due largely to an increase in circulating levels of human placental lactogen (hPL) (Fig. 30.1). The net effect is to ensure that glucose is preferentially supplied to the fetus rather than the mother. Following delivery of the placenta, there is a rapid decline in hPL and reversal of insulin resistance. During pregnancy, fasting plasma glucose decreases slightly, while post-prandial blood glucose may increase. Glycosuria may occur, even in women who do not have diabetes, due to the

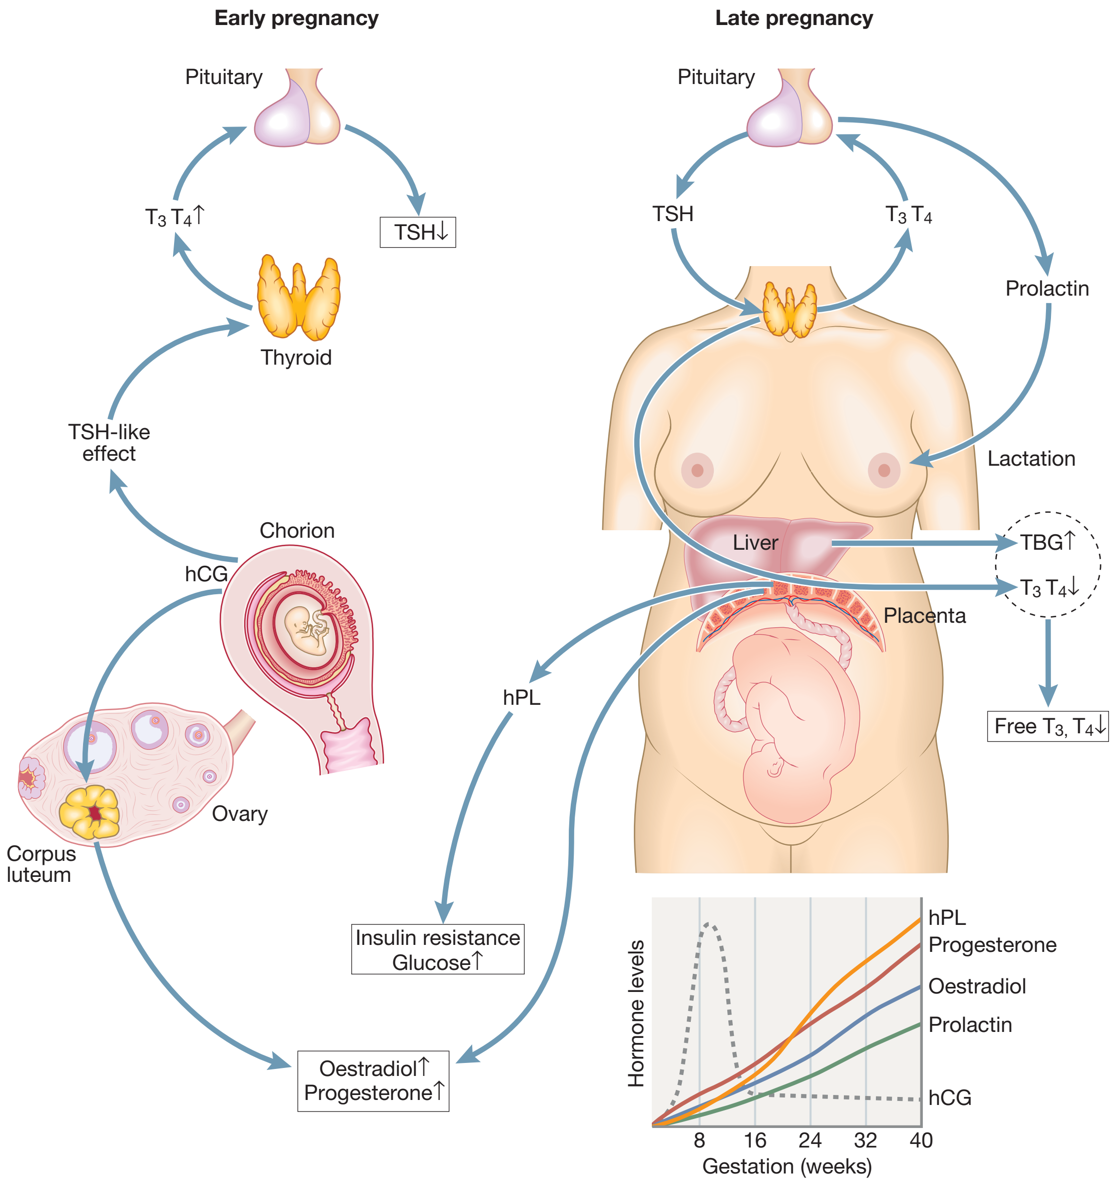

Fig. 30.1 Hormonal changes in pregnancy. In early pregnancy, oestradiol and progesterone are mainly derived from the corpus luteum in response to human chorionic gonadotrophin (hCG), secreted by the trophoblast. The raised levels of hCG also act on the thyroid to stimulate T_3 (triiodothyronine) and T_4 (thyroxine) production, which in turn suppresses thyroid-stimulating hormone (TSH) production by the pituitary. Later in pregnancy, oestradiol and progesterone are derived from the placenta, which also produces human placental lactogen (hPL), impairing glucose tolerance. There is a progressive reduction of free T_3 and T_4 during pregnancy as the result of T_3 and T_4 degradation by the placenta and increased secretion of thyroxine-binding globulin (TBG) by the liver.

increased GFR. Insulin secretion in the fetus is driven by fetal glucose levels, which in turn are dependent on maternal glucose concentrations. Accordingly, in women with diabetes, maternal hyperglycaemia stimulates fetal insulin secretion, which increases fetal growth, resulting in increased birth weight or macrosomia.

Haematological system

Haemoglobin normally falls by about 20% during pregnancy since plasma volume increases more than red cell volume: the so-called physiological anaemia of pregnancy. The reduction in haematocrit lowers blood viscosity but this is offset by an elevation in levels of several clotting factors, resulting in a hypercoagulable state that increases the risk of venous and arterial thrombosis.

Respiratory system

Tidal volume (TV) increases during pregnancy due to an increased vital capacity and reduced residual volume, and by term the increase in TV is about 200 mL. These changes are required to meet the 20% increase in oxygen demand that occurs during pregnancy. The PCO_2 level decreases but this is offset by an increase in renal excretion of bicarbonate, such that the blood pH remains relatively stable. Respiratory rate is unaffected by pregnancy.

Investigations

The profound changes in physiology and anatomy that occur during pregnancy cause changes in the normal reference ranges for several hormones, electrolytes and other analytes, as summarised in Box 30.1. While many investigations can proceed as normal during pregnancy, invasive procedures should generally be avoided unless the potential benefit clearly outweighs the risk. Investigations that can be performed in pregnancy are shown in Box 30.2.

30.1 Common laboratory changes during pregnancy

Laboratory test	Change	Cause
Haematology		
Haematocrit	Decrease	Extracellular volume expansion
Routine biochemistry		
GFR	Increase	Increased renal blood flow
Urea and creatinine	Decrease	Increased GFR
Alkaline phosphatase	Increase	Release by placenta
Glucose	Decrease (fasting) Increase (post-prandial)	Raised insulin Insulin resistance
Hormones		
T_4	Increase (first trimester) Decrease (later pregnancy)	Stimulation of thyroid by hCG Placental degradation
TSH	Decrease (first trimester)	Increased T_4 due to stimulation of thyroid by hCG
Prolactin	Increase	Increased production by pituitary
Oestradiol Progesterone	Progressive increase	Production by corpus luteum then placenta
hCG	Increase then decrease	Production by trophoblast
hPL	Progressive increase	Production by placenta

(GFR = glomerular filtration rate; hCG = human chorionic gonadotrophin; hPL = human placental lactogen; TSH = thyroid-stimulating hormone)

Imaging

Imaging during pregnancy should be undertaken only when the clinical benefit outweighs the potential risks to mother and fetus. In suspected pulmonary embolus, radionuclide ventilation/perfusion ($\dot{V}/\dot{Q}$) scanning is preferred over computed tomographic pulmonary angiography (CTPA) in women with a normal chest X-ray since $\dot{V}/\dot{Q}$ scans expose the maternal breast and lungs to less radiation than CTPA. However, if the chest X-ray is abnormal, CTPA should be performed, since it is more likely to yield a definitive diagnosis. The radiation exposure for both investigations is well below the maximum recommended fetal radiation dose in pregnancy (5 rad). Chest X-rays may also be performed safely at any gestation during pregnancy if clinically indicated, since the radiation exposure is very low for the fetus. Magnetic resonance imaging (MRI) is safe in the second and third trimesters and is useful in the assessment of proximal deep vein thrombosis (DVT) and neurological disorders. However, gadolinium-containing contrast agents should be used only if absolutely necessary. If gadolinium contrast agents are used in women who are breastfeeding, the milk should be discarded for 24 hours. Ultrasound imaging is safe during pregnancy and useful in the assessment of patients with DVT or intra-abdominal pathology.

Presenting problems in pregnancy

Breathlessness

The causes of breathlessness during pregnancy are summarised in Box 30.3. Many women experience mild breathlessness as part of normal pregnancy, which is known as physiological

30.2 Investigations in pregnancy*

Investigation	Use during pregnancy	Comment
Renal biopsy	Can be performed during pregnancy	<22 weeks is safest; 23–28 weeks is period of highest risk
Gastroscopy	Safe during pregnancy Left lateral position is recommended in the second half of pregnancy	Fetal monitoring should be offered pre- and post-procedure Low-dose sedation recommended
Colonoscopy	Safe during pregnancy	Fetal monitoring should be offered pre- and post-procedure Low-dose sedation recommended
Flexible sigmoidoscopy	Safe during pregnancy	Fetal monitoring should be offered pre- and post-procedure Low-dose sedation recommended
Magnetic resonance imaging	Not contraindicated at any gestation	Theoretical risks to fetus in first trimester
Computed tomography	Can be performed at any gestation	Radiation exposure to fetus and mother must be considered and addressed in counselling
X-ray	Safe at any gestation	
Ultrasound	Safe at any gestation	
Echocardiogram	Safe at any gestation	
Ambulatory electrocardiogram	Safe at any gestation	

*For any investigation, the potential benefit must outweigh the risk.

30.3 Breathlessness during pregnancy

Cause	Management
Physiological breathlessness of pregnancy	No treatment required
Asthma	Treatment as in non-pregnant women
Pneumonia	Treatment with antibiotic as in non-pregnant women
Valvular heart disease	Treatment as in non-pregnant women
Heart failure	Treatment as in non-pregnant women
Peripartum cardiomyopathy (PPCM)	Treatment as in non-pregnant women Early delivery if haemodynamic deterioration
Pulmonary embolus	Treatment as in non-pregnant women

breathlessness of pregnancy. It is thought to be progesterone-mediated and is classically of gradual onset and present at rest and on exercise. Physiological breathlessness does not require investigation but severe or persistent breathlessness should be investigated, especially if accompanied by chest pain. The diagnostic approach in pregnant patients with suspected pulmonary embolism differs from that in non-pregnant women. Measurement of D-dimer is not helpful since values normally increase progressively throughout pregnancy. Accordingly, the first-line investigation in suspected pulmonary embolism is a $\dot{V}/\dot{Q}$ scan in a patient with a normal chest X-ray and CTPA in a patient with an abnormal chest X-ray.

Chest pain

Chest pain does not occur during normal pregnancy but the incidences of acute coronary syndrome (ACS) and aortic dissection are both increased. Accordingly, if a pregnant woman develops acute severe chest pain suggestive of either of these conditions, she should be investigated and treated in the same way as a non-pregnant woman.

Circulatory collapse

The differential diagnosis of circulatory collapse is wide and causes unrelated to pregnancy are discussed on page 199. Obstetric causes include pulmonary embolism, haemorrhage and amniotic fluid embolism (AFE). AFE usually presents with collapse and profound shock during delivery or immediately afterwards, often with profound and early coagulopathy. It can be difficult to differentiate AFE from other causes of maternal collapse, and the diagnosis is clinical when other causes of collapse have been excluded. Management is supportive, with oxygenation, careful fluid balance and, in some cases, correction of coagulopathies, ventilatory support and vasopressors.

Another important cause of circulatory collapse is obstetric haemorrhage, which can be divided into ante-partum and post-partum subtypes. Ante-partum haemorrhage is defined as bleeding from the vagina after 24 weeks' gestation. Primary post-partum haemorrhage is defined as occurring in the first 24 hours after delivery, and secondary post-partum haemorrhage after 24 hours. Haemorrhage may be concealed, and physiological changes such as hypotension, tachycardia and tachypnoea may be late signs. Management is supportive with administration of blood, intravenous fluids and oxygen. Patients with post-partum haemorrhage may also benefit from uterotonic agents such as oxytocin. If the bleeding fails to settle, surgical intervention or interventional radiology may be required.

Headache

Migraine and tension headache may occur during pregnancy and should be assessed along the usual lines, as described on page 1095. Important causes of headache that are specific to pregnancy are pre-eclampsia, which should be suspected in patients with hypertension, oedema and proteinuria, and cerebral venous thrombosis, which should be suspected when there is a neurological deficit or seizures.

Nausea and vomiting

Nausea and vomiting are common during the first trimester of pregnancy and do not usually require any specific investigation or treatment. Other causes of nausea and vomiting are summarised in Box 30.4. Severe vomiting with significant weight loss and/or electrolyte disturbance suggests hyperemesis gravidarum, which is discussed in more detail on page 1277.

30.4 Differential diagnosis of severe nausea and vomiting in pregnancy

Gastrointestinal
- Peptic ulcer disease
- Gastroenteritis
- Appendicitis
- Pancreatitis

Endocrine and metabolic
- Thyrotoxicosis
- Addison's disease
- Hyperparathyroidism
- Diabetic ketoacidosis

Neurological
- Space-occupying lesion
- Migraine

Pregnancy-associated conditions
- Molar pregnancy
- Acute fatty liver of pregnancy
- Hyperemesis gravidarum

Genitourinary
- Urinary tract infection

Psychological
- Bulimia nervosa

Cardiovascular
- Myocardial infarction

Oedema

A mild degree of ankle oedema can occur in normal pregnancy but significant oedema raises suspicion of pre-eclampsia. This should be considered in patients who are also hypertensive and those with proteinuria. Further details are on page 1276.

Seizures

The causes and management of seizures during pregnancy are summarised in Box 30.5. An important cause is eclampsia, which should be borne in mind in patients with no previous history of seizures and accompanying features such as hypertension,

30.5 Causes of seizures during pregnancy

Cause	Management
Epilepsy	Similar to that in non-pregnant women Avoid valproate
Eclampsia	Antihypertensives Magnesium sulphate Careful fluid balance
Hypoglycaemia	Glucose
Hyponatraemia	Saline infusion
Alcohol withdrawal	Supportive treatment
Drugs	Supportive treatment
Stroke	As in non-pregnant women
Cerebral venous thrombosis	Low-molecular-weight heparin
Thrombotic thrombocytopenic purpura	Plasma exchange Immunosuppressives

oedema and proteinuria. Seizures can also occur secondary to electrolyte disturbances associated with hyperemesis gravidarum or hypoglycaemia. Other disorders that are more common during pregnancy and can present with seizures include cerebral venous thrombosis and thrombotic thrombocytopenic purpura (TTP).

Medical disorders in pregnancy

Many disorders present specific management problems before pregnancy, during pregnancy and in the puerperium; the most important of these are discussed in more detail below.

Hypertension

Hypertension is one of the most common medical problems during pregnancy, occurring in about 10–15% of women. The causes and classification are summarised in Box 30.6.

Pre-existing hypertension

If hypertension is discovered during the first half of pregnancy, it usually indicates that there was pre-existing hypertension. This is most likely to be due to essential hypertension but secondary causes also need to be considered. Hypertension during pregnancy should be managed with vasodilators or methyldopa (Box 30.7), taking care to avoid hypotension, which can cause placental hypoperfusion and increase the risk of fetal growth restriction, stillbirth and miscarriage. Angiotensin-converting enzyme (ACE) inhibitors should be stopped in hypertensive women who are planning to become pregnant and should be avoided during pregnancy since they have fetotoxic effects. Diuretics should also be avoided unless there is heart failure, as they can reduce circulating volume and cause placental hypoperfusion.

Gestational hypertension

Gestational hypertension usually presents in the second half of pregnancy and most often resolves by 3 months post-partum. It should be managed actively with one of the drugs listed in Box 30.7, to reduce the risk of progression to pre-eclampsia.

30.6 Classification of hypertension during pregnancy

Hypertension	Definition
Hypertension in pregnancy	Blood pressure ≥140/90 mmHg on two separate occasions, at least 4 hrs apart
Pre-existing hypertension	Hypertension prior to pregnancy or occurring before 20 weeks' gestation
Gestational hypertension	Hypertension occurring after 20 weeks' gestation without proteinuria or any other features of pre-eclampsia
Pre-eclampsia	Hypertension occurring after 20 weeks' gestation with proteinuria, maternal organ dysfunction or uteroplacental dysfunction
Eclampsia	Generalised seizures in a pregnant woman previously diagnosed with pre-eclampsia
White coat hypertension	Hypertension that only occurs in a clinical environment

Adapted from Tranquilli AL, Dekker G, Magee L, et al. The classification, diagnosis and management of the hypertensive disorders of pregnancy: a revised statement from the ISSHP. Pregnancy Hypertens 2014; 4:97–104.

30.7 Drug treatment of hypertension during pregnancy

Medication	Mechanism of action
Labetalol	α- and β-receptor blocker
Nifedipine **Amlodipine**	Calcium channel blockers
Methyldopa	Central action
Doxazosin	α-receptor blocker

Pre-eclampsia and eclampsia

Pre-eclampsia is a disorder of vascular endothelial dysfunction that affects about 10% of all pregnancies worldwide. The risk factors for pre-eclampsia are shown in Box 30.8 and the clinical features illustrated in Figure 30.2. Management includes control of blood pressure, administration of magnesium sulphate as prophylaxis against seizures, correction of coagulation abnormalities and monitoring of fluid balance. If pre-eclampsia occurs early in pregnancy, medical management should be initiated with the aim of controlling the condition and maintaining the fetus in utero as long as possible. If these measures are ineffective and eclampsia supervenes (see below), then urgent delivery should be considered, provided the fetus is viable, since this results in an immediate cure.

30.8 Risk factors for pre-eclampsia

- Previous history of pre-eclampsia
- Multiple pregnancy
- Primiparity
- Genetic predisposition
- Obesity
- Increased maternal age
- Pre-existing medical conditions:
  - Chronic kidney disease
  - Hypertension
  - Diabetes mellitus
  - Systemic lupus erythematosus and connective tissue disease

Adapted from Duckitt K, Harrington D. Risk factors for pre-eclampsia at antenatal booking: systematic review of controlled studies. BMJ 2005; 330:565–567.

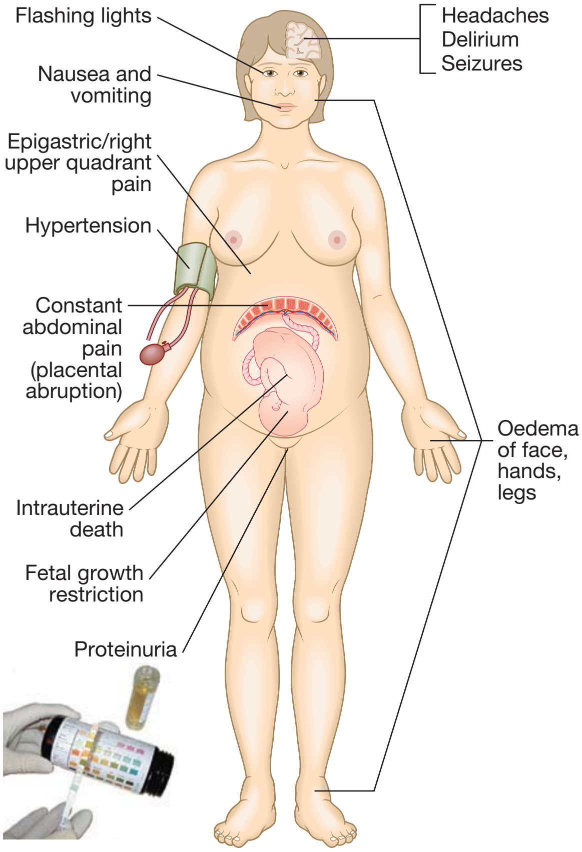

Fig. 30.2 Symptoms and signs of pre-eclampsia.

Eclampsia occurs in about 1% of pregnancies and is associated with significant mortality. It usually presents with seizures on a background of pre-eclampsia but rarely can occur before the onset of hypertension and proteinuria. Treatment is with intravenous magnesium sulphate and delivery of the fetus as soon as possible. Women with pre-eclampsia are more likely to develop hypertension, chronic kidney disease, and cerebrovascular and ischaemic heart disease in later life.

Respiratory disease

Asthma

Women with asthma should be managed aggressively during pregnancy, since poorly controlled asthma is associated with pre-eclampsia, fetal growth restriction, low birth weight and pre-term birth. The management is very similar to that in non-pregnant individuals. Short-acting and long-acting β-agonists, inhaled and oral glucocorticoids and theophylline can be used freely. There is less experience with leukotriene receptor agonists during pregnancy but they can be given if necessary. It is advisable to involve an anaesthetist or intensivist at an early stage in patients with severe exacerbations of asthma since airway management is more difficult in late pregnancy.

Respiratory infection

The most common causes of pneumonia during pregnancy are summarised in Box 30.9. Diagnosis and management are broadly the same as in non-pregnant patients. Prompt treatment of infections is important since mothers with pneumonia are more likely to deliver early and have low-birth-weight infants compared with healthy pregnant women.

i 30.9 Causes of pneumonia during pregnancy

Bacterial	
• *Streptococcus pneumoniae*	• *Haemophilus influenzae*
• *Mycoplasma pneumoniae*	• *Staphylococcus aureus*
• *Legionella*	
Viral	
• Influenza viruses	• Varicella zoster

Adapted from Lim W, Macfarlane J, Colthorpe C. Pneumonia in pregnancy. Thorax 2001; 56:398–405.

Bacterial infections

Antibiotics should be given, depending on the causal organism and sensitivities, along with supplemental oxygen and fluids as required. Penicillins, cephalosporins and macrolides such as erythromycin are all safe during pregnancy but tetracyclines should be avoided because they may be embryotoxic and can cause staining of the teeth in the fetus (see Box 6.19, p. 120).

Viral infections

Viral pneumonia is more common and often more severe during pregnancy. Varicella zoster pneumonia in particular is associated with a high fetal and maternal mortality rate. It presents with cough, breathlessness and pyrexia, and is usually preceded by a vesicular rash up to 1 week before. Varicella infection can be diagnosed clinically, with laboratory confirmation by culture or polymerase chain reaction (PCR) of fluid from vesicles, or by serology. Varicella pneumonia causes an interstitial pneumonitis with a characteristic nodular appearance on chest X-ray (p. 1270). Women with confirmed varicella zoster pneumonia should be admitted to hospital for supportive care and treatment with intravenous aciclovir for 7–10 days.

Tuberculosis

Tuberculosis (TB) may occur during pregnancy and in the UK is more common among African and Asian women. Untreated TB is associated with premature delivery and low birth weight. Transmission to the fetus can occur but is unusual. If the diagnosis of TB is confirmed, then antituberculous chemotherapy should be given as normal, since the benefit of treating TB in pregnancy outweighs any potential risks from the medication. A proportion of pregnant women with TB have coexisting human immunodeficiency virus (HIV) infection, which confers a poorer prognosis and also requires treatment with antiretroviral therapy, as described on page 318.

Gastrointestinal disease

Hyperemesis gravidarum

Hyperemesis gravidarum is a serious condition that affects about 0.5% of pregnant women. It typically presents during the first trimester with severe nausea, vomiting and other clinical features (Box 30.10). It is associated with significant morbidity and mortality, due to malnutrition and electrolyte imbalance. Wernicke's encephalopathy may develop as the result of thiamin deficiency. Recurrence is common in successive pregnancies.

i 30.10 Clinical features of hyperemesis gravidarum

- Weight loss of >5%
- Severe nausea and vomiting
- Dehydration
- Ketosis
- Electrolyte imbalance:
  - Hyponatraemia
  - Hypokalaemia
  - Hypomagnesaemia

The cause is unknown and the diagnosis is one of exclusion, since alternative causes of severe nausea and vomiting need to be ruled out, particularly if the onset of symptoms occurs after the first trimester. Management is with lifestyle advice and support, intravenous fluids, electrolyte replacement and antiemetics. Thiamin and glucocorticoids may be required in the most severe cases.

Inflammatory bowel disease

Women with inflammatory bowel disease (IBD) should be counselled prior to planning a pregnancy. Medications such as azathioprine, sulfasalazine, 5-aminosalicylic acid (5-ASA), glucocorticoids and tumour necrosis factor alpha (TNF-α) inhibitors can be continued as normal during pregnancy but methotrexate must be stopped at least 3 months before conception because of its teratogenic effects. Since poorly controlled IBD is associated with an increased risk of pre-term birth, low birth weight and miscarriage, it is important for the disease to be well controlled before conception. The activity of IBD can increase during pregnancy and ulcerative colitis is more likely to flare than Crohn's disease. Women who experience disease flares should be managed by both medical and obstetric teams, and monitored closely. The TNF-α inhibitors infliximab and adalimumab are actively transported across the placenta in the third trimester and there is theoretical concern about immunosuppression in the neonate. Infants of mothers who have been treated with TNF-α inhibitors during the second and third trimesters should not be given live vaccines and should be monitored closely for any signs of infection. Most women with uncomplicated IBD can have a normal vaginal delivery and do not need a caesarean section, but the need for this should be assessed on an individual basis by obstetric and medical teams.

Diabetes

It is important to institute meticulous glucose control in pregnancy, as maternal diabetes is associated with increased risks of congenital malformations, stillbirth, pre-eclampsia, pre-term delivery, operative delivery, neonatal hypoglycaemia and admission to neonatal intensive care.

Gestational diabetes

Gestational diabetes is defined as diabetes with first onset or recognition during pregnancy. This definition will include a few patients who develop type 1 diabetes during pregnancy, where prompt action and early insulin treatment will be required, and some patients who develop type 2 diabetes, or had unknown pre-existing type 2 diabetes, in whom the diabetes does not remit after pregnancy. However, in most cases, gestational diabetes develops due to an inability to increase insulin secretion adequately to compensate for pregnancy-induced insulin resistance, and most women can expect to return to normal glucose tolerance immediately after pregnancy. Risk factors for gestational diabetes are shown in Box 30.11.

i 30.11 Risk factors for gestational diabetes

- Body mass index >30 kg/m^2
- Previous macrosomic baby weighing ≥4.5 kg
- Previous gestational diabetes
- Family history of diabetes (first-degree relative with diabetes)
- Family origin with a high prevalence of diabetes:
  - South Asian (specifically women whose country of family origin is India, Pakistan or Bangladesh)
  - Black Caribbean
  - Middle Eastern

The diagnosis of gestational diabetes is based on maternal blood glucose measurements that are associated with increased fetal growth. An international consensus recommended that glucose values diagnostic of gestational diabetes should be lower than those for non-gestational diabetes (see Box 20.31, p. 753). Controversy remains about who should be screened, and the screening strategy depends, in part, on the population risk. It is widely accepted that women at high risk for gestational diabetes should have an oral glucose tolerance test at 24–28 weeks, and some guidelines recommend that all high-risk women should be screened by measuring HbA_{1c}, fasting blood glucose or random blood glucose at the first booking visit. It should be noted that measurements of HbA_{1c} cannot reliably be used to diagnose diabetes in early pregnancy and until 3 months post-partum, since HbA_{1c} levels fall due to increased red cell turnover.

Management

The aim is to normalise maternal blood glucose concentrations and reduce the risk of excessive fetal growth. The first element of management is dietary modification, in particular by reducing consumption of refined carbohydrate. Women with gestational diabetes should undertake regular pre- and post-prandial self-monitoring of blood glucose, aiming for pre-meal blood glucose levels of <5.3 mmol/L (96 mg/dL) and a 1-hour post-prandial level of <7.8 mmol/L (142 mg/dL) or a 2-hour post-prandial level of <6.0 mmol/L (109 mg/dL). If pharmacological treatment is necessary, metformin, glibenclamide or insulin can all be used. Glibenclamide should be used rather than other sulphonylureas because it does not cross the placenta. Other oral therapies or injectable incretin-based therapies should not be given in pregnancy.

After delivery, maternal glucose usually returns to pre-pregnancy levels. In the UK, it is currently recommended that women with gestational diabetes should have a fasting blood glucose measured at 6 weeks post-partum and have HbA_{1c} concentrations measured annually to screen for the development of diabetes. This is because even those whose glucose tolerance returns to normal post-partum are at increased risk for developing type 2 diabetes, with a 5-year risk between 15 and 50%, depending on the population. Therefore, all women who have had gestational diabetes should be given diet and lifestyle advice to reduce their risk of developing type 2 diabetes (p. 743).

Pregnancy in women with established diabetes

Maternal hyperglycaemia early in pregnancy (during the first 6 weeks post conception) can adversely affect fetal development, causing cardiac, renal and skeletal malformations, of which the caudal regression syndrome (abnormal development of the lower

part of the spine) is the most characteristic. The risk of fetal abnormalities is about 2% for non-diabetic women and about 4% for women with well-controlled diabetes (HbA_{1c} <53 mmol/mol) but more than 20% for those with poor glycaemic control (HbA_{1c} >97 mmol/mol). Therefore, it is important for women with diabetes to aim to achieve good glycaemic control before becoming pregnant. In addition, high-dose folic acid (5 mg daily, rather than the usual 400 μg) should be initiated before conception to reduce the risk of neural tube defects.

As for gestational diabetes, mothers should attempt to maintain near-normal blood glucose levels while avoiding hypoglycaemia throughout their pregnancy, as this minimises excessive fetal growth and neonatal hypoglycaemia. This is often difficult to achieve, however. Pregnancy is also associated with an increased risk of ketosis, particularly, but not exclusively, in women with type 1 diabetes. Ketoacidosis during pregnancy is dangerous for the mother and is associated with a high rate (10–35%) of fetal mortality.

Pregnancy is linked with a worsening of diabetic complications, most notably retinopathy and nephropathy, so careful monitoring of eyes and kidneys is required throughout pregnancy. If heavy proteinuria and/or renal dysfunction exist prior to pregnancy, there is a marked increase in the risk of pre-eclampsia, and renal function can deteriorate irreversibly during pregnancy. These risks need to be carefully discussed before a woman with diabetes is considering pregnancy. The outlook for mother and child has been vastly improved over recent years but pregnancy outcomes are still not equivalent to those of non-diabetic mothers. Perinatal mortality rates remain 3–4 times those of the non-diabetic population (at around 30–40 per 1000 pregnancies) and the rate of congenital malformation is increased 5–6-fold.

Endocrine disease

Thyroid disease

Iodine deficiency

Iodine deficiency is a major public health issue in many countries, particularly in South-east Asia, the Western Pacific and Central Africa. Severe iodine deficiency in pregnancy is associated with miscarriage, stillbirth and cretinism, with significant cognitive impairment, gait abnormalities and deafness in the affected child. More moderate iodine deficiency is associated with milder forms of cognitive impairment and affects millions of people. The World Health Organisation recommends a daily iodine intake of 250 μg/day for pregnant women. Treatment of iodine deficiency in the first and second trimesters can prevent impaired cognitive development but is less effective if started in the third trimester.

Hypothyroidism

Untreated hypothyroidism is associated with subfertility and so is uncommon in pregnancy. Subclinical hypothyroidism is more common, and is often due to poor adherence to levothyroxine in known primary hypothyroidism. Most pregnant women with primary hypothyroidism require an increase in the dose of levothyroxine of approximately 25–50 μg daily to maintain normal TSH levels because there is an increased requirement for thyroxine during pregnancy. Furthermore, inadequately treated maternal hypothyroidism may be associated with impaired brain development in the fetus. Because of this, hypothyroid women should be monitored closely if planning a pregnancy; they should be advised to have their thyroid function checked as soon as possible after conception and increase their daily levothyroxine dose if necessary. During pregnancy, serum TSH and free T_4 should be measured during each trimester and the dose of levothyroxine adjusted to maintain a normal TSH level. Rarely, hypothyroidism may present during pregnancy with weight gain, constipation and lethargy. The diagnosis is easily missed since these symptoms are common in normal pregnancy. If suspected, the diagnosis can be confirmed by checking thyroid function tests, which show a raised TSH and low free T_4.

Hyperthyroidism

The coexistence of pregnancy and thyrotoxicosis is unusual, since anovulatory cycles are common in thyrotoxic patients and autoimmune disease tends to remit during pregnancy, due to suppression of the maternal immune response. Thyroid function tests must be interpreted in the knowledge that thyroid-binding globulin, and hence total T_4 and T_3 levels, are increased in pregnancy and that the normal range for TSH is lower (see Box 18.18, p. 651). Despite this, a fully suppressed TSH is usually indicative of Graves' disease. When thyroid disease during pregnancy is being dealt with, both mother and fetus must be considered, since maternal thyroid hormones, TSH receptor antibodies (TRAb) and antithyroid drugs can all cross the placenta to some degree, exposing the fetus to the risks of thyrotoxicosis, iatrogenic hypothyroidism and goitre. Moreover, poorly controlled thyrotoxicosis can result in fetal tachycardia, intrauterine growth retardation, prematurity, stillbirth and possibly even congenital malformations.

Antithyroid drugs are the treatment of first choice for thyrotoxicosis in pregnancy. Newly diagnosed hyperthyroidism during pregnancy can be treated with β-adrenoceptor antagonists (β-blockers) in the short term, followed by antithyroid drugs. Propylthiouracil (PTU) is the preferred antithyroid drug because treatment with carbimazole during the first trimester has been associated with the occurrence of choanal atresia and aplasia cutis. Hyperthyroid women who become pregnant while taking carbimazole or PTU should be advised to continue their current drug in pregnancy, with close monitoring. Both carbimazole and PTU cross the placenta and are effective in treating thyrotoxicosis in the fetus caused by transplacental passage of TRAb. To avoid fetal hypothyroidism, which can affect brain development and cause goitre, it is important to use the smallest dose of antithyroid drug (typically <150 mg PTU or 15 mg carbimazole per day) that will maintain maternal free T_4, T_3 and TSH concentrations within their respective reference ranges. Thyroid surgery is sometimes necessary because of poor drug adherence, drug hypersensitivity or failure of medical treatment and is most safely performed during the second trimester. Radioactive iodine is absolutely contraindicated throughout pregnancy, as it invariably induces fetal hypothyroidism. Frequent review of mother and fetus (monitoring heart rate and growth) is important during pregnancy and in the puerperium. Serum TRAb levels can be measured in the third trimester to predict the likelihood of neonatal thyrotoxicosis. PTU is the drug of choice in the breastfeeding mother, as it is excreted in the milk to a much lesser extent than carbimazole. Thyroid function should be monitored periodically in the breastfed child.

Post-partum thyroiditis

Post-partum thyroiditis typically presents 3–4 months after delivery. It is discussed in more detail on page 647.

Pituitary disease

Prolactinoma

Prolactinomas are the most common pituitary tumours in young women. Although fertility is reduced in patients with prolactinoma, pregnancies can occur and if this happens the tumour may enlarge as part of the physiological pituitary enlargement that takes place during normal pregnancy. Macroprolactinomas (≥10 mm) are at greater risk of enlarging and may cause optic chiasm compression. If women known to have a prolactinoma become pregnant, they should have visual field testing each trimester, followed by pituitary imaging by MRI if enlargement is suspected from changes in visual fields or from symptoms. Measurement of serum prolactin is generally not helpful, since levels increase anyway as part of normal pregnancy. Dopamine receptor agonists such as cabergoline and bromocriptine should normally be stopped during pregnancy, but can be reintroduced if necessary in patients with an enlarging prolactinoma that is threatening the visual fields.

Diabetes insipidus

Women with pre-existing diabetes insipidus may find that their symptoms worsen in pregnancy due to placental production of vasopressinase, a protease that degrades vasopressin (antidiuretic hormone, ADH). Because of this, pregnant women with diabetes insipidus may need higher doses of desmopressin until delivery. The development of symptoms suggestive of diabetes insipidus, such as thirst and polyuria, during pregnancy should raise suspicion of acute fatty liver of pregnancy (AFLP), the syndrome of haemolysis, elevated liver enzymes and low platelets (HELLP) or pre-eclampsia, as all of these conditions are also associated with decreased breakdown of vasopressinase by the liver.

Sheehan's syndrome

This is a form of post-partum hypopituitarism caused by infarction of the pituitary, usually associated with hypotension from major post-partum haemorrhage. It can present with failure to establish lactation after birth, amenorrhoea or other features of hypopituitarism. The diagnosis can be confirmed by tests of pituitary function and treated with hormone replacement, as described on page 682.

Parathyroid disease

Primary hyperparathyroidism

Primary hyperparathyroidism (PHPT) is uncommon in women of child-bearing age, but if pregnancy does occur in a patient with pre-existing PHPT, careful monitoring is required. Women with mild disease can be managed conservatively but if serum calcium levels rise above 2.85 mmol/L (11.5 mg/dL), consideration should be given to parathyroidectomy, as fetal mortality is high (up to 40%) in patients with severe hypercalcaemia. If parathyroidectomy is required, it should ideally be performed during the second trimester. Anecdotal evidence suggests that the calcimimetic drug cinacalcet can be used for medical management of PHPT during pregnancy.

Familial hypocalciuric hypercalcaemia

Familial hypocalciuric hypercalcaemia (FHH) is a benign disorder caused by mutations in the calcium-sensing receptor, which is described on page 664. Although FHH poses no risk for pregnant women, the hypercalcemia can suppress PTH secretion in neonates that do not inherit the FHH mutation, resulting in severe hypocalcaemia. Infants of mothers with FHH should have their serum calcium levels monitored during the first few days of life; if hypocalcaemia is detected, intravenous calcium should be given.

Adrenal disease

Women with known adrenal insufficiency can continue their glucocorticoid and mineralocorticoid replacement during pregnancy as normal. Rarely, adrenal insufficiency can present for the first time during pregnancy. If this occurs, the diagnosis is challenging because total cortisol normally increases during pregnancy, and short Synacthen tests (p. 672) can be falsely normal. Specialist assessment is required. In women with Conn's syndrome who become pregnant, amiloride should be substituted for spironolactone to prevent anti-androgenic effects on a male fetus.

Human immunodeficiency virus infection

The course of HIV disease is not altered by pregnancy but treatment with antiretroviral therapy should be given during pregnancy to women that are HIV-positive, as outlined on page 326. In some societies, routine HIV testing is recommended at an early stage in pregnancy in all women.

Inflammatory rheumatic disease

Most women with inflammatory rheumatic disorders have successful pregnancies but it is critically important for them to be given pre-conception counselling and to review medication use, optimise disease control and make them aware of the risks that pregnancy might pose to their condition and vice versa.

Rheumatoid arthritis

Women with rheumatoid arthritis should have a medication review; methotrexate, leflunomide and mycophenolate should be stopped and, if necessary, an alternative substituted before conception (Box 30.12). Rheumatoid arthritis often improves during pregnancy, particularly in those who are negative for rheumatoid factor or anti-cyclic citrullinated peptide antibodies. There is an increased risk of pre-eclampsia, pre-term birth and small babies for women with active disease, emphasising the importance of maintaining disease control during pregnancy. Glucocorticoids, hydrochloroquine, azathioprine and sulfasalazine can all be continued as normal but non-steroidal anti-inflammatory drugs (NSAIDs) should be avoided after 20 weeks (Box 30.12). Inhibitors of TNF-α are safe during pregnancy and can be continued if necessary to maintain control of the disease. Most TNF-α inhibitors are actively transported across the placenta and this can lead to immunosuppression in the neonate if these drugs are used during the second and third trimesters. An exception is certolizumab, which is a pegylated antibody, and this is a good option for women who require TNF-α inhibition during pregnancy. Experience with other biological therapies during pregnancy is limited. Disease flares are common in the post-partum period, regardless of serology, and this can pose a problem for breastfeeding and care of the infant. Glucocorticoids are a good short-term option to control such flares, pending reintroduction of other disease-modifying antirheumatic drugs (DMARDs) that might have been stopped prior to pregnancy.

Systemic sclerosis

Pregnancy in women with diffuse systemic sclerosis (SSc), those with pulmonary hypertension or renal involvement and those with disease of recent onset (<4 years) poses risks to mother and

30.12 Safety of antirheumatic drugs during pregnancy and breastfeeding

Drug	Safe during pregnancy	Safe during breastfeeding	Comment
Non-steroidal anti-inflammatory drugs (NSAIDs)	Yes (<20 weeks)	Yes	
Hydroxychloroquine	Yes	Yes	
Glucocorticoids	Yes	Yes	A good short-term option for disease flares
Azathioprine	Yes	Yes	
Sulfasalazine	Yes	Yes	Co-prescribe with folic acid
Ciclosporin	Yes	Yes	Data on breastfeeding limited
Tacrolimus	Yes	Yes	
Mycophenolate	No	No	Stop before planning pregnancy
Methotrexate	No	No	Stop 3 months before planning pregnancy
Leflunomide	No	No	Stop 2 years before planning pregnancy
Cyclophosphamide	No	No	
Tumour necrosis factor (TNF) inhibitors	Yes	Yes	Avoid live vaccines in the neonate for 6 months

Adapted from Ateka-Barrutia O, Nelson-Piercy C. Connective tissue disease in pregnancy. Clin Med 2013; 131:580–584.

30.13 Systemic sclerosis (SSc) and pregnancy

Subtype	Effect of disease on pregnancy
Localised SSc	Good prognosis Raynaud's may improve Oesophagitis may worsen
CREST syndrome	Good prognosis Raynaud's may improve Oesophagitis may worsen
Diffuse SSc	Increased risk of: Pre-term delivery Pre-eclampsia Fetal growth restriction Low-birth-weight babies Maternal and fetal mortality

(CREST = calcinosis, Raynaud's phenomenon, oesophageal involvement, sclerodactyly and telangiectasia)

fetus. In milder forms of the disease, however, the prognosis is better (Box 30.13). Raynaud's phenomenon often improves during pregnancy due to vasodilatation but oesophageal symptoms may worsen. Renal crises are no more frequent during pregnancy, but if one occurs, ACE inhibitors should be given. Although these are normally contraindicated in pregnancy, the potential benefit in this situation outweighs the risk to the fetus. Glucocorticoids, which can be given to promote fetal lung maturation in premature babies, should be avoided in women with SSc where possible because they may provoke renal crisis.

Systemic lupus erythematosus

Pregnancy in women with systemic lupus erythematosus (SLE) poses several risks to both mother and fetus, especially if there is renal involvement. There is an increased risk of pre-eclampsia, thrombosis, fetal growth restriction, pre-term delivery, miscarriage and fetal death. There is also a higher risk of lupus flare during the puerperium. Good control of disease is paramount, since women with SLE who conceive when their disease has been quiescent for at least 6 months are less likely to have complications than

30.14 Differential diagnosis of lupus flare during pregnancy

Clinical finding	Lupus flare	Pre-eclampsia	Normal pregnancy
Hypertension	Yes	Yes	No
Proteinuria	Yes	Yes	No
Red cells/casts in urine	Yes	No	No
Liver function tests	Normal	Abnormal	Normal
Anti-double-stranded DNA	Increase	Unchanged	Unchanged
C3 and C4	Low	Elevated or unchanged from baseline	Unchanged

those who conceive when their disease has recently been active. It can be difficult to assess disease activity during pregnancy because symptoms such as oedema, hair loss, joint pain and fatigue, which occur in active SLE, are also common during normal pregnancies. The features in Box 30.14 can help differentiate between an SLE flare, normal pregnancy and pre-eclampsia.

All women with SLE should be tested for anti-Ro and anti-La antibodies, since they can cross the placenta and cause neonatal complete heart block or cutaneous lupus, respectively. Medications should be reviewed prior to pregnancy, to ensure they are safe, and an alternative substituted if necessary (see Box 30.12). The management of patients with antiphospholipid antibodies (aPL) is described below.

30

Anti-phospholipid syndrome

Primary antiphospholipid syndrome (APS) is associated with an increased risk of adverse pregnancy outcomes, including thrombosis, miscarriage, fetal death and pre-eclampsia. This applies to primary APS and that associated with connective tissue diseases such as SLE. During pregnancy, women with APS should be managed with low-dose aspirin in combination with low-molecular-weight heparin (LMWH).

Cardiac disease

Congenital heart disease

Women who have a history of surgically corrected congenital heart disease generally tolerate pregnancy well, but are more likely to have babies with congenital heart disease and should be offered fetal cardiac scans. Acyanotic heart diseases, such as atrial septal defect, ventricular septal defect and patent ductus arteriosus, all have a good prognosis in pregnancy. Unrepaired cyanotic heart disease has a very poor prognosis in pregnancy, as does pulmonary hypertension, regardless of the underlying cause. Women with mechanical heart valves require anticoagulation throughout pregnancy but their anticoagulation should be planned with consideration of substituting warfarin with LMWH and aspirin during the first trimester to reduce the risk of warfarin embryopathy. If necessary, warfarin can be used during pregnancy, particularly in the second and third trimesters.

Valvular heart disease

The physiological changes of pregnancy may also unmask previously undiagnosed valvular disease. Women with regurgitant lesions, such as mitral regurgitation and aortic regurgitation, tolerate pregnancy better than those with stenotic lesions. Mitral stenosis causes a reduction in blood flow from the left atrium to left ventricle in diastole, which worsens during pregnancy due to the increased heart rate and hypervolaemia. Those with moderate to severe mitral stenosis (valve area $< 1.5\ cm^2$) are at particular risk and may develop arrhythmias, tachycardia and pulmonary oedema. Most patients can be managed medically with β-blockers, LMWH and furosemide as necessary. Surgical intervention is indicated if there is continued haemodynamic compromise despite optimal medical management.

Myocardial infarction

Pregnancy increases the risk of myocardial infarction. While atherosclerosis is the main cause in non-pregnant individuals, coronary artery dissection and coronary thrombosis secondary to the hypercoagulable state are more common causes during pregnancy. Management is similar to that of non-pregnant women, except that statins and glycoprotein IIb/IIIa inhibitors such as apixaban should be avoided. Clopidogrel can be given but should be stopped around the time of delivery to reduce the risk of uterine bleeding and to allow spinal anaesthesia to be used if necessary. Stenting can be performed, but bare-metal stents are preferred because drug-eluting stents require dual antiplatelet therapy that cannot be continued around the time of delivery.

Aortic dissection

Pregnancy is an independent risk factor for aortic dissection and this should be considered when a woman presents with acute severe chest pain during pregnancy. The vast majority of cases in pregnancy are 'type A', involving the ascending aorta (see Fig. 16.72, p. 506), and require careful control of hypertension, caesarean section to deliver the fetus, and emergency surgery to treat the aneurysm.

Peripartum cardiomyopathy

Peripartum cardiomyopathy (PPCM) presents with heart failure secondary to left ventricular systolic dysfunction towards the end of pregnancy or in the months following delivery. It is a diagnosis of exclusion, made when other causes of heart failure have been ruled out. The cause is unknown but PPCM is more prevalent in women who are older, multiparous, hypertensive and Afro-Caribbean. It is treated by conventional medications for heart failure, including ACE inhibitors if necessary, and delivery of the baby. Many women recover within 3–6 months of diagnosis but the prognosis is variable. There is a significant chance of reduction in cardiac function in subsequent pregnancies.

Dilated cardiomyopathy

Dilated cardiomyopathy carries a poor prognosis if the pre-pregnancy ejection fraction is below 30% or if symptoms are in New York Heart Association grades 3 or 4. Management is as described for PPCM.

Renal disease

Renal tract infection

Pregnancy predisposes women to urinary tract infection. If asymptomatic bacteriuria is discovered during pregnancy, it should be treated promptly with antibiotics, to prevent ascending renal tract infection. Pyelonephritis is more common in pregnancy due to the physiological dilatation of the upper renal tract; if it does occur, it can trigger premature labour.

Acute kidney injury

Acute kidney injury (AKI) may occur during pregnancy or in the puerperium due to a variety of causes (Box 30.15). Women with AKI caused by pre-eclampsia are prone to pulmonary oedema, and need very careful fluid balance to avoid fluid overload. In the post-partum period, AKI may occur as the result of post-partum haemorrhage or pre-eclampsia, and sometimes these occur in combination. Although pre-eclampsia resolves after delivery, AKI can be at its worst in the first few days post-partum, especially when exacerbated by obstetric haemorrhage.

Glomerular disease

Proteinuria caused by glomerular disease is usually exacerbated during pregnancy, and nephrotic syndrome may develop without any alteration in the underlying disease activity in individuals who had only slight proteinuria before pregnancy. This further increases the risk of venous thromboembolism, the leading cause of maternal deaths in developed countries.

Chronic kidney disease

Women with chronic kidney disease (CKD) are at increased risk of pre-eclampsia, fetal growth restriction, miscarriage, pre-term delivery and fetal death (Fig. 30.3). Pregnancy can also cause acceleration of maternal renal decline. The factors that influence pregnancy outcome for women with CKD are baseline renal function, hypertension, degree of proteinuria and the underlying cause of CKD. Women with CKD should have pre-pregnancy counselling, be closely monitored by a multidisciplinary team throughout pregnancy, and be given low-dose aspirin as prophylaxis against pre-eclampsia.

Renal replacement therapy

Fertility is reduced among women on renal replacement therapy and there is increased risk of adverse pregnancy outcomes.

i 30.15 Causes of acute kidney injury in pregnancy

Mechanism	Cause	Features
Pre-renal	Hyperemesis gravidarum	Nausea and vomiting Dehydration Presentation in first trimester
	Post-partum haemorrhage	Vaginal bleeding immediately post-partum
	Placental abruption	Abdominal pain or vaginal bleeding in second or third trimester
	Septic abortion	Presentation with hypotension, shock and pyrexia
Renal	Pre-eclampsia	Presentation in second and third trimesters with new-onset hypertension and proteinuria
	Thrombotic thrombocytopenic purpura	Possible antenatal or post-partum presentation with headache, irritability and drowsiness Haematology shows thrombocytopenia and microangiopathic haemolytic anaemia
	Acute fatty liver of pregnancy	Presentation with vomiting and abdominal pain in third trimester Abnormal liver function tests Liver ultrasound can be normal
	Acute interstitial nephritis	Most common cause is use of non-steroidal anti-inflammatory drugs
Post-renal	Acute urinary retention	Usual presentation is in third trimester due to enlarged uterus causing ureteric obstruction; sometimes presents post-partum

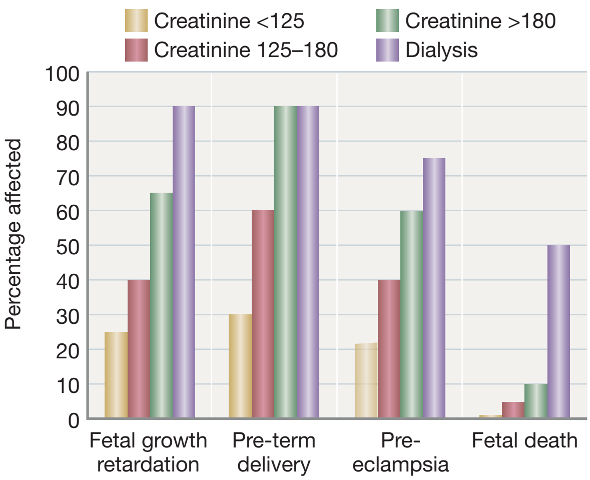

Fig. 30.3 Adverse pregnancy outcomes in chronic kidney disease. Creatinine is in μmol/L. To convert to mg/dL, multiply by 0.011. *Data from Williams D, Davison D. Chronic kidney disease in pregnancy. BMJ 2008; 336:211–115.*

Despite this, many women receiving renal replacement therapy have successful pregnancies. More intensive dialysis is recommended in pregnancy, and particular attention should be paid to addressing issues around blood pressure, fluid balance and anaemia.

Renal transplant recipients

Pregnancy should be delayed for a minimum of 12 months following renal transplantation, to allow the graft to stabilize, on minimum immunosuppressive drugs. The outcome is best for women with a well-functioning graft, with no proteinuria or hypertension. Women with renal transplants can deliver vaginally but in practice there is a higher incidence of caesarean section in this group, due to the higher incidence of pre-term delivery.

Liver disease

Specific causes of liver disease during pregnancy are discussed below.

i 30.16 Criteria for diagnosis of acute fatty liver of pregnancy

- Vomiting
- Abdominal pain
- Polydipsia/polyuria
- Encephalopathy
- Elevated bilirubin (> 14 μmol/L (> 0.82 mg/dL))
- Low glucose (< 4 mmol/L (< 72.4 mg/dL))
- Elevated urate (> 340 μmol/L (> 5.7 mg/dL))
- Leucocytosis (> 11×10^9/L)
- Ascites or bright liver on ultrasound
- Elevated transaminases (alanine/aspartate aminotransferase (ALT/AST) > 42 U/L)
- Elevated ammonia (> 47 μmol/L (> 81.7 mg/dL))
- Renal impairment (creatinine > 150 μmol/L (> 1.7 mg/dL))
- Coagulopathy (prothrombin time > 14 secs or activated partial thromboplastin time > 34 secs)
- Microvascular steatosis on liver biopsy

Acute fatty liver of pregnancy can be diagnosed when ≥6 of the above features are present in the absence of another explanation.

Adapted from Ch'ng CL, Morgan M, Hainsworth I, et al. Prospective study of liver dysfunction in pregnancy in Southwest Wales. Gut 2002; 51:876–880.

Acute fatty liver of pregnancy

Acute fatty liver of pregnancy (AFLP) is a rare and serious condition that typically presents in the third trimester with vomiting, abdominal pain, jaundice and other symptoms (Box 30.16). It is more common in first pregnancies and multiple pregnancies, and is associated with male fetuses. Rarely, fulminant liver failure may occur. The diagnosis can usually be made on the basis of the clinical features, abnormal liver function tests (LFTs) and the appearances of fatty liver on ultrasound. A liver biopsy is rarely needed to make the diagnosis but shows microvascular steatosis. Management is with supportive care and by delivery of the fetus. The development of AFLP has been linked in some cases with an inherited deficiency of the enzyme long-chain acyl-CoA dehydrogenase (LCHAD) in the baby.

HELLP syndrome

The syndrome of haemolysis, elevated liver enzymes and low platelets (HELLP) is thought to be part of the spectrum of pre-eclampsia. It usually presents antenatally but can also appear for the first time in the postnatal period. The presenting symptoms can be the same as those of pre-eclampsia but can also include headache, right upper quadrant pain and visual disturbance. HELLP can be complicated by liver haematoma and capsular rupture. Management involves supportive care, control of hypertension, correction of coagulopathy and delivery of the fetus.

Obstetric cholestasis

Obstetric cholestasis is estimated to affect about 1% of pregnancies in Caucasians, although the prevalence is higher in Chinese and South Asian populations. The cause is incompletely understood but the condition is thought to be due in part to the cholestatic effect of high oestrogen levels. The typical presentation is in the third trimester with pruritus, particularly affecting the soles and palms. Laboratory testing reveals raised levels of bile acids and abnormal LFTs. The diagnosis can be made on the basis of these clinical features when other causes of liver dysfunction and pruritus have been excluded. Treatment is with ursodeoxycholic acid in a starting dose of 250 mg twice daily, which usually improves symptoms and liver function. Aqueous cream with menthol can also be effective in soothing pruritus. There is an increased risk of fetal mortality with evidence of a particularly high risk when bile acid levels are over 40 μmol/L (97.9 μg/mL). Treatment therefore aims to bring bile acids below 40 μmol/L and some centres induce labour before 40 weeks in an effort to reduce the risk. The risk of recurrence in future pregnancies is high.

Viral hepatitis

The course of hepatitis B is unchanged in pregnancy, but it is important to identify women who have active infection to reduce the risk of vertical transmission to the fetus; this risk is up to 90% in women who are hepatitis B e-antigen positive. Vaccinations and immunoglobulin should be given to infants of mothers who test positive for hepatitis B, and antiviral agents should be given to the mother after delivery. Vertical transmission rates of hepatitis C are low in the absence of HIV infection and so no action is required for the infant, unless there is co-infection with HIV; in this case, antiviral drugs should be considered. Pregnant women are at greater risk of contracting hepatitis E than the non-pregnant population. It is transferred via the faeco-oral route, and is usually a mild self-limiting illness outside of pregnancy. However, it can cause fulminant hepatic failure in up to 20% of pregnant women.

Neurological disease

Epilepsy

Women with epilepsy should have pre-pregnancy counselling and should be advised to take high-dose folic acid from pre-conception; their antiepileptic drugs (AEDs) should also be reviewed. Maternal treatment with sodium valproate is associated with a higher rate of fetal malformations than other AEDs, and a reduction in intelligence quotient and an increased risk of autistic spectrum disorder in the offspring. Where possible, sodium valproate should be substituted for another AED with a better safety profile in pregnancy, such as lamotrigine, levetiracetam or carbamazepine. While pregnancy does not generally affect the frequency of seizures in women with well-controlled epilepsy, those who enter pregnancy with poorly controlled epilepsy are likely to deteriorate. The plasma levels of some AEDs such as lamotrigine can fall in pregnancy and checking drug levels can be helpful. Seizures are more common at the time of delivery and women should be advised to deliver in a unit staffed with personnel able to manage this.

Idiopathic intracranial hypertension

Idiopathic intracranial hypertension (IIH) may worsen during pregnancy due to weight gain. Treatment with acetazolamide can be continued during pregnancy but should be avoided in the first trimester due to lack of safety data. The mode of delivery is not affected by IIH and spinal analgesia can be given as normal.

Migraine

Migraine often improves during pregnancy but if attacks occur they should be managed with simple analgesia and antiemetics. If necessary, prophylaxis can be given with aspirin, β-blockers or tricyclic antidepressants. Safety data on use of triptans during pregnancy are limited but reassuring. Triptans can therefore be used for the treatment of migraine if other therapies are ineffective.

Stroke

Stroke is twice as common in pregnant women as in non-pregnant women of the same age. The risk is highest during the third trimester and puerperium. The management of stroke during pregnancy is similar to that in non-pregnant patients. The risk of cerebral venous thrombosis is greatly increased during pregnancy. The presentation is with headache, seizures and neurological deficits such as hemiparesis. If the diagnosis is suspected, neuroimaging should be performed with MRI or CT venography. Management of acute infarct should be as for the non-pregnant patient and include consideration of thrombolysis.

Psychiatric disorders

Mood changes are common during pregnancy but more severe psychiatric disorders, such as depression or psychosis, typically present within 2–4 weeks of delivery. These disorders are discussed in more detail on page 1206 and in Box 28.33.

Haematological disease

Anaemia

The causes of anaemia during pregnancy are summarised in Box 30.17. Iron deficiency anaemia is most commonly due to a 20% increased demand for iron. In most cases, it responds well to oral iron supplementation, with a rise in haemoglobin of approximately 0.8 g/L per week. If the haemoglobin does not rise following a 4-week trial of iron supplementation, alternative causes of anaemia should be considered. Non-adherence to oral iron is common and intravenous iron should be considered in women with iron deficiency and failure of oral treatment. It is generally not necessary to investigate iron deficiency anaemia during pregnancy unless there is clinical evidence of gastrointestinal blood loss, which should be investigated in the normal way.

30.17 Causes of anaemia in pregnancy

Microcytic	
• Iron deficiency • Haemoglobinopathies	• Thalassaemia
Normocytic	
• Anaemia of chronic disease • Haemorrhage	• Haemolysis
Macrocytic	
• Vitamin B_{12}/folate deficiency • Liver disease	• Alcohol excess

Rhesus disease

Women who are negative for the Rhesus antigen should be offered treatment with anti-RhD immunoglobulin around the time of delivery to reduce the risk of haemolytic disease of the newborn. More details are provided on page 933 and in Box 23.19.

Thrombocytopenia

The causes of thrombocytopenia during pregnancy are summarised in Box 30.18. The most common cause is gestational thrombocytopenia, which typically occurs towards the end of pregnancy and resolves spontaneously after delivery. It is not associated with adverse pregnancy outcomes and requires no specific intervention. Pregnancy may occur in women with pre-existing idiopathic thrombocytopenic purpura (ITP, p. 971). This should be managed with glucocorticoids and/or immunoglobulin, with the aim of maintaining the platelet count above 80×10^9/L at the time of delivery, in case spinal anaesthesia or caesarean section is required. Thrombocytopenia may also occur as a component of haemolytic uraemic syndrome (HUS, p. 408) and thrombotic thrombocytopenic purpura (TTP, p. 979). Both are characterised by microangiopathic haemolytic anaemia, acute kidney injury and thrombocytopenia, but in TTP neurological symptoms and fever also occur. These conditions are rare but important to recognise since up to one-quarter of cases occur during pregnancy and the post-partum period. TTP is managed with plasma exchange, fresh frozen plasma and sometimes glucocorticoids or rituximab. Platelet transfusion should be avoided.

30.18 Causes of thrombocytopenia during pregnancy

- Gestational thrombocytopenia
- Idiopathic thrombocytopenic purpura
- Systemic lupus erythematosus
- HELLP (haemolysis, elevated liver enzymes and low platelets)
- Haemolytic uraemic syndrome
- Thrombotic thrombocytopenic purpura

Venous thromboembolism

The risk of venous thromboembolism (VTE) is 4–5 times higher in pregnancy than in non-pregnant women. DVT is the most common presentation and predominantly affects the left leg in pregnancy, for reasons that are incompletely understood. Doppler ultrasound scan is the investigation of choice, but MRI can also be used if proximal clot is suspected. Measurement of D-dimer is not useful in pregnancy because levels rise as part of normal pregnancy. Treatment of VTE in pregnancy is with LMWH at a higher dose than for the non-pregnant woman, based on the patient's early pregnancy (booking) weight. Women with a previous history of VTE who are receiving warfarin or other oral anticoagulants as prophylaxis should have these stopped prior to conception and LMWH should be substituted.

31 Adolescent and transition medicine

Historically, childhood illnesses were characterised by a series of acute episodes, often infective, on a background of an otherwise healthy patient. Adult medicine traditionally comprised patients with progressive conditions, and increasing pathology with advancing age. A number of factors have led to the recognition that boundaries between adult medicine and paediatric care are not clear-cut, and recent evidence has confirmed that anticipating and carefully planning the transition of children with long-term conditions (LTCs) into adult services improve care and outcomes. About 14% of children in the developed world are diagnosed with an LTC and in the majority of patients the disorder will persist into adulthood. Common illnesses include asthma, epilepsy, congenital heart disease, diabetes and childhood cancer (Box 31.1). Similar trends are developing worldwide, with increasing survival rates of children with complex pathology, and increasing prevalence of lifestyle-related conditions such as obesity, hypertension and type 2 diabetes. Specific factors that make transition planning important in young people with LTCs are outlined in Figure 31.1.

Planning the process of transition from paediatric to adult health services and improving the assessment of young people as they enter those adult services have been shown to impact positively on long-term health outcomes. There is a need for physicians to gain new skills in the care of young people and adults who have conditions that have arisen in childhood. This includes developing specific skills in the management of adolescents and young adults, managing the process of transition and developing knowledge of relevant medical conditions. The overall approach to transition medicine, as well as important disease-specific issues, will be considered in this chapter.

31.1 Important long-term conditions of childhood that affect adult health

Neurology

Transition from paediatric to adult health services

Effectiveness of transition planning

A review of the effectiveness of transition planning has confirmed improved health outcomes when specific interventions to improve coordination between adult and paediatric services are implemented. Most research in this field has been undertaken with young people with diabetes, and many of the outcome measures relate to that condition. The principles of transition planning and the potential benefits are, however, likely to be generalisable to other LTCs that present in childhood. Young people with serious LTCs are among the most complex and high-risk patients to care for in adulthood, and it is important to work closely with them as they move to adult services, to try to improve their long-term outcome.

General principles of transition planning

Paediatric services are organised and delivered in a very different way to adult medical services. They encompass a period of life that spans from infancy to independence, and progress from taking parents' views as paramount to needing to recognise

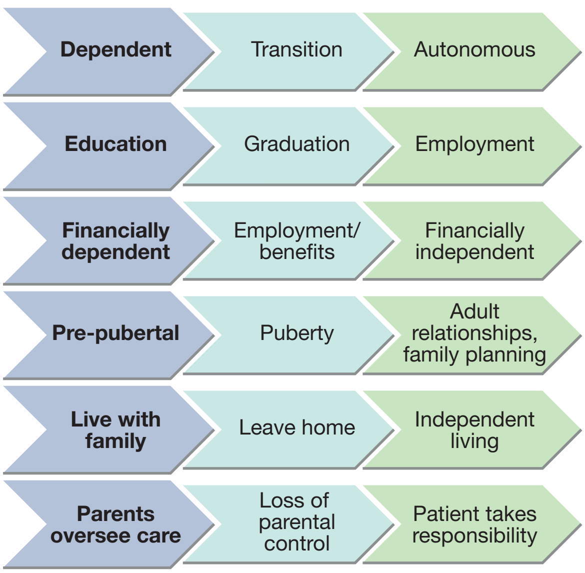

Fig. 31.2 Lifestyle changes during transition to adulthood.

the wishes of the young person. After transition, young people move from medical services that have been family-centred and focused around maximising the child's development, to a service that encourages patient autonomy, in which employment and reproduction are important measures of outcome. At the same time as undergoing transition within medical services, young people are making multiple other transitions in their lives as they move from a dependent to an independent way of living (Fig. 31.2). They often move away from the family home, and parents who formerly held responsibility for patient management, coordination of care, communication and consent to treatments will be demoted to an advisory role. Paediatric services are not well placed to meet this change in focus from the patient as a child to the patient as an independent adult, and young people benefit from the move to adult services as long as their specific needs as a young adult are recognised.

Principles of prescribing during transition

Hepatic drug metabolism increases from neonatal levels during childhood, eventually decreasing to adult levels after puberty. Once puberty has been completed, teenagers can be considered, in pharmacokinetic and pharmacodynamic terms, to behave like adults. It is important to remember that many young people have considerably lower body mass and therefore body mass index (BMI) than adults, and care needs to be taken to avoid excessive dosage in physically smaller patients. Likewise, obesity needs consideration in terms of prescribing and drug doses. The general advice is that when prescribing a dose per kilogram, the optimal weight for height rather than actual weight should be used for obese young people.

A systematic approach to transition planning

Several steps need to be undertaken to develop a successful programme for transition of care. The key components are summarised in Box 31.2. The first step is to establish a policy in consultation with young people and train staff in the policy. Subsequently, systems need to be developed to identify patients in need of transition and track them as they pass through the programme. Adult health-care providers need to be identified and processes developed for introducing the young person to the adult team. This should be followed by written communication between the paediatric and adult teams, and then a first consultation with the adult team at which the transfer can be reviewed and

i 31.2 Core elements in developing a transitional care programme

Establishing transition policy

- Develop policy, with input from young people
- Train staff in operation of policy

Tracking and monitoring

- Establish process to identify patients
- Develop systems to track individual progress
- Incorporate transition planning into clinical care

Transition readiness

- Identify suitable adult care provider
- Establish process for introduction to adult team
- Provide written information about joint first consultation

Transition planning

- Ensure communication between paediatric and adult teams
- Identify need for handover consultation
- Prepare written medical handover:
  - Diagnosis
  - Current treatment
  - Previous key issues
- Send relevant information in advance
- Provide information and community support

Transfer to adult services

- Arrange first consultation
- Review transfer package with team
- Identify concerns of young person
- Review young person's health priorities
- Update medical summary and emergency care plans

Integration into adult services

- Communicate with paediatrics and confirm transfer
- Help young adult to access other adult services
- Continue individualised care plan tailored to young person
- Seek feedback from young adult about transition

i 31.3 Key features in assessing readiness for transition to adult services

(K) Knowledge

1. Describes condition, effects and prognosis
2. Understands medication purpose and effects
3. Understands treatment purposes and effects
4. Knows key team members and their roles

(S) Self-advocacy

1. Can attend part/whole clinic appointment on their own
2. Knows how to make appointments/alter appointments
3. Has understanding of confidentiality
4. Orders repeat prescriptions
5. Takes some/complete responsibility for medication/other treatment
6. Knows where to get help

(H) Health and lifestyle

1. Understands importance of diet/exercise/dental care
2. Understands impact of smoking/alcohol/substance use
3. Understands sexual health issues/pregnancy/sexually transmitted infections

(A) Activities of daily living

1. Self-care/meal preparation
2. Independent travel/mobility
3. Trips/overnight stays away from home
4. Benefits/financial independence

(V) Vocational

1. Current and future education/impact of condition on career plans
2. School attendance and performance
3. Work experience and access to careers advice
4. Outside activities and interests
5. Disclosure to school/employer

(P) Psychosocial

1. Self-esteem/self-confidence
2. Body/self-image
3. Peer relationships/bullying
4. Support networks/family/disclosure to friends
5. Coping strategies

(T) Transition

1. Understands concept of transition
2. Agrees transition plan
3. Attends transition clinic
4. Visits adult unit (if appropriate)
5. Sees primary care team/other clinical staff independently

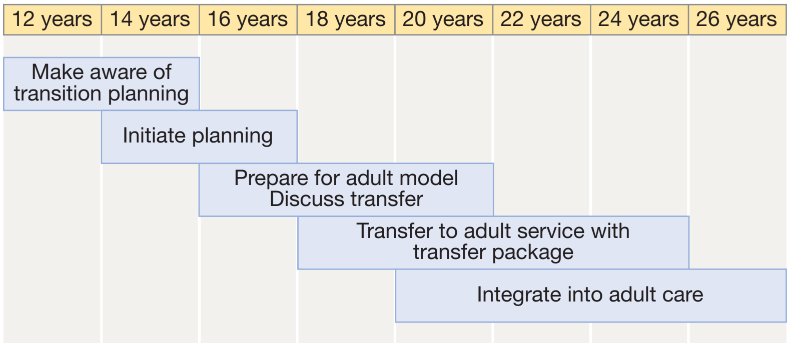

Fig. 31.3 Timing of transition.

a care plan developed. There should subsequently be written communication between the adult and paediatric teams to confirm that handover has occurred, followed eventually by integration of the young person's care into the adult service.

A number of organisations have published guidelines to planning transition services. Two of the best known include the 'Ready Steady Go' programme in the UK and the American Academy of Paediatrics' 'Got Transition' (see 'Further information'). Details of the sorts of competencies that a young person might need before making a full transition to adult medical services are outlined in Box 31.3.

When should transition happen?

The optimum timing for transition is not specifically defined; it is a process that evolves over a number of years, during which puberty and then adolescence occur. Transition should generally be initiated at around 12 years of age. Completion time then varies from person to person, also depending on the model of adult services available. Most commonly, full transition occurs between 16 and 18 years of age (Fig. 31.3). This coincides with many other areas where young people are considered to have made the transition to adulthood, such as the completion of formal education. Marriage and children often follow.

Functional anatomy and physiology

Puberty and adolescence are developmental stages through which children progress during the second decade of life. During this phase, several physical, biochemical and emotional changes occur. The most important are discussed in more detail below.

Endocrine changes

The hormonal and physical stages of progression through puberty in males and females are summarised in Figure 31.4. Puberty is initiated by pulsatile increases in gonadotrophin-releasing hormone (GnRH) by the hypothalamus, which in turn stimulates pulsatile release of luteinising hormone (LH) and follicle-stimulating hormone (FSH) by the pituitary. In males, the increased production of LH stimulates Leydig cells in the testes to produce testosterone, and FSH acts on Sertoli cells to stimulate sperm production, as described on page 651 and shown in Figure 18.13. The rise in testosterone increases skeletal growth, promotes development of the male genital organs and stimulates growth of pubic, facial and axillary hair. In females, FSH and LH act on the ovary to promote follicle production, ovulation and menstruation, as described on page 652 and shown in Figure 18.14. Other hormonal changes in all adolescents include a rise in adrenal androgens and a rise in growth hormone, which in turn stimulates production of insulin-like growth factors 1 and 2 (IGF-1 and IGF-2). Insulin production also rises by about 30% during puberty. These hormonal changes contribute to the biological, morphological and psychological changes seen during the teenage years. Adolescence (as opposed to puberty) comprises not only the physical changes of puberty, but also the wider emotional and psychological changes of progression into early adulthood. The emotional and psychological changes are associated with physical maturation but also with sociocultural influences. The normal feelings and behavioural development of normal adolescence are complex but tend to follow fairly predictable patterns.

Physical changes

In girls, there is an increased rate of growth, followed soon after by the development of breasts and pubic hair. Menstruation typically starts after the rate of growth has peaked. In boys, puberty begins with testicular enlargement, followed soon after by a growth spurt and the development of pubic hair. In clinical practice, Tanner staging is used as a method of documenting progression of physical changes that occur during puberty (Fig. 31.5). The average age at onset of puberty in the UK is about 11 years in girls and 12 years in boys but normal puberty has a very wide range of onset. Factors that are important in predicting age of onset of normal puberty include family history (age of onset is strongly predicted by the parents' pattern of onset) and body mass, with heavier children entering puberty at a younger age. The current trends towards improved nutritional status and increased obesity in particular are driving earlier onset of puberty. Delayed puberty is defined to have occurred when the age at onset is more than 2.5 standard deviations above the national average, which in the UK is about 13 years in girls and 14 years in boys. If puberty is delayed beyond this point, investigations may be needed to determine the underlying cause, as detailed on page 653. Many children who have had long-term health conditions during childhood experience a delayed onset of puberty because chronic ill health slows longitudinal growth and causes functional hypogonadotrophic hypogonadism. Glucocorticoid therapy also contributes to growth retardation in children with chronic inflammatory diseases. An X-ray of the left wrist can be used to assess bone age accurately, and a bone age that is more than 2 years behind the chronological age should prompt consideration of further investigations (p. 654).

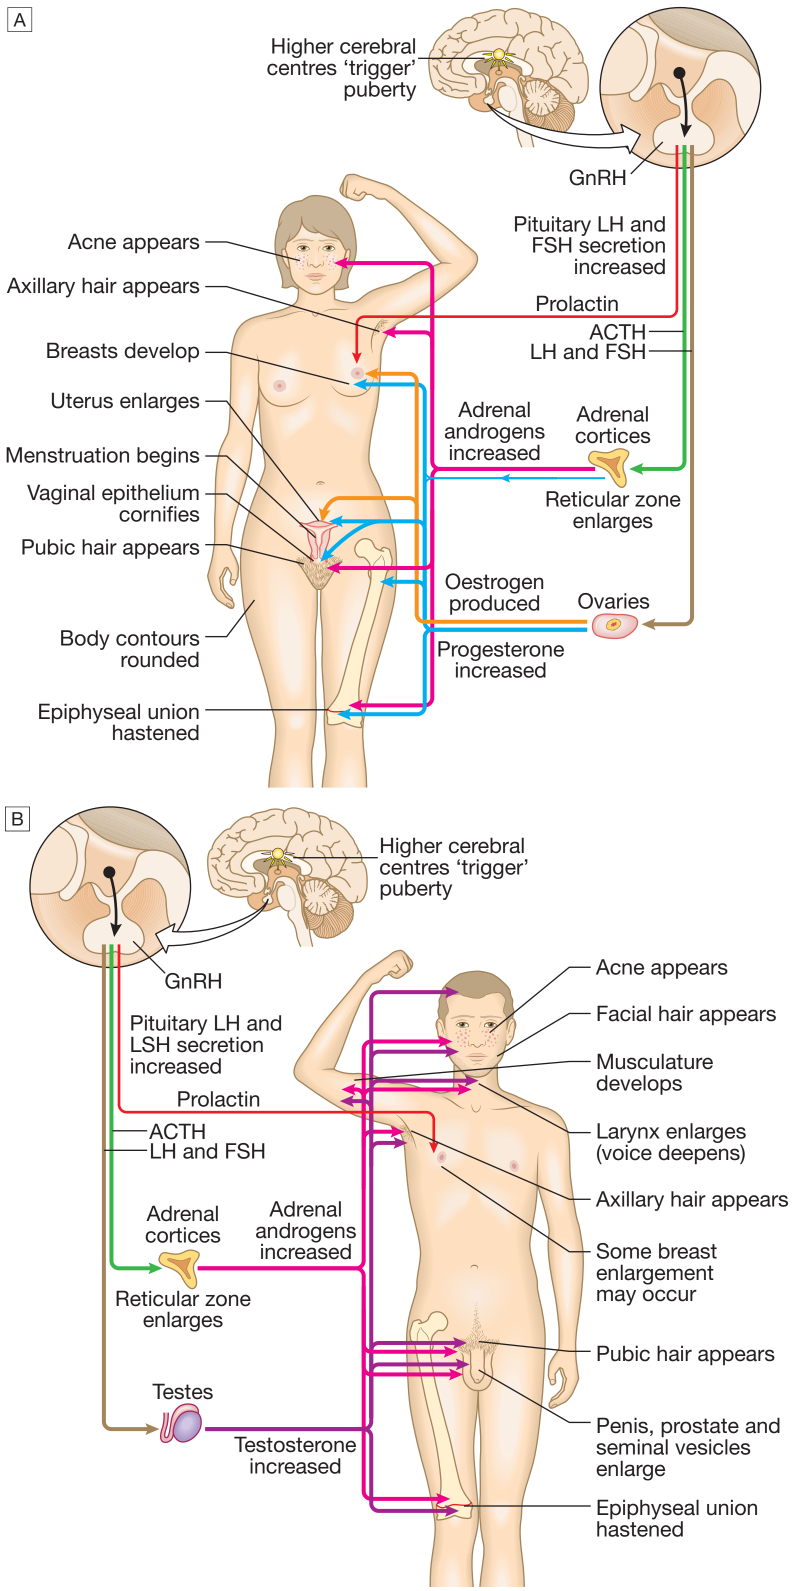

Fig. 31.4 Hormonal events of puberty. A In the ovary, FSH acts on granulosa cells to stimulate oestrogen production, whereas LH acts on theca cells to stimulate progesterone production. Androgens are also produced in small amounts by theca cells in response to LH (not shown). B In the male, LH acts on interstitial Leydig cells to stimulate testosterone production. FSH with testosterone acts on Sertoli cells to stimulate spermatogenesis. (ACTH = adrenocorticotrophic hormone; FSH = follicle-stimulating hormone; GnRH = gonadotrophin-releasing hormone; LH = luteinising hormone) *From Smith RP. Netter's Obstetrics and gynecology, 2nd edn. Philadelphia: Saunders, Elsevier, Inc.; 2008.*

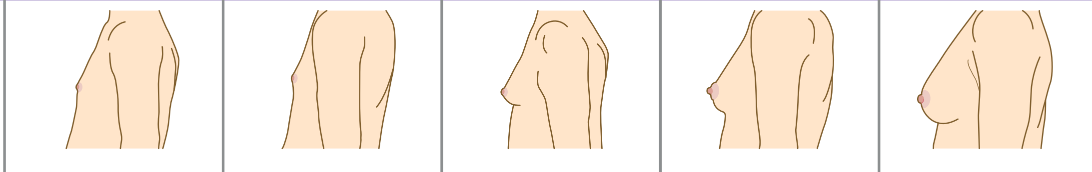

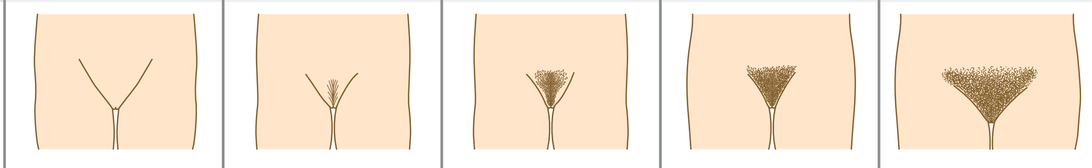

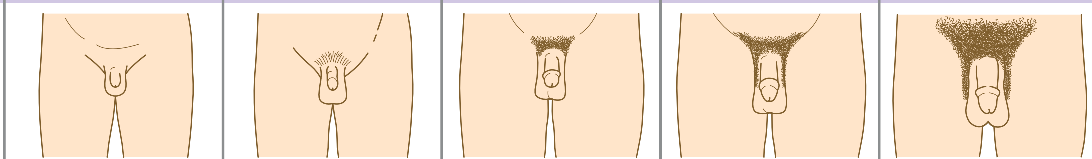

Tanner stage	I	II	III	IV	V
Female					
					
Breast	Pre-adolescent	Elevation of breast and papilla as a small mound	Further enlargement of breast and areola with no separation of contours	Projection of areola and papilla to form mound above breast	Mature stage. Projection of papilla with recession of areola to contour of breast
					
Pubic hair	None	Sparse, long and straight	Darker, coarse and curled hair	Darker, coarse and curled hair but covering smaller area than in adult. No spread to medial surface of thighs	Dark, coarse and curled hair extending to inner thighs
Male					
					
Genitalia	Pre-adolescent	Growth of testes and scrotum. Skin on scrotum reddens and becomes wrinkled	Growth of penis and further growth of testes and scrotum. Skin of scrotum becomes darker and more wrinkled	Further growth in length and width of penis, testes and scrotum	Penis, testes and scrotum of adult size
Pubic hair	None	Sparse, long and straight	Darker, coarse and curled hair	Darker, coarse and curled hair but covering smaller area than in adult	Dark, coarse and curled hair extending toward umbilicus

Fig. 31.5 Tanner staging of puberty.

Cognitive and behavioural changes

As young people move from their early teenage years to later adolescence there is a move away from the family towards personal independence. This is often characterised by change from a self-centred focus, associated with a sense of awkwardness and worries about being normal, towards increased self-confidence and an awareness of weaknesses in parents and others in authority. In late adolescence, young people reach a stage of self-reliance, increased emotional stability and improved ability to think ideas through. Finally, young adults begin to develop firm belief systems, autonomy and independence. With time, there is reduced conflict with parents and other figures in authority and full maturity develops.

In terms of cognition, there is a transition from being mostly interested in the present, in short-term outcomes and instant gratification, through to increased concern for the future and a greater focus on one's longer-term role in life. Sexuality and relationships clarify during adolescence, and individuals move from early awkwardness and uncertainty to a firmer sense of their sexual identity, and then development of more serious and longer-term relationships. In terms of morals and values, young people move from a period of risk-taking behaviour and experimentation through to understanding the potential consequences of such behaviour for their future health and well-being. Young adults develop a greater capacity for setting personal goals and an increased focus on self-esteem. Finally, family, social and cultural traditions regain some of their previous importance, and by the time young people emerge from adolescence, they have usually developed insight and a greater focus on self-esteem and long-term well-being. It is the development of these more mature personality traits that are important for the more active role in health care that is needed to function well within an adult model of medicine. Some teenagers do vary slightly from these broad patterns but the feelings and behaviours described are, in general, considered normal for each stage of adolescence. Understanding these changes in emotional and psychological behaviour underpins the approaches that are needed to meet the challenges of managing long-term conditions in older teenagers and young adults.

31.4 Biochemical changes during transition

Analyte	Comment
Alanine aminotransferase (ALT)	Increased during adolescence Activity may continue to rise, at least in men, until middle age
Alkaline phosphatase (ALP)	Activity higher in infancy, decreases during childhood, and rises again with skeletal growth during puberty Peak in females at median 11 years and in males at 13 years Levels decrease rapidly after puberty, particularly in girls; adult levels achieved after epiphyses fused
Insulin-like growth factor 1	Levels 30% higher during adolescence
Serum creatinine	Increases steadily from infancy to puberty parallel to development of skeletal muscle; until puberty, there is little difference in concentration between males and females
Uric acid concentration	Decreases from high levels at birth until 7–10 years of age, then increases, especially in boys, until 16 years

Investigations

Several changes take place during adolescence in terms of skeletal growth, organ development and body composition, which can influence the interpretation of results. Examples include fusion of the epiphyses as puberty progresses, increases in bone mineral content and density as the skeleton grows, and changes in the reference range of certain biochemical tests. Most of these changes occur gradually during puberty and there are rarely abrupt alterations in adult biochemical concentrations. It is important to use age-adjusted biochemical reference ranges until puberty has been completed. Several biochemical changes take place in the composition of body fluids between infancy and puberty.

Some of the key changes in biochemical markers are outlined in Box 31.4. More detail on reference ranges for specific analytes is provided in Box 35.9 (p. 1363). The elevation in alkaline phosphatase (ALP) levels during adolescence relates to the bone isoenzyme produced by osteoblasts in the growing skeleton during the growth spurt. Further investigations for raised levels of ALP are not required in adolescence, as long as other liver function tests, including γ-glutamyl transferase (GGT), are normal.

In general, under normal physiological conditions, the reference ranges of most biochemical tests remain fairly constant between puberty and menopause in women and between puberty and middle age in men.

Clinical assessment

The initial patient consultation at transition is of vital importance for establishing a potentially life-long professional relationship with the patient, as well as identifying key features in the history, examination and assessment of their overall needs. Parents commonly attend a first adult appointment with their son or daughter, and it is usually necessary to allow longer for this initial assessment. Often, the first transition appointment is undertaken jointly with the paediatrician in a specialist transition clinic and this will enable a thorough face-to-face handover of all the key facts.

31.5 Features in transition assessment

Features of history and/or examination	Reason
History*	
Main/presenting condition and detailed review of clinical course	Understand detail and severity of illness; understand which treatments have been undertaken and which have been successful
Family history: Draw family tree of all first-degree and any relevant/affected second-degree family members	Many long-term conditions arising during childhood have significant genetic and familial factors to be taken into account
Current drug therapy, significant previous therapies	Many drugs have significant long-term implications, levels may need monitoring, may have teratogenic effects to consider
Any surgical or other relevant medical history	Understand which treatments have been undertaken and which have been successful
Pubertal status/age of menarche	Helps assess disease severity plus patterns of growth Informs about patient's reproductive health and family-planning wishes
Social history: In education or in work? Receiving appropriate benefits/support? Financial or other practical concerns? Living with parents/left home?	Assesses wider effects of patient's health on their independent living, as well as their financial and practical circumstances Can be a proxy measure of disease severity and identifies their support mechanisms, which also helps in the assessment of their current needs
Systems enquiry	Any other related/unrelated symptoms or problems
Physical examination	
Height, weight, calculation of body mass index Blood pressure Urinalysis if relevant Assessment of pubertal status General physical examination	Although young people are often accompanied by a parent, examine them separately and use this opportunity to consider asking about private matters, such as partners, sexual activity, and drug or alcohol use

*Throughout the first consultation, confidence and competence in decision-making/capacity to consent should be assessed. If there are concerns about capacity, clarify key decision-makers.

A detailed transition referral letter should clearly describe the diagnosis, current and previous treatments, and key interventions that have been undertaken while the patient was under the care of paediatric services. It is important to check the main details with the young person and to make sure there are no other factors that they feel are of relevance. There are a few features in the history that merit special attention, particularly at the first consultation, as outlined in Box 31.5. Many young people with an LTC attend their first adult outpatient department consultation with their parents, and it is important either to create a time to ask personal and lifestyle-related questions separately from the main history – that is, privately – or to make sure that these can be confidentially explored in future.

Presenting problems in transition medicine

Problems with adherence

Adherence is defined as 'the extent to which a person's behaviour, in terms of taking medications, following diets, or executing lifestyle changes, coincides with medical or health advice'. The term 'adherence' is used in preference to 'compliance' because it focuses on whether a person actively adheres to the regimen rather than passively follows the doctor's orders. It also implies partnership and cooperation between the patient and the care-giver. More recently, clinicians have moved to seeking patients' concordance with management plans. Concordance refers to a consultation process that has an underlying ethos of shared decision-making. It has become clear that current levels of adherence do not deliver the full benefits of medication. Historical paternalistic medical practice does not maximise the chances of patients adopting the changes and treatments they need to improve their outcomes. Reaching a concordant position with patients involves a range of approaches (such as patient-centredness or shared decision-making) and a number of specific actions (such as exploring anxieties about medication side-effects, individualising regimes to suit the patient's lifestyle, offering a range of treatment options) and has not been evaluated comprehensively.

Adherence to clinic attendance, investigation and treatment often falls significantly in adolescence and during transition to adult services. Measurement of adherence is challenging and reported rates vary according to the method of assessment. Teenagers may also have varying adherence levels within their treatment regimen. An important example is in patients who have undergone organ transplantation, in whom low adherence to immunosuppressive medication is a significant cause of graft rejection and may cause death. Adherence merits careful consideration when caring for adolescents and young adults, and focusing on strategies to improve adherence at this initial stage of patient management can deliver life-long improvements in health outcomes. Young teenagers mainly believe in things that they have directly experienced and do not fully appreciate the unseen consequences of not taking their medications. In time,

31.6 Factors affecting adherence

Negative factors

- Older adolescent
- Mental health issues with care-giver
- Family conflicts
- Complex therapy
- Medication with side-effects
- Denial of illness

Positive factors

- Positive family functioning
- Close friends
- Internal locus of control
- Treatment with immediate benefits
- Patient's belief in seriousness of illness and efficacy of treatment
- Physician empathy

31.7 SIMPLE strategies to improve adherence

Simplify regimen

- Use once daily/twice daily regimes if possible
- Match regimen to bedtime and meals
- Use pill box or alarms on phone
- Organise services around patient (combined clinics, flexible timing and appointments)

Impart knowledge

- Share decision-making
- Provide clear instructions:
  - Limit to three or four major points
  - Use simple, everyday language
  - Use written information or pamphlets and verbal education at all encounters
- Supply addresses of quality websites
- Provide advice on how to cope with medication costs

Modify patient beliefs

- Empower patients to self-manage their condition:
  - Ask about their needs
  - Ask what might help them become and remain adherent
  - Ensure they understand the risks of not taking their medication
  - Address fears and concerns about taking the medication

Provide communication

- Improve interviewing skills
- Practise active listening
- Provide emotional support – treat the whole patient and not just the disease
- Provide clear, direct and thorough information
- Elicit the patient's input in treatment decisions
- Allow adequate time for patients to ask questions
- Build trust

Leave the bias

- Learn more about low health literacy and how it affects patient outcomes
- Consider care of ethnically and socially diverse patient populations
- Acknowledge biases in medical decision-making (intentional or unintentional)
- Address dissonance of patient–provider race/ethnicity and language
- Take extra time to overcome cultural barriers
- Ask specifically about attitudes, beliefs and cultural norms around medication
- Use culturally and linguistically appropriate targeted patient interventions
- Increase engagement, activation and empowerment
- Tailor education to the patient's level of understanding

Evaluate adherence

- Direct:
  - Number of repeat prescriptions
  - Biomarkers of response
  - Measurement of drug levels
- Indirect:
  - Self-reporting: 'When did you last forget your medicine?'; 'How often have you forgotten your medicines this week?'

adolescents learn to develop hypothetical thinking and to analyse more complex information and decision-making. The ability to engage in formal thinking is inconsistent at first, and at times of stress (such as during an illness) adolescents may regress to more simple ways of problem-solving. Despite their maturing skills, they may remain self-centred and feel invincible. Factors that positively and negatively affect adherence are outlined in Box 31.6. Interventions to improve adherence are summarised in Box 31.7.

Recent literature suggests that two-way communication between patients and professionals about medicines leads to improved satisfaction with care, knowledge of the condition and treatment, adherence, health outcomes and fewer medication-related problems. Younger adults and those coming to adult services following transition from paediatric services have very different expectations in terms of the nature of the patient–doctor relationship and are more likely to require a more collaborative approach to development of management plans to maximise their concordance with treatment in the long term.

High-risk behaviour

The high-risk behaviour that can be undertaken by adolescents is well documented and is seen across many cultures. It is important to assess this by history-taking at the time of transition (Box 31.8) Adolescents who have had LTCs during childhood are at greater risk of undertaking harmful behaviour and there is evidence that a poor long-term health outlook is associated with risk-taking behaviour earlier in life.

31.8 History-taking in adolescent patients: risk-taking behaviours ('HEADS')

From Segal TY. Adolescence: what the cystic fibrosis team needs to know. J R Soc Med 2008; 101(Suppl 1):15–27.

Globally, the leading causes of death among adolescents are road injury, human immunodeficiency virus (HIV) infection, suicide, lower respiratory infections and interpersonal violence; many of these deaths are linked to risk-taking behaviours such as excess alcohol and drug intake. Quite apart from mortality, there are other significant adverse events linked to risk-taking behaviour in adolescents: excess alcohol ingestion is also associated with non-fatal road traffic accidents, unwanted and unprotected sexual activity, and violence as both perpetrator and victim.

There are a number of theories about the neurodevelopmental changes associated with these behaviour changes. At around 11 years of age, the prefrontal cortex (PFC) and parietal lobes begin a period of pruning of neuronal axons. It is theorised that these changes represent the start of the process of increasing frontal lobe control. A separate process that occurs at the same time predisposes the adolescent to risk-taking behaviour and impulsivity: frontostriatal reward circuits mature relatively early and encourage the adolescent towards adult activities such as alcohol and drug use, and sexual intercourse, which carry potential health risks. At this stage, the PFC has not yet matured to the point where the individual can assess risk adequately. The PFC and its connections are structurally unable to provide sufficient control. It is thought that this maturational gap in PFC control of the pleasure-seeking brain systems is responsible for the risk-taking lifestyle that characterises the period of adolescence.

A number of studies have investigated personality and other factors that contribute to different risk-taking behaviours during adolescence: essentially, younger adolescents and females tend to rate activities as being more risky, and are therefore less likely to undertake them. Older males and those of lower educational status are higher risk takers. Specific protective factors include high self-esteem and a strong orientation to an internal locus of control; young people who feel they have less control and influence over themselves and their behaviour are more likely to undertake high-risk activities. Many teenagers with serious long-term health conditions are disempowered in a number of ways and there is evidence that they are predisposed to be high risk takers during adolescence. Examples of risk-taking behaviour include not only alcohol and drug intake, but also non-adherence to medicines and other aspects of health care, such as diet in diabetes.

It is not easy to affect behaviour during this period of non-adherence. Isolated educational intervention is not sufficient to improve outcome; for example, there is a wealth of evidence showing that teenagers know about the behaviours needed to prevent transmission of HIV, but many do not adhere to this advice. Long-term health-care providers have an invaluable role in supporting adolescents during this period of their development as adults, as many important health-related and lifestyle habits are established during this period: more than 90% of smokers start smoking in adolescence, and life-long habits around eating and exercise are laid down during the teenage years. Focusing on the needs of the emerging adult for autonomy and using the highest levels of communication and patient engagement significantly improve outcomes for patients with LTCs.

Unplanned pregnancy

In many parts of the world, females commonly undergo their first pregnancy during or just after adolescence. The median age for

i 31.9 Adolescent pregnancy rates

Region	Pregnancy rate (/1000 women aged 15–19 years)
Tanzania	124
Kenya	94
Jamaica	71
Mexico	65
South Africa	52
USA	33
Pakistan	28
New Zealand	26
UK	26
Spain	11
France	6
Japan	5.3
Italy	4.5
South Korea	2.2

first pregnancy varies from 19 years in India and parts of Asia, through to 25 years in the USA and around 30 years in Australia and Western Europe. Teenage pregnancy rates are high across the world (Box 31.9). Information from the UK suggests that 1 in 6 pregnancies is unplanned, and 1.5% of women between the ages of 18 and 45 face an unplanned pregnancy each year. It is therefore vital to anticipate and discuss the issues surrounding reproductive health with all young people before and during transition, as well as during early adulthood. Young people with serious LTCs have a number of additional factors to be taken into consideration when discussing reproduction, and these discussions need to take place long before a family is planned. General physicians do not need to be able to undertake complex genetic counselling and investigation, but should be able to provide advice about the recurrence risk of common inherited conditions, as well as that of the more common multifactorial LTCs, many of which have an inherited or genetic component.

Clinical presentations

In almost every clinical setting, there is the potential for a young adult with a serious LTC that has arisen during childhood to present to adult physicians. Medical services can improve the care and outcome for this vulnerable group by planning a systematic approach to transition, as described above, and by focusing the clinical consultation on issues of relevance and importance to each particular patient. The key issues to consider for a number of the most common LTCs of childhood are discussed below.

Neurological disease

Epilepsy

Epilepsy is a chronic disorder, the hallmark of which is recurrent, unprovoked seizures (p. 1097). Epilepsy that has presented during childhood, as opposed to adulthood, is less often associated with underlying central nervous system malignancy and is well controlled with first-line anticonvulsants in around 80% of cases. Young people who still have epilepsy or are on anticonvulsant therapy as they progress into adulthood are more likely to have underlying structural brain disease, such as cerebral palsy, or have more complex or syndromic epilepsy. In many of them, epilepsy may be associated with learning difficulties or other neurological conditions.

Epilepsy presents several problems during transition. Adherence to medication can be an issue and patients with low adherence to epilepsy medicines have higher mortality, higher hospital admission rates and higher emergency department attendances. Conversely, high adherence rates at initiation of epilepsy therapy are associated with improved long-term seizure freedom and higher seizure freedom at 4 years. Epilepsy can also affect employment options for young people, as about 30% of patients still have breakthrough seizures while on treatment. Certain types of employment, such as working within the emergency services or armed forces, or becoming a pilot or driver of a heavy goods vehicle, may therefore not be possible. Driving restrictions may also limit options for some other occupations (p. 1103). Young women with epilepsy should be advised that oral contraceptives are less effective with enzyme-inducing antiepileptic drugs; they should also be made aware of the risk of teratogenicity with many antiepileptic drugs, most notably sodium valproate, which should be avoided in pregnancy if at all possible. Pre-conceptual counselling is desirable for all young girls with epilepsy and pre-conceptual folic acid supplementation is advisable to reduce the risk of neural tube defects.

Alcohol use in moderation does not affect seizure control in the majority of patients, but withdrawal from alcohol in dependent patients is epileptogenic and heavy alcohol use should be discouraged. Information about marijuana and epilepsy risk is lacking, but regular marijuana use and excess drinking are associated with poor adherence to medication regimes and increased seizure risk.

Cerebral palsy

Cerebral palsy comprises a range of non-progressive neurological impairments, present from the time of birth or arising in early childhood. Although the neuropathology is non-progressive, the manifestation of problems can evolve, with progressive motor dysfunction related to increased spasticity and possibly progressive seizure activity.

Patients with severe cerebral palsy present specific problems during transition and early adulthood. They may be paraplegic or quadriplegic and most non-ambulatory individuals have significant intellectual disability. This group of patients will be unable to live independently during adulthood and need ongoing long-term care. Delivering medical care to these individuals poses several problems, including practical issues such as consideration of capacity and consent to treatment. Other comorbidities include gastro-oesophageal reflux (often related to abnormal lower oesophageal function), seizures, and feeding difficulties often requiring gastrostomy. These individuals usually require a complex care package involving many members of the multidisciplinary team. There are also risks of abuse and neglect in the care of adults with severe disability and this needs to be borne in mind when considering atypical problems or unusual presentations in this vulnerable patient group. Depending on the severity of the patient's condition, end-of-life care may need to be discussed and planned with the family and other care-givers.

Muscular dystrophy

The muscular dystrophies are a group of diseases that cause progressive weakness and loss of muscle mass. The disorders differ in terms of which muscle groups are affected, the degree of weakness, and the rate of disease and symptom progression. All the inherited muscular dystrophies that present during childhood need active management during transition (p. 1143). One of the most important and most severe conditions is Duchenne muscular dystrophy (DMD), which is associated with a progressive decline in mobility, coupled with cardiac dysfunction due to cardiomyopathy, and respiratory failure requiring respiratory support as the disease progresses. Physicians should ensure that the whole family are aware of the wider genetic issues. Female carriers of the DMD gene can suffer muscle fatigue and are at risk of cardiomyopathy, as well as there being obvious risks for their male offspring. On average, patients with DMD survive until their late teens to early twenties, and those with less severe muscular dystrophies, such as Becker dystrophy, survive until their thirties. Although fertility is reduced, young men with these conditions may themselves father children. Male offspring will be unaffected but all female infants of affected males will be carriers.

As the muscular dystrophies progress, a complex package of care involving a multidisciplinary team is necessary; it should include respiratory input to assess the need for ventilatory support, which is a common endpoint for many patients. At the present time, there is no definitive treatment. Glucocorticoids (0.75 mg/kg/day) have been shown to improve muscle strength and are frequently used, but carry an increased risk of osteoporosis and vertebral fractures. New therapeutic approaches are being developed with the aim of ameliorating disease progression in patients with nonsense mutations (p. 42). One involves the use of drugs such as ataluren, which promotes binding of transfer RNA (tRNA) molecules at the site of stop codons with a mismatch in one base (near-cognate tRNAs). These cause a full-length protein to be produced with an amino acid substitution rather than a truncated non-functional protein. Patients with DMD usually require social and financial support. It is important to consider end-of-life care plans with patients and family members. Involvement from palliative care teams, as well as psychological, spiritual and wider non-medical support, is essential.

Respiratory disease

Cystic fibrosis

Cystic fibrosis (CF) is a single-gene autosomal recessive disorder that affects about 1 in 2000 to 1 in 3000 individuals of Caucasian descent (p. 580). Clinical manifestations are caused by defects in an ion transporter termed the cystic fibrosis transmembrane conductor regulator (CTFR) protein. With improved supportive care, the median survival in the UK is now more than 50 years. It is well recognised that young people with life-limiting conditions face particular challenges during transition: individuals often exhibit high-risk behaviour during adolescence, and this was particularly true in the past when long-term survival rates were poor. The rates of non-concordance with medication and with time-consuming physiotherapy and nebuliser regimes are high and adversely affect outcome and survival. Exercise tolerance and employment are likely to be restricted as time progresses, and patients need particular support managing the slow decline in function and well-being that occurs throughout their adult lives.

In terms of fertility and child-bearing potential, the picture is complex and merits detailed discussion with patients. It is not often discussed openly by the paediatrician or during childhood, other than with the parents when the patient is young. The vas deferens is absent in 98% of males with CF and seminal vesicular dysfunction means that ejaculates are low in volume. While boys are infertile, newer reproductive therapies, such as the availability of intracytoplasmic sperm injection, mean that fatherhood is possible. The opportunity for assisted reproduction should be discussed early so that people can make informed choices at an appropriate stage of their lives. Females with CF who have good nutritional status and reasonable health status have normal fertility and genetic counselling should be offered early. Contraception needs to be discussed with women who are not planning a pregnancy, since pulmonary hypertension is an absolute contraindication for the oral contraceptive pill (OCP). Women also need to be advised about the effects of antibiotics on OCP effectiveness. New orally available small-molecule therapies, including lumacaftor and ivacaftor, have recently been licensed; they can partially rectify functional defects in the CTFR and have improved outcome. These drugs are having a positive effect on symptom control and are potentially disease-modifying. Other therapeutic approaches, including gene therapy and mRNA editing therapies, are also being explored as treatments for CF. Common issues encountered during transition of CF patients are summarised in Box 17.34 (p. 581).

Cardiovascular disease

Congenital heart disease

Congenital heart disease (CHD) is the most common congenital anomaly, affecting about 1% of live births. Among birth defects, CHD is the leading cause of mortality. Maternal illnesses such as rubella and injection of teratogenic agents during pregnancy, along with paternal age, all play roles in pathogenesis. Although some chromosomal anomalies, such as trisomy 13, 18 and 21 and monosomy X (Turner's syndrome), are strongly associated with CHD, these account for only 5% of cases. Microdeletion and single-gene mutations can also be important, such as in DiGeorge syndrome (22q11.2 microdeletion). Overall, the most common congenital valvular anomalies are aortic and pulmonary stenosis. The most common structural anomaly is ventricular septal defect.

There is a wide range of severity of CHD but many patients with life-limiting conditions (usually complex structural anomalies such as tetralogy of Fallot or hypoplastic left heart syndrome) survive to adulthood. Genetic counselling of affected individuals is important, as there is a 1–2% recurrence risk of any cardiac anomaly in offspring. Affected patients should be transitioned to a cardiologist with experience in CHD since this has become a subspecialty in own right. More details are provided on page 531 and in Box 16.103 (p. 537).

Hypertrophic obstructive cardiomyopathy

Hypertrophic obstructive cardiomyopathy (HOCM, p. 539) is a genetic cardiovascular disease characterised by left ventricular wall hypertrophy, impaired diastolic filling and abnormalities of the mitral valve. These features can cause dynamic obstruction of the left ventricular outflow tract, diastolic dysfunction, myocardial dysfunction and an increased risk of supraventricular and ventricular tachyarrhythmias. HOCM is caused by mutations

affecting the genes that encode cardiac sarcomere proteins and is most frequently transmitted as an autosomal dominant trait. It may present for the first time during adolescence with cardiac arrest or sudden cardiac death. Predictive genetic testing is possible but challenging because of the large number of causal mutations. In clinical practice, careful analysis of the family history can be useful in identifying those at risk of inheriting the disease. If no gene anomaly has been identified within a family, first-degree relatives may need screening by electrocardiography (ECG) and echocardiography. Identification of a genetic anomaly is most helpful in allowing identification of family members who do not need echocardiograms or clinical follow-up. Children of affected parents should be screened every 3 years until puberty, and then annually until 20 years of age. If there is no evidence of HOCM in early adulthood, it is unlikely that the condition will develop in later life.

Oncology

Around 1 child in 500 will develop cancer by the age of 14 years. Leukaemia is the most common, accounting for about 33% of cases; central nervous system tumours are the next most common, accounting for around 25% of all childhood cancers. Fifty years ago, 75% of children diagnosed with cancer died, but overall survival rates now range from 75% to 80%. Between 60% and 70% of young adults who have survived childhood cancer will develop at least one medical disability, most commonly as a result of their therapy rather than their primary cancer. There is a 3–6-fold increased risk of a second cancer, with an absolute risk of about 10% before 50 years of age. It is therefore important for these individuals to be kept under surveillance during transition and beyond.

Endocrine and reproductive disturbances are the most common late effects, affecting 40–60% of survivors. Infertility can be an issue in both males and females receiving cytotoxic medications, unless it has been possible to store semen and ovarian tissue in advance of treatment. Other long-term risks include hypopituitarism, growth hormone deficiency and pubertal delay (especially in boys) from brain irradiation. Radiotherapy to the neck can cause hypothyroidism and increases the risk of thyroid cancer. Total-body irradiation offered as conditioning for bone marrow transplantation affects both ovarian and testicular function, and many of the chemotherapeutic agents used have adverse effects on fertility. Chemotherapy-induced ovarian failure is typically associated with high-dose alkylating agents such as cyclophosphamide, and this is an independent risk factor for premature ovarian failure. In recent years, patients have been offered ovarian and testicular tissue retention and fertility issues are being discussed with families during childhood, but often the patients themselves have limited levels of knowledge of the details. Chemotherapy and radiotherapy in childhood significantly reduce ovarian reserves. When combined with the progressive ovarian decline that occurs in all women throughout adulthood there is a significant risk of premature menopause or ovarian failure, with 8% of survivors affected. Young women need to be aware of these risks during their early adulthood to help with family and lifestyle planning; for example, they may wish to plan to have children earlier in their adult life rather than risking ovarian decline.

Cardiomyopathy is another complication of anthracyclines such as doxorubicin and daunorubicin. Serious cardiac complications include arrhythmias, dilated cardiomyopathy from myocardial necrosis, and angina or myocardial infarction arising from vaso-occlusion or vasospasm.

In addition to physical effects, children who have faced life-threatening illness in childhood may experience psychological and family difficulties during adulthood. Cognitive impairment is more common in children who have received chemotherapy or radiotherapy to the brain, and problems can include lower IQ, problems with memory and attention, poor hand–eye coordination and behaviour/personality problems, combined with the well-recognised and physical complications of cancer treatment in childhood.

Increasing recognition of these issues has resulted in active monitoring programmes for survivors of childhood cancer, who are best seen in specialist 'late effects' multidisciplinary clinics, where teams include oncologists, psychologists and specialists from other relevant disciplines.

Renal disease

Chronic kidney disease (CKD, p. 415) accounts for some of the most complex long-term illnesses in childhood. The most common causes during childhood and adolescence are shown in Box 31.10. The primary pathology can be varied and many conditions have no specific treatment, but the overall approach to management of progressive renal insufficiency is the same. Internationally agreed definitions of CKD staging in children differ from those in adults and are summarised in Box 31.11. In adults the rate of albumin excretion is included in CKD definitions, as outcome correlates with the level of albuminuria, but in children similar data are lacking and so the staging system is based on glomerular filtration rate alone. The majority of children with

31.10 Causes of renal impairment in childhood and adolescence

- Obstructive uropathy
- Renal hypoplasia/dysplasia
- Reflux nephropathy
- Focal segmental glomerular sclerosis
- Polycystic kidney disease

31.11 Staging of chronic kidney disease (CKD) in children over 2 years of age*

Stage	Glomerular filtration rate (GFR) (mL/min/1.73 m^2)	Description
1	>90	Normal or high
2	60–89	Mildly decreased
3a	45–59	Mildly to moderately decreased
3b	30–44	Moderately to severely decreased
4	15–29	Severely decreased
5	<15	Kidney failure

*Kidney Disease: Improving Global Outcomes (KDIGO) 2012 classification. Chronic kidney disease is defined either as GFR <60 mL/min/1.73 m^2 for >3 months, regardless of whether other CKD markers are present, or as GFR <60 mL/min/1.73 m^2 accompanied by evidence of structural damage or other markers of kidney abnormalities, including proteinuria, albuminuria, and pathological abnormalities in histology or imaging. In adults, albumin excretion is also included in CKD staging as the level of albuminuria correlates to outcome. These data are lacking in children and so albuminuria is not used to classify paediatric CKD.

CKD stage 3 or higher will ultimately require renal replacement therapy but the timescale for reaching this stage can vary widely. The mainstay of support is to delay progression by treatment of secondary factors that are known to be associated with progressive decline in renal function: namely, hypertension, proteinuria and anaemia.

Organ transplantation

Children requiring renal replacement therapy are the most common recipients of kidney transplants in childhood. Liver and heart transplantation, followed by lung and small bowel transplantation, are well-recognised but less commonly undertaken procedures. Non-adherence to immunosuppressive regimes during adolescence is a well-known risk factor for graft failure. The reported incidence of graft failure due to non-adherence is 10–15% but this is likely to be an under-estimate. Rates of non-adherence are highest among adolescents and young adults. As well as non-adherence to immunosuppression, non-adherence to testing and clinic attendance adversely affects the care and outcome of around 1 in 8 kidney transplant patients. Poor adherence is associated with patients with worse psychological status and family dysfunction; adherence has been shown to improve with education and increased motivational factors, as might be expected. This offers the opportunity to improve graft survival. At present, 50% of cadaveric grafts and around 68% of live donor grafts are still functioning 10 years post-transplant. There is no clear difference between children and adults in survival of transplanted kidneys.

Many medications used in transplant medicine and in renal disease can have long-term effects on health. Inhibition of linear growth is seen even with low doses of glucocorticoids, such as 0.125 mg/kg/day on a long-term basis. Alternate-day regimes are generally considered preferable in childhood. The height reduction associated with long-term glucocorticoid use in childhood is dose-dependent, and even for children with asthma treated with inhaled glucocorticoids, an average height reduction of 1.2 cm is reported. This is can also be associated with delayed puberty, as well as an increased risk of osteoporosis in adulthood. Post-transplant lymphoproliferative disorders (PTLDs) are a well-recognised and potentially life-threatening complication in solid organ recipients. PTLD is the most common malignancy complicating solid organ transplantation, accounting for 20% of all cancers. They represent a range of lymphoproliferative disorders, from infectious mononucleosis and lymphoid hyperplasia to malignant lymphoma. Most cases of PTLD are associated with Epstein–Barr virus (EBV), leading to uncontrolled B-cell proliferation and tumour formation. Up to 10% of solid organ transplant recipients develop PTLD but the risk is almost four times higher in patients under 20 years of age, as opposed to those aged 20–50. This increased risk relates mainly to the development of EBV infection after transplantation; most adults are already EBV-seropositive at the time of transplantation and therefore at lower risk of this complication. The type of organ transplant that has been undertaken predicts PTLD risk, with the cumulative incidence over 5 years ranging from 1–2% in haematopoietic cell transplant and liver transplants, 1–3% in renal transplants, 2–6% in heart transplants and 2–9% in lung transplants to as high as 11–33% in intestinal or multi-organ transplants. The different rates possibly relate to the varying degrees of immunosuppression required. The incidence of PTLD is highest in the first year after transplantation, when it is associated with the highest levels of immunosuppression.

Diabetes

Adherence and concordance with medication are a particular challenge in adolescents who have developed diabetes during childhood (p. 753). Studies of adolescents with type 1 diabetes have revealed that 25% were neglecting insulin injections, 81% were not following their diet, and 29% were not measuring their glucose level and were completing a daily diary with fictitious results. Research has also shown that the outcome of diabetes is improved with a formal transition programme (Box 31.12). Good control of diabetes is particularly important during this phase since microvascular disease often emerges around time of transition, although it can occur sooner in patients with early-onset diabetes.

31.12 Impact of transition planning on outcome in diabetes

Intervention	Outcome measures
Disease-specific education	Lower HbA_{1C}
Generic education/skills training	Fewer acute complications: Hypoglycaemia Admissions with ketoacidosis
Transition coordinator	Lower rate of loss to follow-up
Joint paediatric/adult clinic	Fewer chronic complications: Hypertension Nephropathy Retinopathy
Separate young adult clinic	Improved self-management Improved disease-specific knowledge
Out-of-hours phone support	Improved screening for complications
Enhanced follow-up	Better quality-of-life scores

Gastrointestinal disease

Inflammatory bowel disease

The prevalence of inflammatory bowel disease (IBD, p. 813) in childhood is increasing, and the incidence of Crohn's disease (CD) in particular is rising in both children and adults, probably due to currently undefined environmental factors. Current treatment aims are outlined in Box 31.13. Standard measures include exclusive enteral nutrition for 6–8 weeks using a whole-protein (polymeric) formula, which induces initial remission in 80% of children. This is equivalent to glucocorticoid therapy but offers improved nutritional status and superior mucosal healing. Glucocorticoids can also be used to induce remission, as well as to treat exacerbations, but should be followed up by immunosuppressive therapy with azathioprine or methotrexate. Adolescents and children are more likely than adults to require biologics and around 20% need treatment with tumour necrosis factor alpha (TNF-α) inhibitors such as infliximab or adalimumab. Around 20% of children with CD require surgery within 5 years of diagnosis; limited resections and stricturoplasty are considered best practice to preserve gut length and prevent short bowel syndrome (p. 707).

Children with ulcerative colitis (UC) are more likely than adults to present with pancolitis (approximately 80% versus 40–50% in adults). Mild disease should be treated initially with oral 5-ASA preparations such as mesalamine or sulfasalazine. If the response is inadequate, oral glucocorticoids can be used, but caution must be exercised because of the adverse effects on skeletal growth and bone mineral density. Thiopurines such as 6-mercaptopurine or azathioprine are frequently used as steroid-sparing agents,

i 31.13 Treatment strategy in Crohn's disease

- Induce and maintain clinical remission
- Optimise nutrition
- Optimise bone health
- Optimise growth and pubertal progress
- Minimise adverse drug effects

with progression to anti-TNF-α therapy for those who still do not respond. There is less evidence for efficacy of TNF-α inhibitors in adolescents with UC than those with CD; they seem to be effective at inducing an initial response but less useful for maintaining long-term remission, since a significant proportion of patients still require colectomy (20% at 1 year) or long-term glucocorticoids. Ciclosporin is probably more effective than infliximab in teenagers with refractory UC. As with other adolescents who have long-term conditions, adherence to medication is particularly important to reduce the risk of relapse. In terms of lifestyle advice, smoking is a particular risk since it increases both the rate and severity of relapses. Body image can be a particular challenge for young adults with IBD, and those with colostomies or fistulae, for example, can find this part of their illness particularly difficult. Delayed puberty and short stature are important comorbidities, partly related to medication side effects and also to the nature of the inflammatory bowel disease itself.

Rheumatology and bone disease

Juvenile idiopathic arthritis

Juvenile idiopathic arthritis (JIA) is the term used to describe a wide variety of inflammatory rheumatic diseases that present during childhood (p. 1026). Oligoarticular juvenile arthritis has a good prognosis and often remits during adulthood, and so transitioning patients to adult rheumatology services may not always be required. The same does not hold true for systemic JIA and polyarticular JIA, which often require long-term immunosuppressive therapy through transition and beyond into adulthood. Smoking is a risk because it increases the activity of inflammatory disease and reduces the effectiveness of biologics. Adherence to and concordance with medication remain a challenge, as in other chronic diseases. Functional limitation secondary to joint damage may limit employment opportunities. Contraceptive advice is important in patients on methotrexate.

Glucocorticoid-induced osteoporosis

Osteoporosis is a complication of long-term glucocorticoid therapy that may be required in patients with inflammatory disease, transplantation and DMD.

There is a paucity of evidence about best practice in glucocorticoid-induced osteoporosis in children and adolescents, but in general the teenage years are a period of considerable bone mineral deposition and offer a chance to enhance bone mineral density significantly. It is important to ensure adequate calcium and vitamin D intake and to supplement if necessary. Therapy with bisphosphonates can be considered in symptomatic patients, although the evidence base for prevention of fractures is poor.

Osteogenesis imperfecta

Osteogenesis imperfecta (p. 1055) typically presents with multiple low-trauma fractures during infancy and childhood. Although fractures become less common during adolescence due to the increase in bone mass, they still occur frequently during transition and in young adults. Intravenous bisphosphonates are widely used in the treatment of children with osteogenesis imperfecta (those with long-bone deformities, vertebral compression fractures, and three or more fractures per year, in whom the benefit:risk ratio is thought to be positive), although the evidence base for prevention of fractures is poor and based on observational studies.

There is much debate about whether continuing bisphosphonate therapy into adulthood is beneficial due to concerns about suppression of bone turnover in the long term. Affected individuals and their parents can find this change in treatment strategy confusing and it is important to explain the underlying rationale in order to manage expectations.

Hypophosphataemic rickets

Hypophosphataemic rickets is described in more detail on page 1052. Adherence to phosphate supplements and, to a lesser extent, vitamin D metabolites represents an important issue in optimising management during childhood and this becomes even more challenging in transitioning patients. While skeletal deformity does not progress following closure of the epiphyses, different problems arise in adolescent patients when there is suboptimal control of hypophosphataemia, including painful pseudofractures and arthralgia associated with enthesopathy. The renal phosphate leak tends to improve to an extent during adolescence and the requirement for phosphate is reduced, but most patients still require treatment with active vitamin D metabolites.

Summary

Young people who have suffered long-term conditions during childhood represent a particularly high-risk group of patients as they progress through adolescence to become young and, finally, mature adults. They bring with them specific medical risks and complications related to their previous medical treatment, and knowledge of these is important to identify the long-term complications of the therapies to which they have been exposed. They are a patient group that can display complex and often abnormal illness behaviour. Understanding this and implementing an effective process for transition from paediatric to adult services can reduce the significant risks that these patients face in early adulthood. As they mature and develop more adult intellectual and emotional behaviour patterns, the risks to their health and well-being reduce. Patients in transition can be a particularly challenging group to manage, but investment of time and effort at this stage of their lives can be extremely rewarding and can bring significant improvements in long-term health-related outcomes.

History

- Slow down the pace
- Ensure the patient can hear
- Establish the speed of onset of the illness
- If the presentation is vague, carry out a systematic enquiry
- Obtain full details of:
  - All drugs, especially any recent prescription changes
  - Past medical history, even from many years previously
  - Usual function: Can the patient walk normally? Has the patient noticed memory problems? Can the patient perform all household tasks?
- Obtain a collateral history: confirm information with a relative or carer and the GP, particularly if the patient is confused or communication is limited by deafness or speech disturbance

Examination

- Thorough to identify all comorbidities
- Tailored to the patient's stamina and ability to cooperate
- Includes functional status: cognitive function, gait and balance, nutrition, and hearing and vision

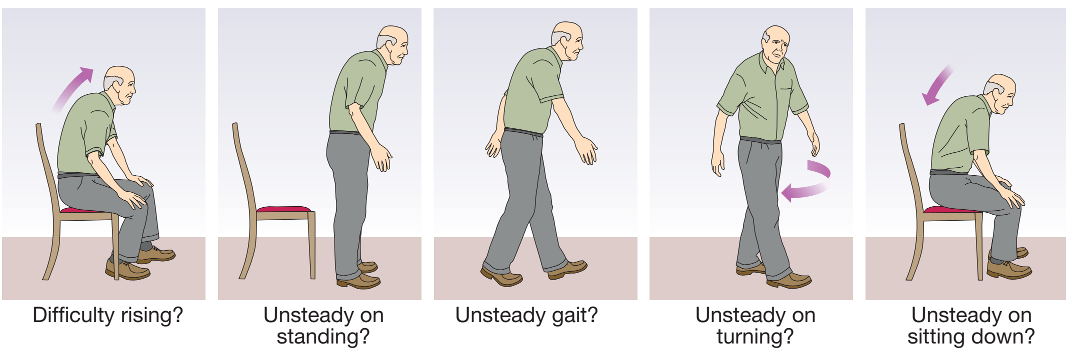
Domains of Comprehensive Geriatric Assessment.

Social assessment

Home circumstances

- Living alone, with another person or in a care home

Activities of daily living (ADL)



- Tasks for which help is needed:
  - Domestic ADL: shopping, cooking, housework
  - Personal ADL: bathing, dressing, walking
- Informal help: relatives, friends, neighbours
- Formal social services: home help, meals on wheels
- Carer stress

Multidisciplinary team (MDT) roles

Team member	Activity assessed and promoted
Physiotherapist	Mobility, balance and upper limb function
Occupational therapist	ADL, such as dressing, cooking Home environment and care needs
Dietitian	Nutrition
Speech and language therapist	Communication and swallowing
Social worker	Care needs and discharge planning; organisation of institutional care
Nurse	Motivation and initiation of activities; promotion of self-care Education Feeding, continence, skin care Communication with relatives and other professionals Assessment of care needs for discharge
Doctor	Diagnosis and management of medical problems Coordinator of assessment, management and rehabilitation programme

12 Get up and go test

To assess gait and balance, ask the patient to stand up from a sitting position, walk 3 m, turn and go back to the chair. A normal performance takes less than 12 seconds.

Sweeping demographic change has meant that older people now represent the core practice of medicine in many countries. A good knowledge of the effects of ageing and the clinical problems associated with old age is therefore essential in most medical specialties. The older population is extremely diverse; a substantial proportion of 90-year-olds enjoy an active healthy life, while some 70-year-olds are severely disabled by chronic disease. The terms ‘chronological’ and ‘biological’ ageing have been coined to describe this phenomenon. Biological rather than chronological age is taken into consideration when making clinical decisions about, for example, the extent of investigation and intervention that is appropriate.

Geriatric medicine is concerned particularly with frail older people, in whom physiological capacity is so reduced that they are incapacitated even by minor illness. They frequently have multiple comorbidities, and acute illness may present in non-specific ways, such as delirium, falls or loss of mobility and day-to-day functioning. These patients are prone to adverse drug reactions, partly because of polypharmacy and partly because of age-related changes in responses to drugs and their elimination (p. 32). Disability is common, but patients’ function can often be improved by the interventions of the multidisciplinary team (p. 1303).

Older people have been neglected in research terms and, until recently, were rarely included in randomised controlled clinical trials. Accordingly, there is often little high-quality evidence on which to base practice.

Demography

The demography of all countries has changed rapidly in recent decades. For example, in the UK, the total population has grown by 11% over the last 30 years, but the number of people aged over 65 years has grown by 24%. The steepest rise occurred in those aged over 85 – from 600 000 in 1981 to 1.5 million in 2011; this number is projected to increase to 2.4 million by 2026, while the working-age population (20–64 years) is expected to grow by only 4% between 2011 and 2026. Similarly, the proportion of people over 65 in India has increased by 35.5% from 76 million in 2000 to 103 million in 2011, which is almost twice the rate of growth of the general population over this period. In both of these countries and many others across the world, the old-age dependency ratio, which is the ratio of people of working age for each person over retirement age, has substantially increased. Since young people support older members of the population both directly and indirectly through taxation and pension contributions, the consequences of a reduced ratio are far-reaching. It is important to emphasise, however, that many older people support the younger population, through the care of children and other older people.

Life expectancy in the developed world is now prolonged, even in old age (Box 32.1); women aged 80 years can expect to live for a further 10 years. However, rates of disability and chronic illness rise sharply with ageing and have a major impact on health and social services. In the UK, the reported prevalence of a chronic illness or disability sufficient to restrict daily activities is around 25% in those aged 50–64, but 66% in men and 75% in women aged over 85.

i 32.1 Mean life expectancy in years, UK and India

	Males		Females	
	UK	India	UK	India
At birth	79.1	65.1	83.0	67.2
At 60 years	22.8	16.7	25.5	18.9
At 70 years	15.0	10.9	17.1	12.4
At 80 years	8.7	7.5	9.9	8.0

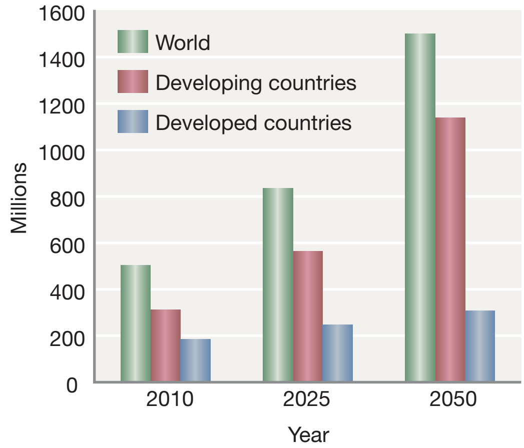


Fig. 32.1 Number of people aged 65 years and over projected in the world population.

Although the proportion of the population aged over 65 years is greater in developed countries, two-thirds of the world population aged over 65 live in developing countries at present, and this is projected to rise to 75% in 2025. The rate of population ageing is much faster in developing countries (Fig. 32.1) and so there will be less time to adjust to its impact.

Functional anatomy and physiology

Biology of ageing

Ageing can be defined as a progressive accumulation through life of random molecular defects that build up within cells and tissues. Eventually, and despite multiple repair and maintenance mechanisms, these result in age-related functional impairment of tissues and organs. There is evidence that variants in many genes contribute to ageing. The implicated genes include those that are involved in regulation of DNA repair, telomere length (p. 41) and insulin signalling. Genetic factors only account for around 25% of the variance in human lifespan, however; nutritional and environmental factors determine the rest. At a cellular level, production of reactive oxygen species is thought to play a major role in ageing. These molecules cause oxidative damage at a number of targets:

- *Nuclear chromosomal DNA*, causing mutations and deletions that ultimately lead to aberrant gene function and potential for malignancy.
- *Telomeres*, the structures at the ends of chromosomes that shorten with each cell division because telomerase (which copies the end of the 3′ strand of linear DNA in germ cells) is absent in somatic cells. When telomeres are sufficiently eroded, cells stop dividing. It has been suggested that telomeres represent a ‘biological clock’ that prevents uncontrolled cell division and cancer. Telomeres are particularly shortened in patients with

premature ageing due to Werner's syndrome, in which DNA is damaged due to lack of a helicase.

- *Mitochondrial DNA and lipid peroxidation*, resulting in reduced cellular energy production and ultimately cell death.
- *Proteins*, especially those that are modified by glycosylation due to spontaneous reactions between proteins and sugars. These damage structure and function of the affected protein, which becomes resistant to breakdown.

The rate at which damage occurs is variable and this is where the interplay with environment, and particularly nutrition, takes place. There is evidence in some organisms that this interplay is mediated by insulin signalling pathways. Chronic inflammation also plays an important role, again in part by driving the production of reactive oxygen species.

Physiological changes of ageing

The physiological features of normal ageing have been identified by examining disease-free populations of older people to separate the effects of pathology from those due to age alone. The fraction of older people who age without disease ultimately declines to very low levels, however, so that use of the term 'normal' becomes debatable. There is a marked increase in inter-individual variation in function with ageing; many physiological processes deteriorate substantially when measured across populations but some individuals show little or no change. This heterogeneity is a hallmark of ageing, meaning that each person must be assessed individually and that the same management cannot be applied unthinkingly to all people of a certain age.

Although some genetic influences contribute to heterogeneity, environmental factors, such as poverty, nutrition, exercise, cigarette smoking and alcohol misuse, play a large part, and a healthy lifestyle should be encouraged even when old age has been reached.

The effects of ageing are usually not enough to interfere with organ function under normal conditions but reserve capacity is significantly reduced. Some changes of ageing, such as depigmentation of the hair, are of no clinical significance. Figure 32.2 shows the many changes that occur with ageing that are clinically important.

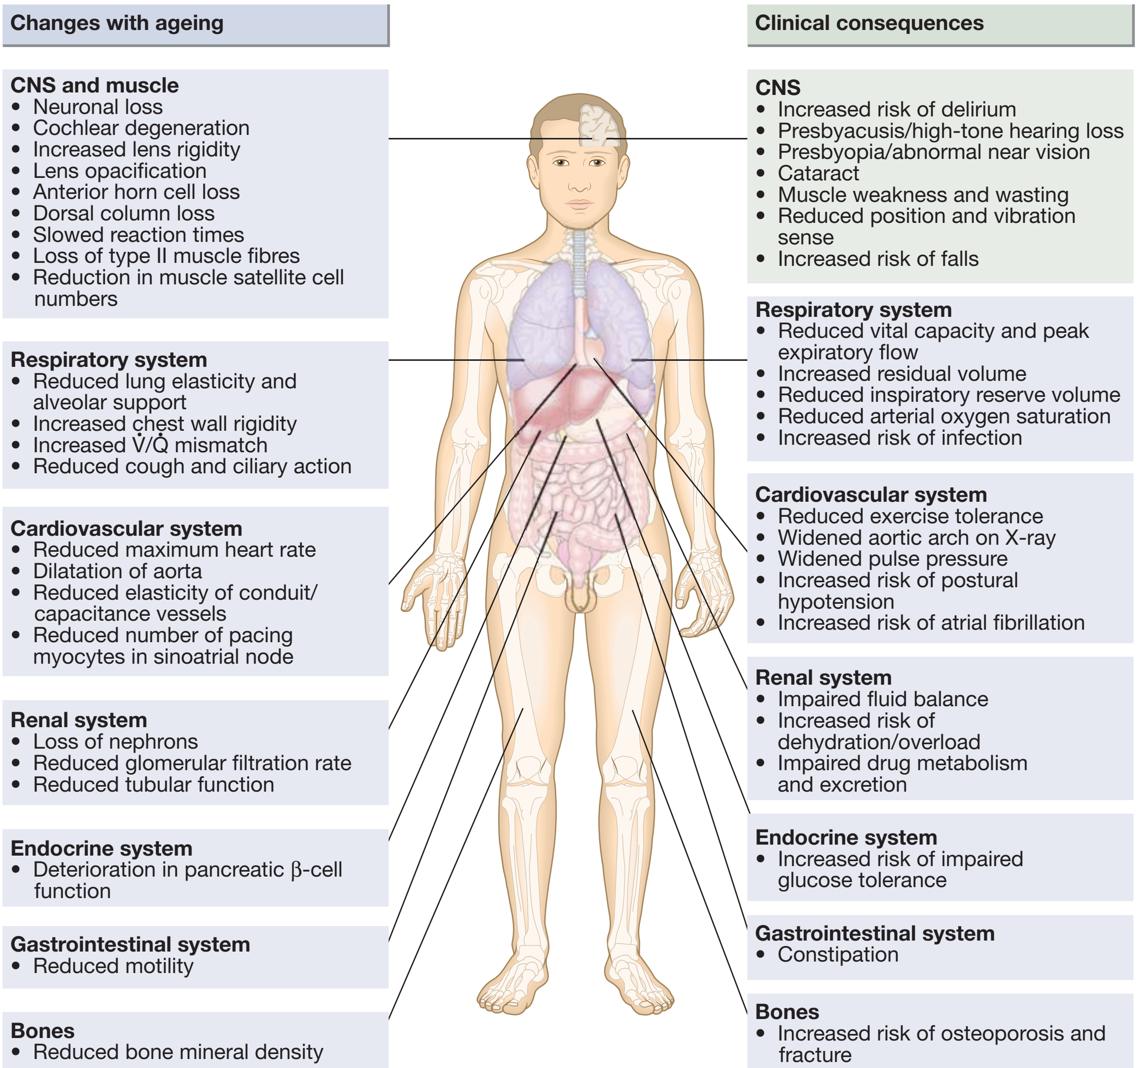

Fig. 32.2 Features and consequences of normal ageing.

Frailty and multimorbidity

Frailty is defined as the loss of an individual's ability to withstand minor stresses because the reserves in function of several organ systems are so severely reduced that even a trivial illness or adverse drug reaction may result in organ failure and death. The same stresses would cause little upset in a fit person of the same age.

It is important to understand the difference between 'disability', 'multimorbidity' and 'frailty'. Disability indicates established loss of function while frailty indicates increased vulnerability to loss of function. Disability may arise from a single pathological event (such as a stroke) in an otherwise healthy individual. After recovery, function is largely stable and the patient may otherwise be in good health. When frailty and disability coexist, function deteriorates markedly even with minor illness, to the extent that the patient can no longer manage independently.

Multimorbidity (the number of diagnoses present) is also not equivalent to frailty; it is quite possible to have several diagnoses without major impact on homeostatic reserve. Multimorbidity is, however, an important concept in its own right and is an almost invariable accompaniment to advanced age. Recent Scottish population-based data show that 60% of those aged 65 and over have at least two chronic diseases. Multimorbidity is a driver for future disability, hospitalisation and death, and often leads to polypharmacy, as multiple medications are used to treat each chronic disease individually. Current health-care systems are poorly equipped to manage multimorbidity; each disease is dealt with by a separate team of specialists, which at best places a high burden on the patient, and at worst leads to mutually incompatible approaches to management of each disease.

Unfortunately, the term 'frail' is often used rather vaguely, sometimes to justify a lack of adequate investigation and intervention in older people. It can be specifically identified, however, by assessing function in a number of domains. Two main approaches to evaluating frailty exist: measurement of physiological function across a number of domains, an example being the Fried Frailty score (Box 32.2), or use of a score based on the number of deficits or problems, such as the Rockwood score.

Frail older people particularly benefit from a clinical approach that addresses both the precipitating acute illness and their underlying loss of reserves. It may be possible to prevent further loss of function through early intervention; for example, a frail woman with myocardial infarction will benefit from specific cardiac investigation and drug treatment, but may benefit even further from an exercise programme to improve musculoskeletal function, balance and aerobic capacity, with nutritional support to restore lost weight. Establishing a patient's level of frailty also helps inform decisions regarding further investigation and management, and the need for rehabilitation.

32.2 How to assess a Fried Frailty score

- Hand grip strength in bottom 20% of healthy elderly distribution*
- Walking speed in bottom 20% of healthy elderly distribution*
- Self-reported exhaustion
- Physical inactivity
- At least 6 kg weight loss within 1 year

Patient is defined as frail if 3 or more factors are present; 1–2 factors indicate a 'pre-frail' state.

*Varies between populations. Grip cut-off is 30 kg for men and 18 kg for women in US adults; 5 m walk time cut-off is 7 seconds in US adults for both sexes.

Investigations

Comprehensive Geriatric Assessment

One of the most powerful tools in the management of older people is the Comprehensive Geriatric Assessment, which identifies all the relevant factors contributing to their presentation (p. 1302). Comprehensive Geriatric Assessment is in fact a misnomer; it is not merely an assessment, but a process of identifying and managing all relevant factors affecting the health and well-being of older people. It is iterative in nature, management being followed by reassessment and a new management plan. In frail patients with multiple pathology, it may be necessary to perform the assessment in stages to allow for their reduced stamina. The outcome should be a management plan that not only addresses the acute presenting problems but also improves the patient's overall health and function.

Comprehensive Geriatric Assessment is performed by a multidisciplinary team (p. 1303). Such an approach was pioneered by Dr Marjory Warren at the West Middlesex Hospital in London in the 1930s; her comprehensive assessment and rehabilitation of supposedly incurable, long-term bedridden older people revolutionised the approach of the medical profession to frail older people and laid the foundations for the modern specialty of geriatric medicine. There is excellent evidence from systematic reviews that Comprehensive Geriatric Assessment, when performed by a specialist team on a specialist geriatric medicine ward, reduces death or deterioration, increases the chances of living independently at home, and may also improve cognitive function in the short to medium term. Current evidence suggests that the process works when delivered on a specialist inpatient unit, but the evidence for effectiveness when it is delivered by a visiting team or in the community is less strong.

Decisions about investigation and treatment

Accurate diagnosis is important at all ages but frail older people may not be able to tolerate lengthy or invasive procedures, and diagnoses may be revealed for which patients could not withstand intensive or aggressive treatment. On the other hand, disability should never be dismissed as due to age alone. For example, it would be a mistake to supply a patient no longer able to climb stairs with a stair lift when simple tests would have revealed osteoarthritis of a hip and vitamin D deficiency, for which appropriate treatment would have restored his or her strength. So how do doctors decide when and how far to investigate?

The views of the patient and family

Older people may have strong views about the extent of investigation and the treatment they wish to receive, and these should be sought from the outset. A key issue is to establish what the patient wants from investigation and treatment. Many

older people do not desire prolongation of life; rather they aspire to maintain physical function, gain relief from symptoms, and preserve the ability to live independently. Such aims differ widely between patients, however, and a careful exploration of what is important to the individual is essential. If the patient wishes, the views of relatives can also be taken into account. If the patient is not able to express a view or lacks the capacity to make decisions because of cognitive impairment or communication difficulties, then relatives' input becomes particularly helpful. They may be able to give information on views previously expressed by the patient or on what the patient would have wanted under the current circumstances. However, families should never be made to feel responsible for difficult decisions.

The patient's general health

Does this patient have the physical and mental capacity to tolerate the proposed investigation? Do they have the aerobic capacity to undergo bronchoscopy? Will delirium prevent them from remaining still in the magnetic resonance imaging (MRI) scanner? The more comorbidities a patient has, the less likely he or she will be able to withstand an invasive intervention.

Will the investigation alter management?

Would the patient be fit for, or benefit from, the treatment that would be indicated if investigation proved positive? The presence of comorbidity and frailty is more important than age itself in determining this. When a patient with severe heart failure and a previous disabling stroke presents with a suspicious mass lesion on chest X-ray, detailed investigation and staging may not be appropriate if they are not fit for surgery, radical radiotherapy or chemotherapy. On the other hand, if the same patient presented with dysphagia, investigation of the cause would be important, as they might be able to tolerate endoscopic treatment (for example, to palliate an obstructing oesophageal carcinoma).

Will management benefit the patient?

It is important to consider whether interventions that might be considered as standard-of-care for younger people are likely to be beneficial in frail older people. For example, while oral anticoagulation might be indicated by guidelines for a patient with atrial fibrillation, such treatment may not accord with the wishes of a patient in a care home who finds regular blood tests distressing, or who is more worried about bleeding than about avoiding a stroke. Another example would be the use of anti-osteoporosis medications to reduce the risk of fracture in very old patents, where the risk of death from other causes would be greater than the risk of fracture.

Advance directives

Advance directives or 'living wills' are statements made by adults at a time when they have the capacity to decide about the interventions they would refuse or accept in the future, should they no longer be able to make decisions or communicate them. An advance directive cannot authorise a doctor to do anything that is illegal and doctors are not bound to provide a specific treatment requested if, in their professional opinion, it is not clinically appropriate. However, any advance refusal of treatment, made when the patient was able to make decisions based on adequate information about their implications, is legally binding in the UK. It must be respected when it clearly applies to the patient's present circumstances and when there is no reason to believe that the patient has changed his or her mind.

Presenting problems in geriatric medicine

Characteristics of presenting problems in old age

Problem-based practice is central to geriatric medicine. Most problems are multifactorial and there is rarely a single unifying diagnosis. All contributing factors have to be taken into account and attention to detail is paramount. Two patients who share the same presenting problem may have completely disparate diagnoses. A wide knowledge of adult medicine is required, as disease in any, and often many, of the organ systems has to be managed at the same time. There are a number of features that are particular to older patients.

Late presentation

Many people (of all ages) accept ill health as a consequence of ageing and may tolerate symptoms for lengthy periods before seeking medical advice. Comorbidities may also contribute to late presentation; in a patient whose mobility is limited by stroke, angina may only present when coronary artery disease is advanced, as the patient has been unable to exercise sufficiently to cause symptoms at an earlier stage.

Atypical presentation

Infection may present with delirium and without clinical pointers to the organ system affected. Stroke may present with falls rather than symptoms of focal weakness. Myocardial infarction may present as weakness and fatigue, without chest pain or dyspnoea. The reasons for these atypical presentations are not always easy to establish. Perception of pain is altered in old age, which may explain why myocardial infarction presents in other ways. The pyretic response is blunted in old age so that infection may not be obvious at first. Cognitive impairment may limit the patient's ability to give a history of classical symptoms.

Acute illness and changes in function

Atypical presentations in frail elderly patients include 'failure to cope', 'found on floor', 'delirium' and 'off feet', but these are *not* diagnoses. The possibility that an acute illness has been the precipitant must always be considered. To establish whether the patient's current status is a change from his or her usual level of function, it helps to ask a relative or carer (by phone if necessary). Investigations aimed at uncovering an acute illness will not be fruitful in a patient whose function has been deteriorating over several months but are important if function has suddenly changed.

Multiple pathology

Presentations in older patients have a more diverse differential diagnosis because multiple pathology is so common. There are frequently a number of causes for any single problem, and adverse effects from medication often contribute. A patient may fall because of osteoarthritis of the knees, postural hypotension due to diuretic therapy for hypertension, and poor vision due to cataracts. All these factors have to be addressed to prevent further falls and this principle holds true for most of the common presenting problems in old age.

32.3 Screening investigations for acute illness

- Full blood count
- Urea and electrolytes, liver function tests, calcium and glucose
- Chest X-ray
- Electrocardiogram
- C-reactive protein: useful marker for occult infection or inflammatory disease
- Blood cultures if pyrexial

Approach to presenting problems in old age

For the sake of clarity, the common presenting problems are described individually but, in reality, older patients often present with several at the same time, particularly delirium, incontinence and falls. These share some underlying causes and may precipitate each other.

The approach to most presenting problems in old age can be summarised as follows:

- *Obtain a collateral history.* Find out the patient's usual status with regard to mobility and cognitive function from a relative or carer. Call these people by phone if they are not present.
- *Check all medication.* Have there been any recent changes?
- *Search for and treat any acute illness* (Box 32.3).
- *Identify and reverse predisposing risk factors.* These depend on the presenting problem.

Falls

Around 30% of those over 65 years of age fall each year and this figure rises to more than 40% in those aged over 80. Although only 10–15% of falls result in serious injury, virtually all fragility fractures in the elderly are caused by falls. Age-related osteoporosis contributes to the dramatic rise in hip and other fragility fractures that occurs with ageing but the most important contributory factor is an increased risk of falling (Fig. 32.3). Falls also lead to loss of confidence and fear, and are frequently the 'final straw' that makes an older person decide to move to institutional care. Management will vary according to the underlying cause.

Acute illness

Falls are one of the classical atypical presentations of acute illness in frail people. The reduced reserves in older people's neurological function mean that they are less able to maintain their balance when challenged by an acute illness. Suspicion should be high when falls have suddenly occurred over a period of a few days. Common underlying illnesses include infection, stroke, metabolic disturbance and heart failure. Thorough examination and investigation are required (Box 32.3). It is also important to establish whether any drug that precipitates falls, such as a psychotropic or hypotensive agent, has been started recently. Once the underlying acute illness has been treated, falls may stop.

Blackouts

A proportion of older people who 'fall' have, in fact, had a syncopal episode. A collateral history from a witness is of utmost importance

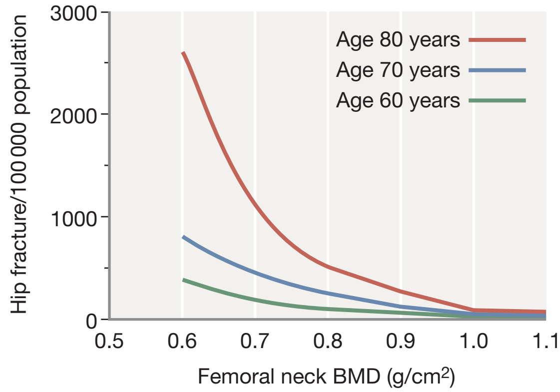

Fig. 32.3 Age and bone mineral density (BMD) interact to influence fracture risk.

32.4 Risk factors for falls

- Muscle weakness
- History of falls
- Gait or balance abnormality
- Use of a walking aid
- Visual impairment
- Arthritis
- Impaired activities of daily living
- Depression
- Cognitive impairment
- Age over 80 years
- Psychotropic medication

in anyone falling over; people who lose consciousness do not always remember having done so. If loss of consciousness is suggested by the patient or witness, it is important to perform appropriate investigations (pp. 181 and 1080).

Mechanical and recurrent falls

Among patients who have tripped or are uncertain how they fell, those who have fallen more than once in the past year and those who are unsteady during a 'get up and go' test (p. 1303) require further assessment. Patients with recurrent falls are commonly frail, with multiple medical problems and chronic disabilities. Obviously, such patients may present with a fall resulting from an acute illness or syncope but they will remain at risk of further falls even when the acute illness has resolved. The risk factors for falls (Box 32.4) should be considered. If problems are identified with muscle strength, balance, vision or cognitive function, the causes of these must be identified by specific investigation, and treatment commenced if appropriate. Careful assessment of the patient's gait may provide important clues to an underlying diagnosis (Box 32.5). Common pathologies identified include cerebrovascular disease (Ch. 26), Parkinson's disease (p. 1112) and osteoarthritis of weight-bearing joints (p. 1007). Calculation of fracture risk using tools such as FRAX or QFracture should be performed and dual X-ray absorptiometry (DXA) bone density scanning considered in patients with a 10-year risk of major fracture of more than 10%.

Prevention of falls and fractures

Falls can be prevented by multiple risk factor intervention (Box 32.6). The most effective intervention is balance and strength training by physiotherapists or exercise practitioners; an alternative with good evidence is tai chi training. An assessment of the

32.5 Abnormal gaits and probable causes

Gait abnormality	Probable cause
Antalgic	Arthropathy
Waddling	Proximal myopathy
Stamping	Sensory neuropathy
Foot drop	Peripheral neuropathy or radiculopathy
Ataxic	Sensory neuropathy or cerebellar disease
Shuffling/festination	Parkinson's disease
Marche à petits pas	Small-vessel cerebrovascular disease
Hemiplegic	Cerebral hemisphere lesion
Apraxic	Bilateral hemisphere lesions

32.6 Interventions to reduce the risk of falls and fractures

- Exercise (should include components of lower limb strength and balance training):
  - Multimodal group exercise and tai chi both effective
- Calcium and vitamin D supplementation:
  - Evidence of effectiveness only in patients in institutional care
  - Large doses of vitamin D may increase risk of falls and fractures
- Home environment assessment and modification
- Medication review:
  - Particularly medications with central actions such as hypnotics but also those with anticholinergic and hypotensive actions
- Cataract surgery:
  - Effective if for first cataract
  - Other vision interventions ineffective and may increase falls risk
- Anti-slip shoes:
  - Effective only in icy conditions
- Cardiac pacemaker for carotid sinus hypersensitivity

patient's home environment for hazards should be undertaken by an occupational therapist, who may also provide personal alarms so that patients can summon help, should they fall again. Rationalising psychotropic medication may help to reduce sedation, although many older patients are reluctant to stop hypnotics. If postural hypotension is present (defined as a drop in blood pressure of >20 mmHg systolic or >10 mmHg diastolic pressure on standing from supine), reducing or stopping hypotensive drugs may be helpful. Evidence supporting the efficacy of other interventions for postural hypotension is lacking but drugs, including fludrocortisone and midodrine, are sometimes used to try to improve dizziness on standing. Other interventions, such as cataract extraction and podiatry, can also have a significant impact on function in those who fall.

If osteoporosis is diagnosed, specific drug therapy should be considered (p. 1046). In the frailest patients, such as those in institutional care, calcium and vitamin D_3 administration has been shown to reduce both falls and fracture rates, probably by exerting positive effects on bone mineral density and on neuromuscular function. Supplementation does not reduce falls risk beyond this very frail group, however, and very high doses of vitamin D may paradoxically increase the risk of falls and fractures.

In the UK, government policy and National Institute for Health and Clinical Excellence guidelines (www.nice.org.uk) for falls prevention have led to the development of specific Falls and Fracture Prevention Services in many parts of the country.

Dizziness

Dizziness is very common, affecting at least 30% of those aged over 65 years in community surveys. It can be disabling in its own right and is also a risk factor for falls. Acute dizziness is relatively straightforward and common causes include:

- *hypotension* due to arrhythmia, myocardial infarction, gastrointestinal bleed or pulmonary embolism
- *posterior fossa stroke* onset
- *vestibular neuronitis*.

Although older people more commonly present with recurrent dizzy spells and often find it difficult to describe the sensation they experience, the most effective way of establishing the cause(s) of the problem is nevertheless to determine which of the following is predominant (even if more than one is present):

- *lightheadedness*, suggestive of reduced cerebral perfusion
- *vertigo*, suggestive of labyrinthine or brainstem disease (p. 1086)
- *unsteadiness/poor balance*, suggestive of joint or neurological disease.

In lightheaded patients, structural cardiac disease (such as aortic stenosis) and arrhythmia must be considered, but disorders of autonomic cardiovascular control, such as vasovagal syndrome and postural hypotension, are the most common causes in old age. Antihypertensive medications may exacerbate these conditions. Further investigation and treatment are described on page 181.

Vertigo in older patients is most commonly due to benign positional vertigo (p. 1086), but if other brainstem symptoms or signs are present, MRI of the brain is required to exclude a cerebello-pontine angle lesion.

Delirium

Delirium is a syndrome of transient, reversible cognitive dysfunction that affects 30% of older hospital inpatients. Differential diagnosis, assessment and management are discussed on page 183.

Urinary incontinence

Urinary incontinence is defined as the involuntary loss of urine and comes to medical attention when sufficiently severe to cause a social or hygiene problem. It occurs in all age groups but becomes more prevalent in old age, affecting about 15% of women and 10% of men aged over 65. It may lead to skin damage if severe and can be socially restricting. While age-dependent changes in the lower urinary tract predispose older people to incontinence, it is not an inevitable consequence of ageing and requires investigation and appropriate treatment. Urinary incontinence is frequently precipitated by acute illness in old age and is commonly multifactorial (Fig. 32.4).

The initial assessment should seek to identify and address contributory factors. If incontinence fails to resolve, further diagnosis and management should be pursued, as described on page 437.

- *Urge incontinence* is usually due to detrusor over-activity and results in urgency and frequency.
- *Stress incontinence* is almost exclusive to women and is due to weakness of the pelvic floor muscles, which allows leakage of urine when intra-abdominal pressure rises, such as on coughing. It may be compounded by atrophic

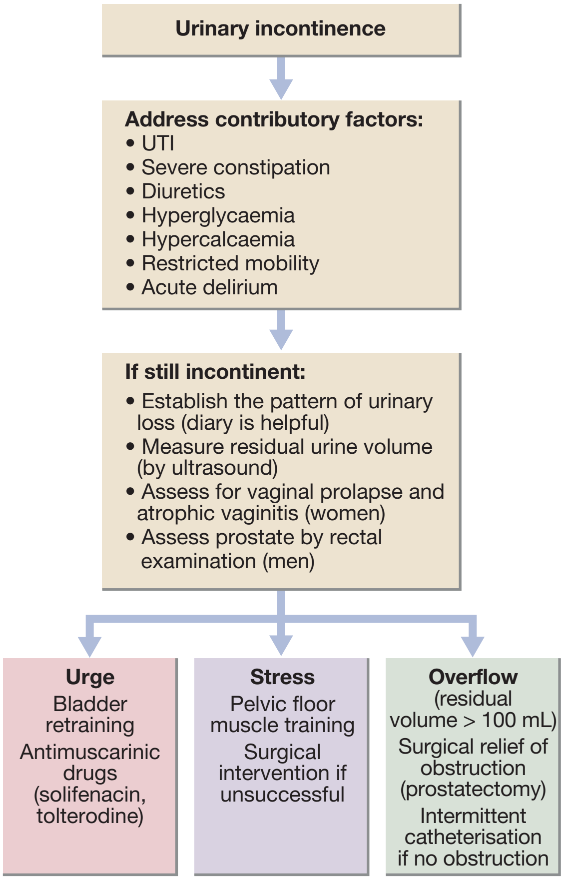

Fig. 32.4 Assessment and management of urinary incontinence in old age. See also page 436 and NICE guideline on the Management of Incontinence in Women: nice.org.uk. (UTI = urinary tract infection)

vaginitis, associated with oestrogen deficiency in old age, which can be treated with oestrogen pessaries.

- *Overflow incontinence* is most commonly seen in elderly men with prostatic enlargement, which obstructs bladder outflow.

In patients with severe stroke disease or dementia, treatment may be ineffective, as frontal cortical inhibitory signals to bladder emptying are lost. A timed/prompted toileting programme may help. Other than in overflow incontinence, urinary catheterisation should never be viewed as first-line management, but may be required as a final resort if the perineal skin is at risk of breakdown or quality of life is affected.

Prescribing and deprescribing

The large number of comorbidities that accompany ageing often leads to polypharmacy. This has been defined as the use of four or more drugs, and is associated with several adverse outcomes including falls, hospitalisation and increased risk of death. While some of these outcomes are caused by drug–drug interactions and adverse effects, others are as much due to the underlying multimorbidities for which the drugs were prescribed in the first place

In view of this, it is essential for prescribing for older people to be appropriate. For many older people, taking multiple drugs is appropriate, as such therapy is required to treat multiple diseases (Box 32.7). However, the more drugs that are taken, the greater the risk of an adverse drug reaction (ADR). ADRs and the effects of drug interactions are discussed on page 21. They may result in symptoms, abnormal physical signs and altered laboratory test results (Box 32.8). ADRs are the cause of around 5% of all hospital admissions but account for up to 20% of admissions in those aged over 65. The risk of polypharmacy is compounded by age-related changes in pharmacodynamic and pharmacokinetic factors (p. 14), and by impaired homeostatic mechanisms, such as baroreceptor responses, plasma volume and electrolyte control.

Older people are thus especially sensitive to drugs that can cause postural hypotension or volume depletion (Box 32.8). Non-adherence to drug therapy also rises with the number of drugs prescribed.

The clinical presentations of ADRs are diverse, so for *any* presenting problem in old age the possibility that the patient's medication is a contributory factor should *always* be considered. Failure to recognise this may lead to the use of a further drug to treat the problem, making matters worse, when the better

32.7 Factors leading to polypharmacy in old age

- Multiple pathology
- Poor patient education (see Box 2.20, p. 31)
- Lack of routine review of all medications
- Patient expectations of prescribing
- Over-use of drug interventions by doctors
- Attendance at multiple specialist clinics
- Poor communication between specialists

32.8 Common adverse drug reactions in old age

Drug class	Adverse reaction
NSAIDs	Gastrointestinal bleeding and peptic ulceration Renal impairment
Diuretics	Renal impairment, electrolyte disturbance Gout Hypotension, postural hypotension
Warfarin	Bleeding
ACE inhibitors	Renal impairment, electrolyte disturbance Hypotension, postural hypotension
β-blockers	Bradycardia, heart block Hypotension, postural hypotension
Opiates	Constipation, vomiting Delirium Urinary retention
Antidepressants	Delirium Hyponatraemia (SSRIs) Hypotension, postural hypotension Falls
Benzodiazepines	Delirium Falls
Anticholinergics	Delirium Urinary retention Constipation

(ACE = angiotensin-converting enzyme; NSAIDs = non-steroidal anti-inflammatory drugs; SSRIs = selective serotonin re-uptake inhibitors)

course would be to stop or reduce the dose of the offending drug or to find an alternative.

Appropriate prescribing and deprescribing

The key to appropriate prescribing is first to ensure that medications are started only for reasons that accord with the patient's goals and wishes. Thoughtless adherence to guidelines quickly leads to polypharmacy that may be inappropriate. Some medications (such as chronic use of non-steroidal anti-inflammatory medications) are much less suitable for older people because of the much higher risk of side-effects. Other medications, such as statins and bisphosphonates, lack evidence of efficacy in very old people, who may not live for long enough to derive benefit.

Deprescribing is as important as prescribing in older people. Regular review of medications should be undertaken to ensure that medications are still required, to establish that they are still working, to check that they are not causing side-effects, and to ascertain whether the patient is actually taking them. If any of the above issues is problematic, the medication should be deprescribed. This may need to be done in a controlled manner, with dose reduction to ensure that rebound symptoms or withdrawal effects do not occur. The patient or carer should therefore be asked to bring all medication for review rather than the doctor relying on previous records; such reviews should take place regularly, not just at a point of crisis such as after a fall or on hospital admission.

Other problems in old age

A vast range of other presenting problems in older people present to many medical specialties. End-of-life care is an important facet of clinical practice in old age and is discussed on page 1354. Relevant sections in other chapters are referenced in Box 32.9.

Within each chapter, 'In Old Age' boxes highlight the areas in which presentation or management differs from that in younger individuals.

i 32.9 Other presenting problems in old age

• Hypothermia	p. 166
• Dizziness and blackouts	p. 181
• Delirium	p. 183
• Infection	pp. 218 and 228
• Fluid balance problems	p. 360
• Heart failure	p. 466
• Atrial fibrillation	p. 472
• Hypertension	p. 512
• Under-nutrition	p. 710
• Diabetes mellitus	p. 732
• Peptic ulceration	p. 801
• Anaemia	p. 954
• Painful joints	p. 992
• Bone disease and fracture	pp. 994 and 1049
• Stroke	p. 1147
• Dementia	p. 1191

Rehabilitation

Rehabilitation aims to improve the ability of people of all ages to perform day-to-day activities and to optimise their physical, mental and social capabilities. Acute illness in older people is often associated with loss of their usual ability to walk or care for themselves, and common disabling conditions such as stroke, fractured neck of femur, arthritis and cardiorespiratory disease become increasingly prevalent with advancing age. Doctors tend to focus on health conditions and impairments but patients are more concerned with the effect on their activities and ability to participate in everyday life.

The rehabilitation process

Rehabilitation is a problem-solving process focused on improving the patient's physical, psychological and social function. It entails:

- *Assessment.* The nature and extent of the patient's problems can be identified using the International Classification of Functioning, Disability and Health framework, which focuses on health conditions (such as stroke), the associated physical impairments (such as arm weakness caused by the stroke), the effect on activity (such as the inability to dress oneself due to arm weakness) and restriction of participation in activities (such as inability to go out of the house due to the inability to dress oneself). Such an approach helps to ensure a whole-person approach to participation in society, rather than a focus merely on disease. Specific assessment scales, such as the Elderly Mobility Scale or Barthel Index of Activities of Daily Living (Box 32.10), are useful to quantify components of disability but additional assessment is needed to determine the underlying causes or the interventions required in individual patients.
- *Goal-setting.* Goals should be specific to the patient's problems, realistic, and agreed between the patient and the rehabilitation team.
- *Intervention.* This includes the active treatments needed to achieve the established goals and to maintain the patient's health and quality of life. Interventions include hands-on treatment by therapists using a functional, task-orientated approach to improve day-to-day activities, and also psychological support and education. The emphasis on the type of intervention will be individualised, according to the patient's disabilities, psychological status and progress. The patient and carer(s) must be active participants.
- *Re-assessment.* There is ongoing re-evaluation of the patient's function and progress towards the goals by the rehabilitation team, the patient and the carer. Interventions may be modified as a result.

Multidisciplinary team working

The core rehabilitation team includes all members of the multidisciplinary team (p. 1303). Others may also be involved, such as audiometrists to correct hearing impairment, podiatrists for foot problems, and orthoticists where a prosthesis or splinting is required. Good communication and mutual respect are essential. Regular team meetings allow sharing of assessments, agreement on rehabilitation goals and interventions, evaluation of progress and planning for the patient's discharge home. Rehabilitation is *not* when the doctor orders 'physiotherapy' or 'a home visit' and takes no further role.

32.10 How to assess dependency using the Modified Barthel Index*

Mobility	Independent = 3 Needs help = 2 Wheelchair independent = 1 Immobile = 0
Stairs	Independent = 2 Needs help = 1 Unable = 0
Transfers (e.g. from bed to chair)	Independent = 3 Needs minor help = 2 Needs major help = 1 Unable = 0
Bladder	Continent = 2 Occasional incontinence = 1 Incontinent = 0
Bowels	Continent = 2 Occasional incontinence = 1 Incontinent = 0
Grooming	Independent = 1 Needs help = 0
Toilet use	Independent = 2 Needs help = 1 Unable = 0
Feeding	Independent = 2 Needs help = 1 Unable = 0
Dressing	Independent = 2 Needs some help = 1 Completely dependent = 0
Bathing	Independent = 1 Needs help = 0

*The 20-point version is illustrated. The total score reflects the degree of dependency; scores of 14 and above are usually consistent with living in the community; scores below 10 suggest the patient is heavily dependent on carers.

Rehabilitation outcomes

There is evidence that rehabilitation improves functional outcomes in older people following acute illness, stroke and hip fracture. It also reduces mortality after stroke and hip fracture. These benefits accrue from complex multicomponent interventions, but occupational therapy to improve personal ADLs and individualised exercise interventions have now been shown to be effective in improving functional outcome in their own right.

Oncology

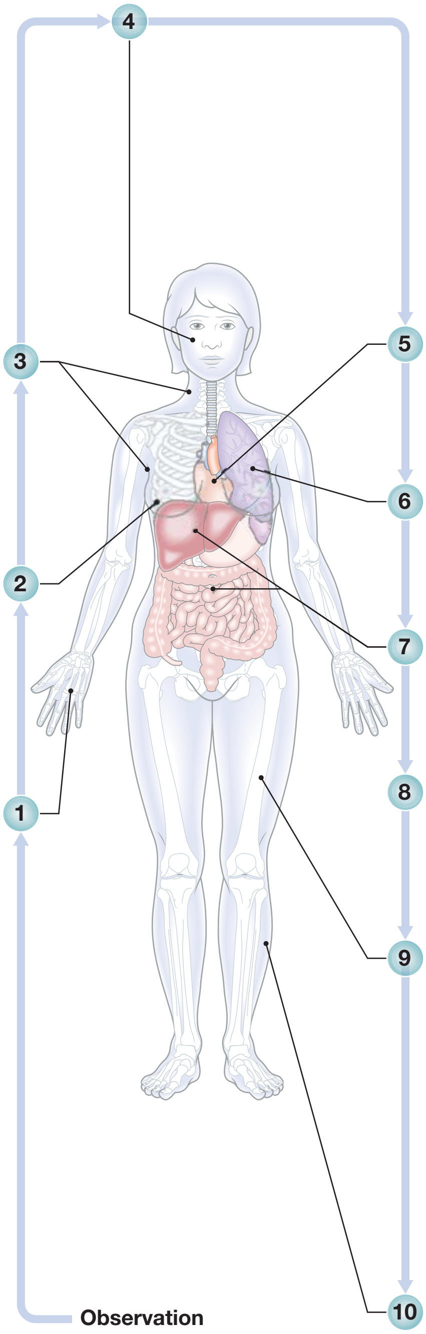
Clinical examination of the cancer patient

4 Face
Conjunctival pallor
Icterus, jaundice
Horner's syndrome
Cushingoid features

3 Lymph nodes
Neck
Supraclavicular
Axillary
Antecubital
Inguinal
Para-aortic

2 Breast

▲ Skin tethering above the nipple



1 Hands
Clubbing
Signs of smoking
Pallor
Tylosis of palms

▲ Finger clubbing in lung cancer

▲ Cushing's syndrome in a patient with ectopic adrenocorticotrophic hormone (ACTH) production

Observation
- Skin changes
- Ascites
- Cushingoid appearance
- Cachexia
- Dehydration

5 Cardiovascular
Superior vena cava (SVC) obstruction
Atrial fibrillation
Pericardial effusion
Hypo-/hypertension

▲ SVC obstruction in a patient with a mediastinal mass

6 Respiratory
Stridor
Consolidation
Pleural effusion

7 Abdomen
Surgical scars
Umbilical nodule
Mass in epigastrium
Visible peristalsis
Abdominal distension
Ascites
Hepatomegaly
Splenomegaly
Renal mass
Pelvic or adnexal mass

▲ Ascites (ovarian carcinoma)

8 Neurological

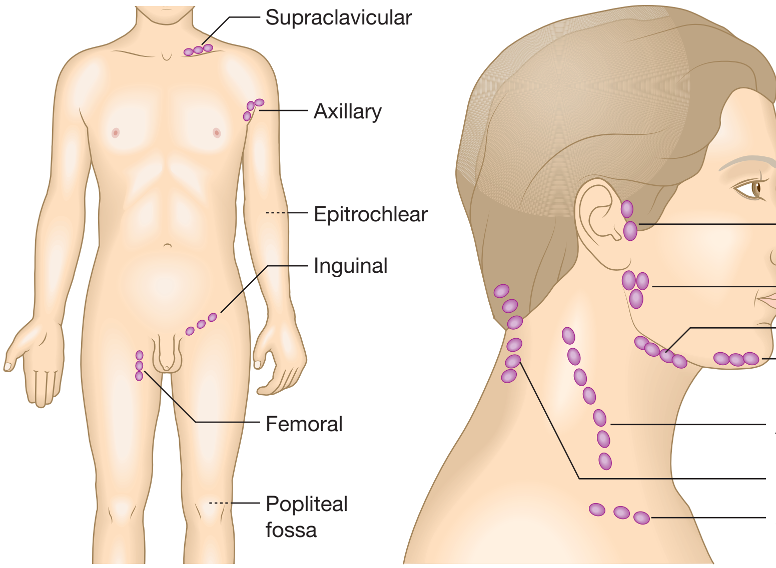
Sensory deficit
Spinal cord compression
Memory deficit
Personality change

9 Skeletal survey
Focal bone tenderness (pelvis, spine, long bones)
Wrist tenderness (hypertrophic pulmonary osteoarthropathy)

10 Periphery
Calf tenderness, venous thrombosis
Clubbing (if present in hands)

i Examination of the skin



Important features of skin lesions that should alert suspicion include:

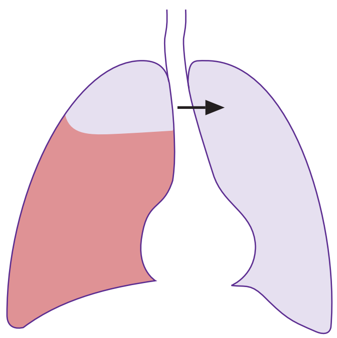
- Asymmetry: irregular shape
- Bleeding
- Border: not a smooth edge
- Colour: uneven, variegated or changing colour
- Diameter: >6 mm in diameter or growing
- Itching or pain in a pre-existing mole

7 Abdominal examination

- Are there scars from previous surgery?
- Is the umbilicus everted, suggesting ascites?
- Is there a firm nodule at the umbilicus due to ovarian or gastric cancer metastasis, causing a Sister Mary Joseph nodule (p. 1334)?
- Is there smooth hepatomegaly – possibly primary liver cancer or heart failure?
- Is the liver firm or knobbly, suggesting metastasis?
- Is the ascites too tense to demonstrate hepatomegaly?
- Are other masses palpable in the abdomen?
- Are there signs of obstruction or paralytic ileus with absence of bowel sounds?
- Palpate for inguinal nodes (occasionally involved in ovarian cancer)
- Percuss for flank dullness and shifting dullness
- Perform vaginal and rectal examinations to detect adnexal or rectal masses

3 Examination of the lymph nodes

5 Superior vena cava obstruction



- Venous distension of neck
- Elevated but non-pulsatile jugular venous pulse
- Venous distension of chest wall
- Facial oedema
- Cyanosis
- Plethora of face
- Oedema of arms

5 Pericardial effusion

- Tachycardia
- Falling blood pressure
- Rising jugular venous pressure
- Muffled heart sounds
- Kussmaul's sign (p. 544)

6 Malignant pleural effusions

Large right pleural effusion

Trachea and apex may be moved to L
Percussion
Stony dull
R mid- and lower zones
Auscultation
Absent breath sounds and diminished or absent vocal resonance R base
Crackles above effusion

Cancer represents a significant economic burden for the global economy and is now the third leading cause of death worldwide. By 2030, it is projected that there will be 26 million new cancer cases and 17 million cancer deaths per year. The developing world is disproportionately affected by cancer and in 2008 developing nations accounted for 56% of new cancer cases and 75% of cancer deaths. These deaths happen in countries with limited or no access to treatment and with low per capita expenditure on health care.

The most common solid organ malignancies arise in the lung, breast and gastrointestinal tract (Fig. 33.1), but the most common form worldwide is skin cancer. Cigarette smoking accounts for more than 20% of all global cancer deaths, 80% of lung cancer cases in men and 50% of lung cancer cases in women worldwide, which could be prevented by smoking cessation. Diet and alcohol contribute to a further 30% of cancers, including those of the stomach, colon, oesophagus, breast and liver. Lifestyle modification could reduce these if steps were taken to avoid animal fat and red meat, reduce alcohol, increase fibre, fresh fruit and vegetable intake, and avoid obesity. Infections account for a further 15% of cancers, including those of the cervix, stomach, liver, nasopharynx and bladder, and some of these could be prevented by infection control and vaccination.

The 10 hallmarks of cancer

The formation and growth of cancer constitute a multistep process, during which sequentially occurring gene mutations result in the formation of a cancerous cell. For cells to initiate carcinogenesis successfully, they require key characteristics, collectively referred to as the hallmarks of cancer.

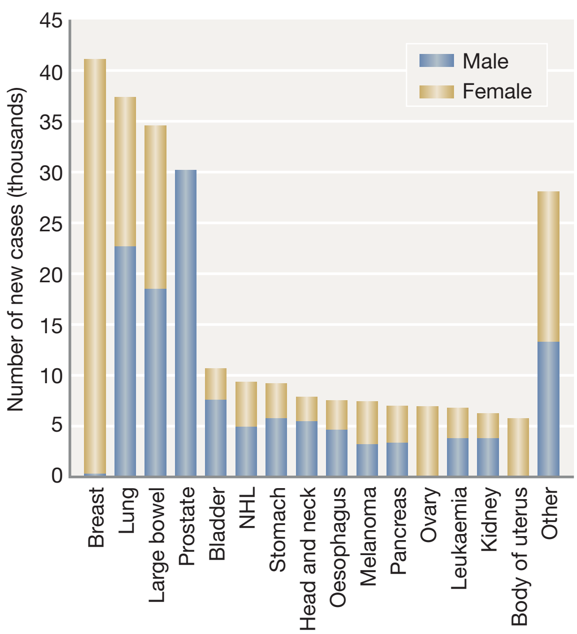

Fig. 33.1 The most commonly diagnosed cancers in the UK. (NHL = non-Hodgkin lymphoma) *Statistics from Cancer Research UK website (http://info.cancerresearchuk.org).*

1. Genome instability and mutation

Random genetic mutations occur continuously throughout all cells of the body and very rarely confer a selective advantage on single cells, allowing overgrowth and dominance in local tissue environments. Multistep carcinogenesis results from successive clonal expansions of pre-malignant cells, each expansion being triggered by acquisition of a random enabling genetic mutation. Under normal circumstances, cellular DNA repair mechanisms are so effective that almost all spontaneous mutations are corrected without producing phenotypic changes, keeping the overall mutation rates very low. In cancer cells, the accumulation of mutations can be accelerated by compromising the surveillance systems that normally monitor genomic integrity and force genetically damaged cells into either senescence or apoptosis. They can therefore become more sensitive to mutagenic actions or develop DNA repair mechanism failure.

2. Resisting cell death

There are three principal mechanisms through which cell death occurs in healthy tissues: apoptosis, autophagy and necrosis.

Apoptosis

This is programmed cell death. It is frequently found at markedly reduced rates in cancers, particularly those of high grade or those resistant to treatment. The cellular apoptotic system has regulatory elements that sense intrinsic and extrinsic pro-apoptotic signals and initiate a cascade of proteolysis and cell disassembly with nuclear fragmentation, chromosomal condensation, and shrinking of the cell with loss of intercellular contact, followed by cellular fragmentation and the formation of apoptotic bodies that are phagocytosed by neighbouring cells. The most important regulator of apoptosis is the *TP53* tumour suppressor gene, often described as the 'guardian of the genome', as it is able to induce apoptosis in response to sufficient levels of genomic damage. The largest initiator of apoptosis via *TP53* is cellular injury, particularly that due to DNA damage from chemotherapy, oxidative damage and ultraviolet (UV) radiation.

Autophagy

This is a catabolic process during which cellular constituents are degraded by lysosomal machinery within the cell. It is an important physiological mechanism; it usually occurs at low levels in cells but can be induced in response to environmental stresses, particularly radiotherapy and cytotoxic chemotherapy, which induce elevated levels of autophagy that are cytoprotective for malignant cells, thus impeding rather than perpetuating the killing actions of these stress situations. Severely stressed cancer cells have been shown to shrink via autophagy to a state of reversible dormancy.

Necrosis

This is the premature death of cells and is characterised by the release of cellular contents into the local tissue microenvironment, in marked contrast to apoptosis, where cells are disassembled in a step-by-step fashion and the resulting cellular fragments are phagocytosed. Necrotic cell death results in the recruitment of inflammatory immune cells, promotion of angiogenesis, and release of stimulatory factors that increase cellular proliferation

and tissue invasion, thereby enhancing rather than inhibiting carcinogenesis.

3. Sustaining proliferative signalling

Cancer cells can sustain proliferation beyond what would be expected for normal cells; this is typically due to growth factors, which are able to bind to cell surface-bound receptors that activate an intracellular tyrosine kinase-mediated signalling cascade, ultimately leading to changes in gene expression and promoting cellular proliferation and growth. Sustained proliferative capacity can result from over-production of growth factor ligands or receptors and production of structurally altered receptors, which can signal in the absence of ligand binding and activation of intracellular signalling pathway components, so that signalling is no longer ligand-dependent.

The cell cycle

The cell cycle is composed of four ordered, strictly regulated phases referred to as G_1 (gap 1), S (DNA synthesis), G_2 (gap 2) and M (mitosis) (Fig. 33.2). Normal cells grown in culture will stop proliferating and enter a quiescent state called G_0 once they become confluent or are deprived of serum or growth factors. The first gap phase (G_1) prior to the initiation of DNA synthesis represents the period of commitment that separates M and S phases as cells prepare for DNA duplication. Cells in G_0 and G_1 are receptive to growth signals, but once they have passed a restriction point, they are committed to enter DNA synthesis (S phase). Cells demonstrate arrest at different points in G_1 in response to different inhibitory growth signals. Mitogenic signals promote progression through G_1 to S phase, utilising phosphorylation of the retinoblastoma gene product (pRB, p. 40). Following DNA synthesis, there is a second gap phase (G_2) prior to mitosis (M), allowing cells to repair errors that have occurred during DNA replication and thus preventing propagation of these errors to daughter cells. Although the duration of individual phases may vary, depending on cell and tissue type, most adult cells are in a G_0 state at any one time.

Cell cycle regulation

The cell cycle is orchestrated by a number of molecular mechanisms: most importantly, by cyclins and cyclin-dependent kinases (CDKs). Cyclins bind to CDKs and are regulated by both activating and inactivating phosphorylation, with two main checkpoints at G_1/S and G_2/M transition. The genes that inhibit progression play an important part in tumour prevention and are referred to as tumour suppressor genes (e.g. *TP53*, *TP21*, *TP16* genes). The products of these genes deactivate the cyclin–CDK complexes and are thus able to halt the cell cycle. The complexity of cell cycle control is susceptible to dysregulation, which may produce a malignant phenotype.

Stimulation of the cell cycle

Many cancer cells produce growth factors, which drive their own proliferation by a positive feedback known as autocrine stimulation. Examples include transforming growth factor-alpha (TGF-α) and platelet-derived growth factor (PDGF). Other cancer cells express growth factor receptors at increased levels due to gene amplification or express abnormal receptors that are permanently activated. This results in abnormal cell growth in response to physiological growth factor stimulation or even in the absence of growth factor stimulation (ligand-independent signalling). The epidermal growth factor receptor (EGFR) is often over-expressed in lung and gastrointestinal tumours and the human epidermal growth factor receptor 2 (HER2)/neu receptor is frequently over-expressed in breast cancer. Both receptors activate the Ras–Raf–mitogen activated protein (MAP) kinase pathway, causing cell proliferation.

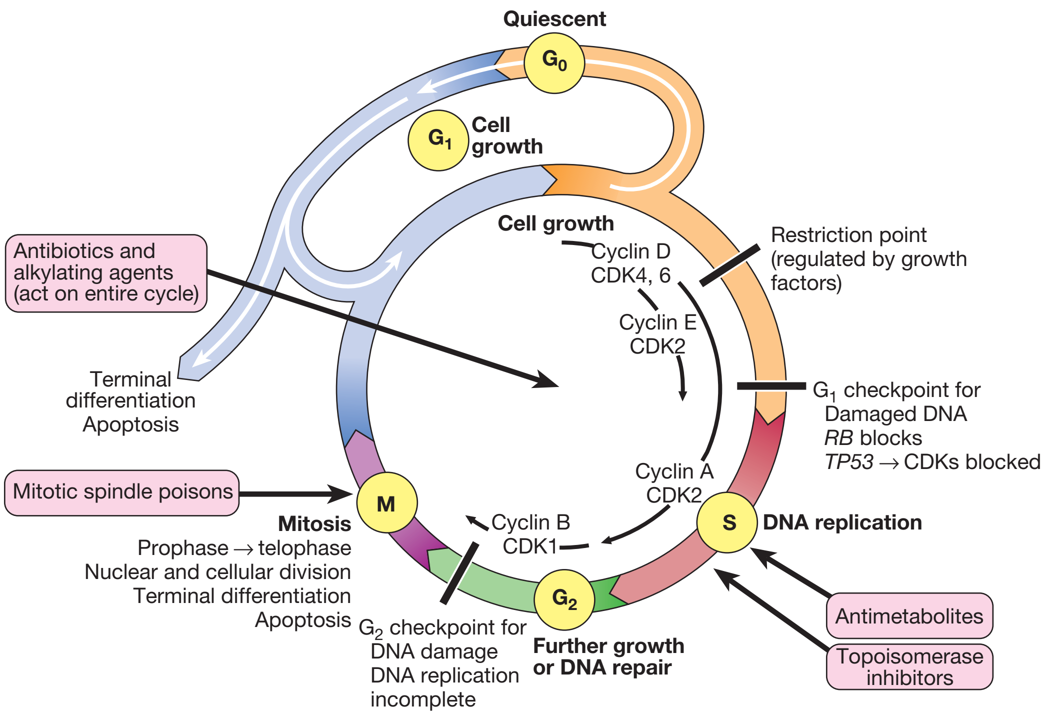

Fig. 33.2 The cell cycle and sites of action of chemotherapeutic agents. (CDK = cyclin-dependent kinase; *RB* = retinoblastoma gene)

4. Evading growth suppressors

In healthy tissues, cell-to-cell contact in dense cell populations acts as an inhibitory factor on proliferation. This contact inhibition is typically absent in many cancer cell populations. Growth-inhibitory factors can modulate the cell cycle regulators and produce activation of the CDK inhibitors, causing inhibition of the CDKs. Mutations within inhibitory proteins are common in cancer. Loss of restriction by disruption of pRB regulation can be found in human tumours, which produces a loss of restraint on transition from G_1 to S phase of the cell cycle. Disruption of *TP53* function will have downstream effects on *p21* that alter the coordination of DNA repair with cycle arrest, and that result in the affected cell accumulating genomic defects. Down-regulation of *p21* and *p27*, which can be found in tumours with normal *TP53* function, correlates notably with high tumour grade and poor prognosis.

5. Enabling replicative immortality

For cancer cells to evolve into macroscopic tumours, they need to acquire the ability for unlimited proliferation. Telomeric DNA sequences, which protect and stabilise chromosomal ends, play a central role in conferring this limitless replicative potential. During replication of normal cells, telomeres shorten progressively as small fragments of telomeric DNA are lost with successive cycles of replication. This shortening process is thought to represent a mitotic clock and eventually prevents the cell from dividing further. Telomerase, a specialised polymerase enzyme, adds nucleotides to telomeres, allowing continued cell division and thus preventing premature arrest of cellular replication. The telomerase enzyme is almost absent in normal cells but is expressed at significant levels in many human cancers.

6. Inducing angiogenesis

All cancers require a functional vascular network to ensure continued growth and will be unable to grow beyond 1 mm^3 without stimulating the development of a vascular supply. Tumours require sustenance in the form of nutrients and oxygen, as well as an ability to evacuate metabolic waste products and carbon dioxide. This entails the development of new blood vessels, which is termed angiogenesis (Figs 33.3 and 33.4).

Angiogenesis is dependent on the production of angiogenic growth factors, of which vascular endothelial growth factor (VEGF) and platelet-derived growth factor (PDGF) are the best characterised. During tumour progression, an angiogenic switch is activated and remains on, causing normally quiescent vasculature to sprout new vessels continually that help sustain expanding tumour growth. Angiogenesis is governed by a balance of pro-angiogenic stimuli and angiogenesis inhibitors, such as thrombospondin (TSP)-1, which binds to transmembrane receptors on endothelial cells and evokes suppressive signals.

A number of cells can contribute to the maintenance of a functional tumour vasculature and therefore sustain angiogenesis. These include pericytes and a variety of bone marrow-derived cells such as macrophages, neutrophils, mast cells and myeloid progenitors.

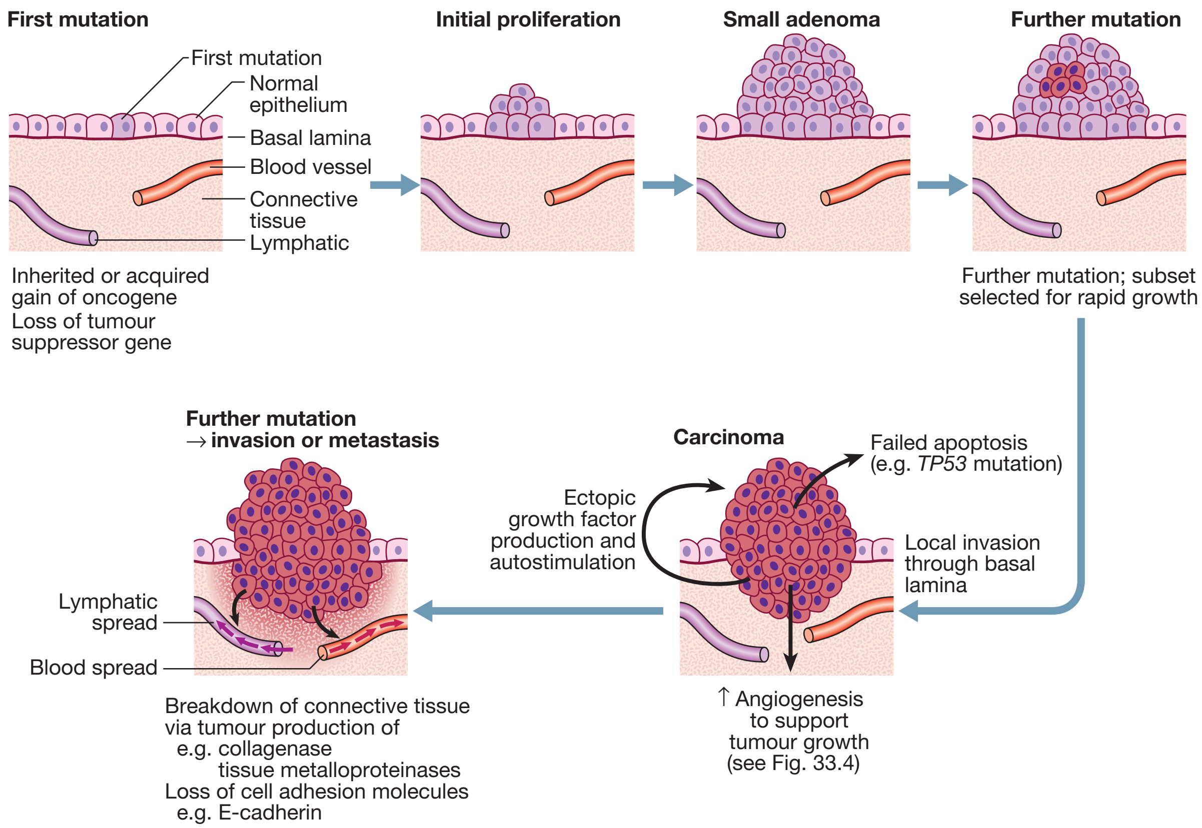

Fig. 33.3 Oncogenesis. The multistep origin of cancer, showing events implicated in cancer initiation, progression, invasion and metastasis.

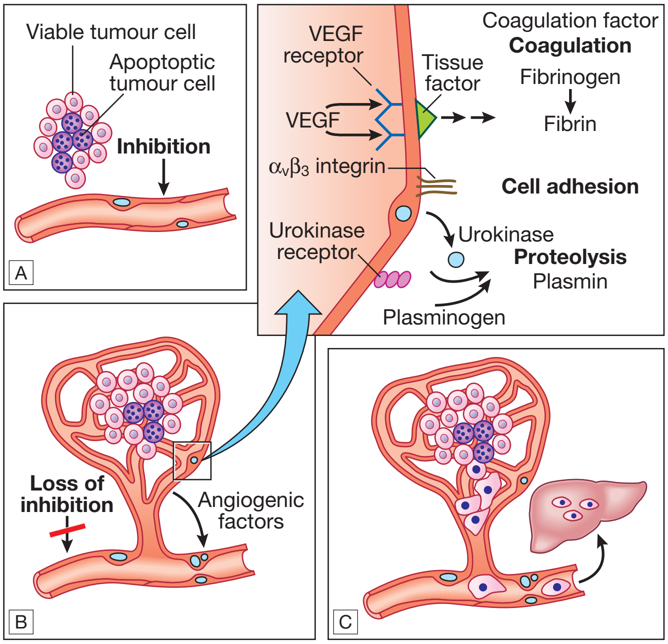

Fig. 33.4 Angiogenesis, invasion and metastasis. **A** For any cancer to grow beyond 1 mm^3, it must evoke a blood supply. **B** New vessel formation results from the release of angiogenic factors by the tumour cells and loss of inhibition of the endothelial cells. **C** The loss of cellular adhesion and disruption of the extracellular matrix allow cells to extravasate into the blood stream and metastasise to distant sites. (VEGF= vascular endothelial growth factor)

7. Activating invasion and metastasis

Invasion and metastasis are complex processes involving multiple discrete steps; they begin with local tissue invasion, followed by infiltration of nearby blood and lymphatic vessels by cancer cells. Malignant cells are eventually transported through haematogenous and lymphatic spread to distant sites within the body, where they form micrometastases that will eventually grow into macroscopic metastatic lesions (see Fig. 33.3).

Cadherin-1 (CDH1) is a calcium-dependent cell–cell adhesion glycoprotein that facilitates assembly of organised cell sheets in tissues, and increased expression is recognised as an antagonist of invasion and metastasis. In situ tumours usually retain CDH1 production, whereas loss of CDH1 production due to down-regulation or occasional mutational inactivation of CDH1 has been observed in human cancers, supporting the theory that CDH1 plays a key role in suppression of invasion and metastasis.

Cross-talk between cancer cells and cells of the surrounding stromal tissue is involved in the acquired capability for invasive growth and metastasis. Mesenchymal stem cells in tumour stroma have been found to secrete CCL5, a protein chemokine that helps recruit leucocytes into inflammatory sites. With the help of particular T-cell-derived cytokines (interleukin (IL)-2 and interferon-gamma (IFN-γ)), CCL5 induces proliferation and activation of natural killer cells and then acts reciprocally on cancer cells to stimulate invasive behaviour. Macrophages at the tumour periphery can foster local invasion by supplying matrix-degrading enzymes such as metalloproteinases and cysteine cathepsin proteases.

8. Reprogramming energy metabolism

Under aerobic conditions, oxidative phosphorylation functions as the main metabolic pathway for energy production; cells process glucose, first to pyruvate via glycolysis and thereafter to carbon dioxide in the mitochondria. While under anaerobic conditions, glycolysis is favoured to produce adenosine triphosphate (ATP). Cancer cells can reprogram their glucose metabolism to limit energy production to glycolysis, even in the presence of oxygen. This has been termed 'aerobic glycolysis'. Up-regulation of glucose transporters, such as GLUT1, is the main mechanism through which aerobic glycolysis is achieved.

This reprogramming of energy metabolism appears paradoxical, as overall energy production from glycolysis is significantly lower (18-fold) than that from oxidative phosphorylation. One explanation may be that the increased production of glycolytic intermediates can be fed into various biosynthetic pathways, including those that generate the nucleosides and amino acids, necessary for the production of new cells.

9. Tumour-promoting inflammation

Almost all tumours show infiltration with immune cells on pathological investigation and historically this finding was thought to represent an attempt of the immune system to eradicate the cancer. It is now clear that tumour-associated inflammatory responses promote tumour formation and cancer progression.

Cytokines are able to alter blood vessels to permit migration of leucocytes (mainly neutrophils), in order to permeate from the blood vessels into the tissue, a process known as extravasation. Migration across the endothelium occurs via the process of diapedesis, where chemokine gradients stimulate adhered leucocytes to move between endothelial cells and pass through the basement membrane into the surrounding tissues. Once within the tissue interstitium, leucocytes bind to extracellular matrix proteins via integrins and CD44 to prevent their loss from the site.

As well as cell-derived mediators, several acellular biochemical cascade systems consisting of pre-formed plasma proteins act in parallel to initiate and propagate the inflammatory response. These include the complement system activated by bacteria, and the coagulation and fibrinolytic systems activated by necrosis, and also in burns and trauma, as well as cancer. Other bioactive molecules, such as growth factors and pro-angiogenic factors, may be released by inflammatory immune cells into the surrounding tumour microenvironment. In particular, the release of reactive

oxygen species, which are actively mutagenic, will accelerate the genetic evolution of surrounding cancer cells, enhancing growth and contributing to cancer progression.

10. Evading immune destruction

The immune system operates as a significant barrier to tumour formation and progression, and the ability to escape from immunity is a hallmark of cancer development. Cancer cells continuously shed surface antigens into the circulatory system, prompting an immune response that includes cytotoxic T-cell, natural killer cell and macrophage production. The immune system is thought to provide continuous surveillance, with resultant elimination of cells that undergo malignant transformation.

However, deficiencies in the development or function of $CD8^+$ cytotoxic T lymphocytes, $CD4^+$ Th1 helper T cells or natural killer cells can each lead to a demonstrable increase in cancer incidence. Also, highly immunogenic cancer cells may evade immune destruction by disabling components of the immune system. This is done through recruitment of inflammatory cells, including regulatory T cells and myeloid-derived suppressor cells, both actively immunosuppressive against the actions of cytotoxic lymphocytes (see Fig. 4.12, p. 80).

Cancers develop and progress when there is loss of recognition by the immune system, lack of susceptibility due to escape from immune cell action and induction of immune dysfunction, often via inflammatory mediators.

Environmental and genetic determinants of cancer

The majority of cancers do not have a single cause but rather are the result of a complex interaction between genetic factors and exposure to environmental carcinogens. These are often tumour type-specific but some general principles do apply.

Environmental factors

Environmental triggers for cancer have mainly been identified through epidemiological studies that examine patterns of distribution of cancers in patients in whom age, sex, presence of other illnesses, social class, geography and so on differ. Sometimes, these give strong pointers to the molecular or cellular causes of the disease, such as the association between aflatoxin production within contaminated food supplies and hepatocellular carcinomas. For many solid cancers, such as breast and colorectal, however, there is evidence of a multifactorial pathogenesis, even when there is a principal environmental cause (Box 33.1).

Smoking is now established beyond all doubt as a major cause of lung cancer, but there are obviously additional predisposing factors since not all smokers develop cancer. Similarly, most carcinomas of the cervix are related to infection with human

33.1 Environmental factors that predispose to cancer

Environmental aetiology	Processes	Diseases
Occupational exposure (see 'Radiation' below)	Dye and rubber manufacturing (aromatic amines) Asbestos mining, construction work, shipbuilding (asbestos) Vinyl chloride (PVC) manufacturing Petroleum industry (benzene)	Bladder cancer Lung cancer and mesothelioma Liver angiosarcoma Acute leukaemia
Chemicals	Chemotherapy (e.g. melphalan, cyclophosphamide)	Acute myeloid leukaemia
Cigarette smoking	Exposure to carcinogens from inhaled smoke	Lung and bladder cancer
Viral infection	Epstein–Barr virus Human papillomavirus Hepatitis B and C viruses	Burkitt's lymphoma and nasopharyngeal cancer Cervical cancer Hepatocellular carcinoma
Bacterial infection	*Helicobacter pylori*	Gastric MALT lymphomas, gastric cancer
Parasitic infection	Liver fluke (*Opisthorchis sinensis*) *Schistosoma haematobium*	Cholangiocarcinoma Squamous cell bladder cancer
Dietary factors	Low-roughage/high-fat content diet High nitrosamine intake Aflatoxin from contamination of *Aspergillus flavus*	Colonic cancer Gastric cancer Hepatocellular cancer
Radiation	UV exposure Nuclear fallout following explosion (e.g. Hiroshima) Diagnostic exposure (e.g. CT) Occupational exposure (e.g. beryllium and strontium mining) Therapeutic radiotherapy	Basal cell carcinoma Melanoma Non-melanocytic skin cancer Leukaemia Solid tumours, e.g. thyroid Cholangiocarcinoma following Thorotrast usage Lung cancer Medullary thyroid cancer Sarcoma
Inflammatory diseases	Ulcerative colitis	Colon cancer
Hormonal	Use of diethylstilbestrol Oestrogens	Vaginal cancer Endometrial cancer Breast cancer

(CT = computed tomography; MALT = mucosa-associated lymphoid tissue; UV = ultraviolet)

papillomavirus (HPV subtypes 16 and 18). For carcinomas of the bowel and breast, there is strong evidence of an environmental component. For example, the risk of breast cancer in women of Far Eastern origin remains relatively low when they first migrate to a country with a Western lifestyle, but rises in subsequent generations to approach that of the resident population of the host country. The precise environmental factor that causes this change is unclear but may include diet (higher intake of saturated fat and/or dairy products), reproductive patterns (later onset of first pregnancy) and lifestyle (increased use of artificial light and shift in diurnal rhythm).

Genetic factors

A number of inherited cancer syndromes are recognised that account for 5–10% of all cancers (Box 33.2). Their molecular basis is discussed in Chapter 3, but in general they result from inherited mutations in genes that regulate cell growth, cell death and apoptosis. Examples include the *BRCA1*, *BRCA2* and *AT* (ataxia telangiectasia) genes that cause breast and some other cancers, the *FAP* gene that causes bowel cancer and the *RB* gene that causes retinoblastoma. Although carriers of these gene mutations have a greatly elevated risk of cancer, none has 100% penetrance and additional modulating factors, both genetic and environmental, are likely to be operative. Exploration of a possible genetic contribution is a key part of cancer management, especially with regard to ascertaining the risk for an affected patient's offspring.

Investigations

When a patient is suspected of having cancer, a full history should be taken; specific questions should be included as to potential risk factors such as smoking and occupational exposures or potential complications of the disease. A thorough clinical examination is essential to identify sites of metastases, and to discover any other conditions that may have a bearing on the management plan (pp. 1314–1315). In order to make a diagnosis and to plan the most appropriate management, information is needed on:

- the type of tumour
- the extent of disease, as assessed by staging investigations
- the patient's general condition and any comorbidity.

33.2 Inherited cancer predisposition syndromes

Syndrome	Malignancies	Inheritance	Gene
Ataxia telangiectasia	Leukaemia, lymphoma, ovarian, gastric, brain, colon	AR	*AT*
Bloom's syndrome	Leukaemia, tongue, oesophageal, colonic, Wilms' tumour	AR	*BLM*
Breast/ovarian	Breast, ovarian, colonic, prostatic, pancreatic	AD	*BRCA1, BRCA2*
Cowden's syndrome	Breast, thyroid, gastrointestinal tract, pancreatic	AD	*PTEN*
Familial adenomatous polyposis	Colonic, upper gastrointestinal tract	AD	*APC, MUTYH*
Familial atypical multiple mole melanoma (FAMMM)	Melanoma, pancreas	AD	*CDKN2A (TP16)*
Fanconi anaemia	Leukaemia, oesophageal, skin, hepatoma	AR	*FACA, FACC, FACD*
Gorlin's syndrome	Basal cell skin, brain	AD	*PTCH*
Hereditary diffuse gastric cancer	Diffuse gastric cancer	AD	*E-cadherin*
Hereditary non-polyposis colon cancer (HNPCC)	Colonic, endometrial, ovarian, pancreatic, gastric	AD	*MSH2, MLH1, MSH6, PMS1, PMS2*
Li–Fraumeni syndrome	Sarcoma, breast, osteosarcoma, leukaemia, glioma, adrenocortical	AD	*TP53*
Multiple endocrine neoplasia (MEN) 1	Pancreatic islet cell, pituitary adenoma, parathyroid adenoma and hyperplasia	AD	*MEN1*
MEN 2	Medullary thyroid, phaeochromocytoma, parathyroid hyperplasia	AD	*RET*
Neurofibromatosis 1	Neurofibrosarcoma, phaeochromocytoma, optic glioma	AD	*NF1*
Neurofibromatosis 2	Vestibular schwannoma	AD	*NF2*
Papillary renal cell cancer syndrome	Renal cell cancer	AD	*MET*
Peutz–Jeghers syndrome	Colonic, ileal, breast, ovarian	AD	*STK11*
Prostate cancer	Prostate	AD	*HPC1*
Retinoblastoma	Retinoblastoma, osteosarcoma	AD	*RB1*
von Hippel–Lindau syndrome	Haemangioblastoma of retina and CNS, renal cell, phaeochromocytoma	AD	*VHL*
Wilms' tumour	Nephroblastoma, neuroblastoma, hepatoblastoma, rhabdomyosarcoma	AD	*WT1*
Xeroderma pigmentosum	Skin, leukaemia, melanoma	AR	*XPA, XPC, XPD (ERCC2), XPF*

(AD = autosomal dominant; AR = autosomal recessive; CNS = central nervous system)

33.3 Eastern Cooperative Oncology Group (ECOG) performance status scale

0	Fully active, able to carry on all usual activities without restriction and without the aid of analgesics
1	Restricted in strenuous activity but ambulatory and able to carry out light work or pursue a sedentary occupation. This group also contains patients who are fully active, as in grade 0, but only with the aid of analgesics
2	Ambulatory and capable of all self-care but unable to work. Up and about more than 50% of waking hours
3	Capable of only limited self-care, confined to bed or chair more than 50% of waking hours
4	Completely disabled, unable to carry out any self-care and confined totally to bed or chair

33.4 TNM classification

Extent of primary tumour*	
TX	Not assessed
T0	No tumour
T1 **T2** **T3** **T4**	Increases in primary tumour size or depth of invasion
Increased involvement of nodes*	
NX	Not assessed
N0	No nodal involvement
N1 **N2/3**	Increases in involvement
Presence of metastases	
MX	Not assessed
M0	Not present
M1	Present

*Exact criteria for size and region of nodal involvement have been defined for each anatomical site.

The overall fitness of a patient is often assessed by the Eastern Cooperative Oncology Group (ECOG) performance status scale (Box 33.3). The outcome for patients with a performance status of 3 or 4 is worse in almost all malignancies than for those with a status of 0–2, and this has a strong influence on the approach to treatment in the individual patient.

The process of staging determines the extent of the tumour; it entails clinical examination, imaging and, in some cases, surgery, to establish the extent of disease involvement. The outcome is recorded using a standard staging classification that allows comparisons to be made between different groups of patients. Therapeutic decisions and prognostic predictions can then be made using the evidence base for the disease. One of the most commonly used systems is the T (tumour), N (regional lymph nodes), M (metastatic sites) approach of the International Union against Cancer (UICC, Box 33.4). For some tumours, such as colon cancer, the Dukes system (p. 832) is used rather than the UICC classification.

Histology

Histological analysis of a biopsy or resected specimen is pivotal in clinching the diagnosis and in deciding on the best form of management. The results of histological analysis are most informative when combined with knowledge of the clinical picture; biopsy results should therefore be reviewed and discussed within the context of a multidisciplinary team meeting.

Light microscopy

Examination of tumour samples by light microscopy remains the core method of cancer diagnosis and, in cases where the primary site is unclear, may give clues to the origin of the tumour:

- Signet-ring cells favour a gastric primary.
- Presence of melanin favours melanoma.
- Mucin is common in gut/lung/breast/endometrial cancers, but particularly common in ovarian cancer and rare in renal cell or thyroid cancers.
- Psammoma bodies are a feature of ovarian cancer (mucin +) and thyroid cancer (mucin –).

Immunohistochemistry

Immunohistochemical (IHC) staining for tumour markers can provide useful diagnostic information and can help with treatment decisions. Commonly used examples of IHC in clinical practice include:

- *Oestrogen (ER) and progesterone (PR) receptors.* Positive results indicate that the tumour may be sensitive to hormonal manipulation.
- *Alpha-fetoprotein (AFP)* and *human chorionic gonadotrophin (hCG) with or without placental alkaline phosphatase (PLAP).* These favour germ-cell tumours.
- *Prostate-specific antigen (PSA)* and *prostatic acid phosphatase (PAP).* These favour prostate cancer.
- *Carcinoembryonic antigen (CEA), cytokeratin* and *epithelial membrane antigen (EMA).* These favour epithelial carcinomas.
- *HER2 receptor.* Breast cancers that have high levels of expression of HER2 indicate that the tumour may respond to trastuzumab (Herceptin), an antibody directed against the HER2 receptor.

The pattern of immunoglobulin, T-cell receptor and cluster designation (CD) antigen expression on the surface is helpful in the diagnosis and classification of lymphomas. This can be achieved by IHC staining of biopsy samples or flow cytometry.

Electron microscopy

Electron microscopy (EM) can sometimes be of diagnostic value. Examples include the visualisation of melanosomes in amelanotic melanoma and dense core granules in neuro-endocrine tumours. EM may help to distinguish adenocarcinoma from mesothelioma, as the ultrastructural properties of these two diseases are different (mesothelioma appears to have long, narrow, branching microvilli while adenocarcinomas appear to have short, stubby microvilli). EM is also useful for differentiating spindle-cell tumours (sarcomas, melanomas, squamous cell cancers) from small round-cell tumours, again due to their ultrastructural differences.

Cytogenetic analysis

Some tumours demonstrate typical chromosomal changes that help in diagnosis. The utilisation of fluorescent in situ hybridisation (FISH) techniques can be useful in Ewing's sarcoma and peripheral neuro-ectodermal tumours where there is a translocation between chromosome 11 and 22–t(11;22)(q24;q12). In some cases, gene amplification can be detected via FISH (e.g. determining over-expression of HER2/neu).

Imaging

Imaging plays a critical role in oncology, not only in locating the primary tumour but also in staging the disease and determining the response to treatment. The imaging modality employed depends primarily on the site of the disease and likely patterns of spread, and may require more than one modality.

Ultrasound

Ultrasound is useful in characterising lesions within the liver, kidney, pancreas and reproductive organs. It can be used for guiding biopsies of tumours in breast and liver. Endoscopic ultrasound is helpful in staging upper gastrointestinal and pancreatic cancers, involving a special endoscope with an ultrasound probe attached.

Computed tomography

Computed tomography (CT) is a key investigation in cancer patients and is particularly useful in imaging the thorax and abdomen. With modern scanners it is possible to visualise the large bowel if it is prepared (CT colonography), allowing accurate detection of colorectal cancers and adenomas ≥10 mm.

Magnetic resonance imaging

Magnetic resonance imaging (MRI) has a high resolution and is the preferred technique for brain and pelvic imaging. It is widely employed for the staging of rectal, cervical and prostate cancers.

Positron emission tomography

Positron emission tomography (PET) visualises metabolic activity of tumour cells and is widely used, often in combination with CT (PET–CT), to evaluate the extent of the disease, particularly in the assessment of potential distant metastasis (Fig. 33.5). It can accurately assess the severity and spread of cancer by detecting tumour metabolic activity following injection of small amounts of radioactive tracers such as fluorodeoxyglucose (FDG). In addition to having a role in diagnosis, PET can be used in some patients to assess treatment response.

Biochemical markers

Many cancers produce substances called tumour markers, which can assist in diagnosis and surveillance. Some are useful in population screening, diagnosis, determining prognosis, response evaluation, detection of relapse and imaging of metastasis. Unfortunately, most tumour markers are neither sufficiently sensitive nor sufficiently specific to be used in isolation for diagnosis and need to be interpreted in the context of the other clinical features. Some can be used for antibody-directed therapy or imaging, however, where they have a greater role in diagnosis. Tumour markers in routine use are outlined in Box 33.5.

Presenting problems in oncology

In the early stages of cancer development, the number of malignant cells is small and the patient is usually asymptomatic. With tumour progression, localised signs or symptoms develop due to mass effects and/or invasion of local tissues. With further progression, symptoms may occur at distant sites as a result of

Fig. 33.5 Positron emission tomography–computed tomography (PET–CT) images. **A** There is a neoplastic lesion (arrow) in the left axilla, evidenced by the increased uptake of fluorodeoxyglucose (FDG) tracers. **B** Imaging after chemotherapy, demonstrating that the abnormal uptake has disappeared and indicating a response to treatment. *Courtesy of Dr J. Wilsdon, Freeman Hospital, Newcastle upon Tyne.*

metastatic disease or from non-metastatic manifestations due to production of biologically active hormones by the tumour or as the result of an immune response to the tumour. The possible presentations are summarised in Boxes 33.6 and 33.7, and common presenting features discussed below. Although the incidence of cancer increases with patient age, the approach to investigation and management is similar at all ages (Box 33.8).

Palpable mass

A palpable mass detected by the patient or physician may be the first sign of cancer. Primary tumours of the thyroid, breast, testis and skin are often detected in this way, whereas palpable lymph nodes in the neck, groin or axilla may indicate secondary spread of tumour. Hepatomegaly may be the first sign of primary liver cancer or tumour metastasis, whereas skin cancer may present as an enlarging or changing pigmented lesion.

Weight loss and fever

Unintentional weight loss is a characteristic feature of advanced cancer, but can have other causes such as thyrotoxicosis, chronic inflammatory disease and chronic infective disorders. Fever can occur in any cancer secondary to infection, but may be a primary feature in Hodgkin and non-Hodgkin lymphoma, leukaemia, renal cancer and liver cancer. The presence of unexplained weight loss or fever warrants investigation to exclude the presence of occult malignancy.

i 33.5 Commonly used serum tumour markers

Name	Natural occurrence	Tumours
Alpha-fetoprotein (AFP)	Glycoprotein found in yolk sac and fetal liver tissue. Transient elevation in liver diseases. Has a role in screening during pregnancy for the detection of neural tube defects and Down's syndrome	Ovarian non-seminomatous germ cell tumours (80%), testicular teratoma (80%), hepatocellular cancer (50%)
Beta-2-microglobulin	A human leucocyte antigen (HLA) common fragment present on surface of lymphocytes, macrophages and some epithelial cells. Can be elevated in autoimmune disease and renal glomerular disease	Non-Hodgkin lymphoma, myeloma
Calcitonin	32-amino-acid peptide from C cells of thyroid. Used to screen for MEN 2	Medullary cell carcinoma of thyroid
Cancer antigen 125 (CA-125)	Differentiation antigen of coelomic epithelium (Müller's duct). Raised in any cause of ascites, pleural effusion or heart failure. Can be raised in inflammatory conditions	Ovarian epithelial cancer (75%), gastrointestinal cancer (10%), lung cancer (5%) and breast cancer (5%)
CA-19.9	A mucin found in epithelium of fetal stomach, intestine and pancreas. It is eliminated exclusively via bile and so any degree of cholestasis can cause levels to rise	Pancreatic cancer (80%), mucinous tumour of the ovary (65%), gastric cancer (30%), colon cancer (30%)
Carcinoembryonic antigen (CEA)	Glycoprotein found in intestinal mucosa during embryonic and fetal life. Elevated in smokers, cirrhosis, chronic hepatitis, ulcerative colitis, pneumonia	Colorectal cancer, particularly with liver metastasis, gastric cancer, breast cancer, lung cancer, mucinous cancer of the ovary
Human chorionic gonadotrophin (hCG)	Glycoprotein hormone, 14 kD α subunit and 24 kD β subunit from placental syncytiotrophoblasts. Used for disease monitoring in hydatidiform mole and as the basis of a pregnancy test	Choriocarcinoma (100%), hydatidiform moles (97%), ovarian non-seminomatous germ cell tumours (50–80%), seminoma (15%)
Placental alkaline phosphatase (PLAP)	Isoenzyme of alkaline phosphatase	Seminoma (40%), ovarian dysgerminoma (50%)
Prostate-specific antigen (PSA)	Glycoprotein member of human kallikrein gene family. PSA is a serine protease that liquefies semen in excretory ducts of prostate. Can be elevated in benign prostatic hypertrophy and prostatitis	Prostate cancer (95%)
Thyroglobulin	Matrix protein for thyroid hormone synthesis in normal thyroid follicles	Papillary and follicular thyroid cancer

i 33.6 Local features of malignant disease

Symptom	Typical site or possible tumour
Haemorrhage	Stomach, colon, bronchus, endometrium, bladder, kidney
Lump	Breast, lymph node (any site), testicle
Bone pain or fracture	Bone (primary sarcoma, secondary metastasis from breast, prostate, bronchus, thyroid, kidney)
Skin abnormality	Melanoma, basal cell carcinoma (rodent ulcer)
Ulcer	Oesophagus, stomach, anus, skin
Dysphagia	Oesophagus, bronchus, gastric
Increasing constipation, abdominal discomfort or pain	Colon, rectum, ovary
Airway obstruction, stridor, cough, recurrent infection	Bronchus, thyroid
Odynophagia, early satiety, vomiting	Bronchus, stomach, oesophagus, colon, rectum
Abdominal swelling (ascites)	Ovary, stomach, pancreas

Thromboembolism

Thrombosis and disseminated intravascular coagulation (DIC) are common complications in patients with cancer. The prothrombotic state is caused by cancer cells activating the coagulation system via factors such as tissue factor, cancer procoagulant and inflammatory cytokines. The interaction between tumour cells, monocytes/macrophages, platelets and endothelial cells can promote thrombus formation, as part of a host response to the cancer (i.e. acute phase, inflammation, angiogenesis) or via a reduction in the levels of inhibitors of coagulation or impairment

33.7 Non-metastatic manifestations of malignant disease

Feature	Common cancer site associations
Weight loss and anorexia	Lung, gastrointestinal tract
Fatigue	Any
Hypercalcaemia	Myeloma, breast, kidney
Prothrombotic tendency	Ovary, pancreas, gastrointestinal tract
SIADH **Ectopic ACTH**	Small cell lung cancer
Lambert–Eaton myasthenic syndrome	Small cell lung cancer
Subacute cerebellar degeneration	Small cell lung cancer, ovarian cancer
Acanthosis nigricans	Stomach, oesophagus
Dermatomyositis/polymyositis	Stomach, lung

(ACTH = adrenocorticotrophic hormone; SIADH = syndrome of inappropriate antidiuretic hormone (vasopressin) secretion)

33.8 Cancer in old age

- **Incidence**: around 50% of cancers occur in the 15% of the population aged over 65 years.
- **Screening**: women aged over 65 in the UK are not invited to breast cancer screening but can request it. Uptake is low despite increasing incidence with age.
- **Presentation**: may be later for some cancers. When symptoms are non-specific, patients (and their doctors) may initially attribute them to age alone.
- **Life expectancy**: an 80-year-old woman can expect to live 8 years, so cancer may still shorten life and an active approach remains appropriate.
- **Prognosis**: histology, stage at presentation and observation for a brief period are better guides to outcome than age.
- **Rate of progression**: malignancy may have a more indolent course. This is poorly understood but may be due to reduced effectiveness of angiogenesis with age, inhibiting the development of metastases.
- **Response to treatment**: equivalent to that in younger people – well documented for a range of cancers and for surgery, radiotherapy, chemotherapy and hormonal therapy.
- **Treatment selection**: chronological age is of minor importance compared to comorbid illness and patient choice. Although older patients can be treated effectively and safely, aggressive intervention is not appropriate for all. Symptom control may be all that is possible or desired by the patient.

of fibrinolysis. Furthermore, the prothrombotic tendency can be enhanced by therapy such as surgery, chemotherapy, hormone therapy and radiotherapy, and by in-dwelling access devices (i.e. central venous catheters). In some patients, the thromboembolism is the first presenting feature of the underlying cancer.

Ectopic hormone production

In some cases, the first presentation of cancer is with a metabolic abnormality due to ectopic production of hormones by tumour cells, including insulin, ACTH, vasopressin (antidiuretic hormone, ADH), fibroblast growth factor (FGF)-23, erythropoietin and

33.9 Ectopic hormone production by tumours

Hormone	Consequence	Tumours
ACTH	Cushing's syndrome	SCLC
Erythropoietin	Polycythaemia	Kidney, hepatoma, cerebellar haemangioblastoma, uterine fibroids
FGF-23	Hypophosphataemic osteomalacia	Mesenchymal tumours
PTHrP	Hypercalcaemia	NSCLC (squamous cell), breast, kidney
Vasopressin (ADH)	Hyponatraemia	SCLC

(ACTH = adrenocorticotrophic hormone; ADH = antidiuretic hormone; FGF = fibroblast growth factor; NSCLC = non-small cell lung cancer; PTHrP = parathyroid hormone-related protein; SCLC = small cell lung cancer)

parathyroid hormone-related protein (PTHrP). This can result in a wide variety of presentations, as summarised in Box 33.9. Further details on the presentation and management of ACTH- and vasopressin-producing tumours are given on page 670, and those of FGF23-producing tumours on page 1053. The management of hypercalcaemia associated with malignancy is discussed below.

Neurological paraneoplastic syndromes

These form a group of conditions associated with cancer that are thought to be due to an immunological response to the tumour that results in damage to the nervous system or muscle. The cancers most commonly implicated are those of the lung (small cell and non-small cell), pancreas, breast, prostate, ovary and lymphoma.

- *Peripheral neuropathy* results from axonal degeneration or demyelination.
- *Encephalomyelitis* can present with diverse symptoms, depending on which region of the brain is involved. Lumbar puncture shows raised protein in the cerebrospinal fluid and a pleocytosis, predominantly that of lymphocytes. In some centres, flow cytometry of the cerebrospinal fluid can be used to detect carcinomatous cells. MRI shows meningeal enhancement, particularly at the level of the brainstem, and anti-Hu antibodies may be detectable in serum. Encephalomyelitis is due to perivascular inflammation and selective neuronal degeneration. Most cases are caused by small cell lung cancer (75%).
- *Cerebellar degeneration* may be the presenting feature of an underlying malignancy and presents with rapid onset of cerebellar ataxia. Diagnosis is by MRI or CT, which may show cerebellar atrophy. Patients with these neurological paraneoplastic syndromes may be found to have circulating anti-Yo, Tr and Hu antibodies, but these are not completely specific and negative results do not exclude the diagnosis.
- *Retinopathy* is a rare complication of cancer and presents with blurred vision, episodic visual loss and impaired colour vision. If left untreated, it may lead to blindness. The diagnosis should be suspected if the electroretinogram is abnormal and anti-retinal antibodies are detected.
- *Lambert–Eaton myasthenic syndrome* (LEMS) is due to underlying cancer in about 60% of cases. It presents with

proximal muscle weakness that improves on exercise and is caused by the development of antibodies to pre-synaptic calcium channels (p. 1143). The diagnosis is made by electromyelogram (EMG), which shows a low-amplitude compound muscle action potential that enhances to near normal following exercise.
- *Dermatomyositis* or *polymyositis* may be the first presentation of some cancers. Clinical features and management of these conditions are discussed on page 1039.

Cutaneous manifestations of cancer

Many cancers can present with skin manifestations that are not due to metastases:
- *Pruritus* may be a presenting feature of lymphoma, leukaemia and central nervous system tumours.
- *Acanthosis nigricans* may precede cancers by many years and is particularly associated with gastric cancer.
- *Vitiligo* may be associated with malignant melanoma and is possibly due to an immune response to melanocytes.
- *Pemphigus* may occur in lymphoma, Kaposi's sarcoma and thymic tumours.
- *Dermatitis herpetiformis* associated with coeliac disease may precede tumour development by many years, and is associated with gastrointestinal lymphoma.

The clinical features and management of these skin conditions are discussed in Chapter 29.

Emergency complications of cancer

Spinal cord compression

Spinal cord compression complicates 5% of cancers and is most common in myeloma, prostate, breast and lung cancers that involve bone. Cord compression often results from posterior extension of a vertebral body mass but intrathecal spinal cord metastases can cause similar signs and symptoms. The thoracic region is most commonly affected.

Clinical features

The earliest sign is back pain, particularly on coughing and lying flat. Subsequently, sensory changes develop in dermatomes below the level of compression and motor weakness distal to the block occurs. Finally, sphincter disturbance, causing urinary retention and bowel incontinence, is observed. Involvement of the lumbar spine may cause conus medullaris or cauda equina compression (Box 33.10). Physical examination reveals findings consistent with an upper motor neuron lesion, but lower motor neuron findings may predominate early on or in cases of nerve root compression.

33.11 Management of suspected spinal cord compression

- Confirm diagnosis with urgent MRI scan
- Administer high-dose glucocorticoids:
  - Dexamethasone 16 mg IV stat
  - Dexamethasone 8 mg twice daily orally
- Ensure adequate analgesia
- Refer for surgical decompression or urgent radiotherapy

Management

Spinal cord compression is a medical emergency and should be treated with analgesia and high-dose glucocorticoid therapy (Box 33.11). Neurosurgical intervention produces superior outcome and survival compared to radiotherapy alone, and should be considered first for all patients. Radiotherapy is used for the remaining patients and selected tumour types when the cancer is likely to be radiosensitive. The prognosis varies considerably, depending on tumour type, but the degree of neurological dysfunction at presentation is the strongest predictor of outcome, irrespective of the underlying diagnosis. Mobility can be preserved in more than 80% of patients who are ambulatory at presentation, but neurological function is seldom regained in patients with established deficits such as paraplegia.

Superior vena cava obstruction

Superior vena cava obstruction (SVCO) is a common complication of cancer that can occur through extrinsic compression or intravascular blockage. The most common causes of extrinsic compression are lung cancer, lymphoma and metastatic tumours. Patients with cancer can also develop SVCO due to intravascular blockage in association with a central catheter or thromboembolism secondary to the tumour.

Clinical features

The typical presentation is with oedema of the arms and face, distended neck and arm veins and dusky skin coloration over the chest, arms and face. Collateral vessels may develop over a period of weeks and the flow of blood in the collaterals helps to confirm the diagnosis. Headache secondary to cerebral oedema arising from the backflow pressure may also occur and tends to be aggravated by bending forwards, stooping or lying down. The severity of symptoms is related to the rate of obstruction and the development of a venous collateral circulation. Accordingly, symptoms may develop rapidly or gradually. Clinical features are summarised in Box 33.12.

33.10 Comparison of features of neurological deficit

Clinical feature	Spinal cord	Conus medullaris	Cauda equina
Weakness	Symmetrical and profound	Symmetrical and variable	Asymmetrical, may be mild
Reflexes	Increased (or absent) knee and ankle reflexes with extensor plantar reflex	Increased knee reflex, decreased ankle reflex, extensor plantar reflex	Decreased knee and ankle reflexes with flexor plantar reflex
Sensory loss	Symmetrical, sensory level	Symmetrical, saddle distribution	Asymmetrical, radicular pattern
Sphincters	Late loss	Early loss	Often spared
Progression	Rapid	Variable	Variable

33.12 Common symptoms and physical findings in superior vena cava obstruction*

Symptoms	
• Dyspnoea (63%) • Facial swelling and head fullness (50%) • Cough (24%)	• Arm swelling (18%) • Chest pain (15%) • Dysphagia (9%)
Physical findings	
• Venous distension of neck (66%) • Venous distension of chest wall (54%)	• Facial oedema (46%) • Cyanosis (20%) • Plethora of face (19%) • Oedema of arms (14%)

*Percentage of patients affected.

Investigations and management

The investigation of choice is a CT scan of the thorax to confirm the diagnosis and distinguish between extra- and intravascular causes. A biopsy should be obtained when the tumour type is unknown because tumour type has a major influence on treatment. CT of the head may be indicated if cerebral oedema is suspected. Tumours that are exquisitely sensitive to chemotherapy, such as germ cell tumours and lymphoma, can be treated with chemotherapy alone, but for most other tumours mediastinal radiotherapy is required. This relieves symptoms within 2 weeks in 50–90% of patients. In many centres, stenting is now increasingly favoured over radiotherapy, as it produces rapid results and can be repeated with reasonable effectiveness. This technique is particularly useful when dealing with tumours that are relatively chemo- or radio-resistant, such as non-small cell lung cancer or carcinoma of unknown primary. Where possible, these measures should be followed by treatment of the primary tumour, as long-term outcome is strongly dependent on the prognosis of the underlying cancer.

Hypercalcaemia

Hypercalcaemia is the most common metabolic disorder in patients with cancer and has a prevalence of up to 20% in cancer patients. The incidence is highest in myeloma and breast cancer (approximately 40%), intermediate in non-small cell lung cancer, and uncommon in colon, prostate and small cell lung carcinomas. It is most commonly due to over-production of PTHrP (80%), which binds to the PTH receptor and elevates serum calcium by stimulating osteoclastic bone resorption and increasing renal tubular reabsorption of calcium. Direct invasion of bone by metastases accounts for around 20% of cases while other mechanisms, such as ectopic PTH secretion, are rare.

Clinical features

The symptoms of hypercalcaemia are often non-specific and may mimic those of the underlying malignancy. They include drowsiness, delirium, nausea and vomiting, constipation, polyuria, polydipsia and dehydration.

Investigations and management

The diagnosis is made by measuring serum total calcium and adjusting for albumin. It is especially important to correct for albumin in cancer because hypoalbuminaemia is common and total calcium values under-estimate the level of ionised calcium. The principles of management are outlined in Box 33.13.

33.13 Medical management of severe hypercalcaemia

- IV 0.9% saline 2–4 L/day
- Zoledronic acid 4 mg IV *or* pamidronate 60–90 mg IV
- For patients with severe, symptomatic hypercalcaemia that is refractory to zoledronic acid, denosumab (initial dose 60 mg SC, with repeat dosing based on response) is an alternative option

Patients should initially be treated with intravenous 0.9% saline to improve renal function and increase urinary calcium excretion. This alone often results in clinical improvement. Concurrently, intravenous bisphosphonates should be given to inhibit bone resorption. Calcitonin acts rapidly to increase calcium excretion and to reduce bone resorption, and can be combined with fluid and bisphosphonate therapy for the first 24–48 hours in patients with life-threatening hypercalcaemia. Bisphosphonates will usually reduce the serum calcium levels to normal within 5 days, but, if not, treatment can be repeated. The duration of action is up to 4 weeks and repeated therapy can be given at 3–4-weekly intervals in the outpatient department. Hypercalcaemia is frequently a sign of tumour progression and the patient requires further investigation to establish disease status and review of the anti-cancer treatment strategy.

Neutropenic fever

Neutropenia is a common complication of malignancy. It is usually secondary to chemotherapy but may occur with radiotherapy if large amounts of bone marrow are irradiated; it may also be a component of pancytopenia due to malignant infiltration of the bone marrow. Neutropenic fever is defined as a pyrexia of 38°C for over 1 hour in a patient with a neutrophil count of $<0.5\times10^9$/L or $<1.0\times10^9$/L if the nadir is anticipated to drop to $<0.5\times10^9$/L in the next 24 hours. The risk of sepsis is related to the severity and duration of neutropenia and the presence of other risk factors, such as intravenous cannulae or bladder catheters. Neutropenic fever is an emergency in cancer patients as, if left untreated, it can result in sepsis with a high mortality rate.

Clinical features

The typical presentation is with high fever, and affected patients are often non-specifically unwell. Examination is usually unhelpful in defining a primary source of the infection. Hypotension is an adverse prognostic feature and may progress to systemic circulatory shutdown and organ failure.

Investigations and management

An infection screen should be performed to include blood cultures (both peripheral and from central lines), urine culture, chest X-ray, and swabs for culture (throat, central line, wound). High-dose intravenous antibiotics should then be commenced, pending the results of cultures. The standard approach is to commence empirical antibiotics according to local hospital policies agreed with microbiologists and based on the local antibiotic resistance patterns observed. First-line empirical therapy is either monotherapy with piperacillin–tazobactam or meropenem, or with the addition of gentamicin. Metronidazole may be added if anaerobic infection is suspected, and teicoplanin where Gram-positive infection is suspected (e.g. in patients with central lines). Antibiotics should be adjusted according to culture results, although these are often negative. If there is no response after 36–48 hours, antibiotics should be reviewed with microbiological advice, and antifungal cover should be considered

(liposomal amphotericin B). Granulocyte–colony-stimulating factor (G–CSF) is not routinely used for all patients with neutropenia and guidelines for use have been established. Other supportive therapy, including intravenous fluids, inotrope therapy, ventilation or haemofiltration, may be required.

Tumour lysis syndrome

The acute destruction of a large number of cells can be associated with metabolic sequelae and is called tumour lysis syndrome. It is usually related to bulky, chemosensitive disease, including lymphoma, leukaemia and germ cell tumours. More rarely, it can occur spontaneously.

Clinical features

Cellular destruction results in the release of potassium, phosphate, nucleic acids and purines that can cause transient hypocalcaemia, hyperphosphataemia, hyperuricaemia and hyperkalaemia. This can lead to acute impairment of renal function and the precipitation of uric acid crystals in the renal tubular system. These can manifest with symptoms associated with multiple underlying electrolyte abnormalities, including fatigue, nausea, vomiting, cardiac arrhythmia, heart failure, syncope, tetany, seizures and sudden death.

Investigations and management

Serum biochemistry should be monitored regularly for 48–72 hours after treatment in patients at risk. Elevated serum potassium may be the earliest biochemical marker but pre-treatment serum lactate dehydrogenase (LDH) correlates with tumour bulk and may indicate increased risk. Good hydration and urine output should be maintained throughout treatment administration. Prophylaxis with allopurinol should be considered and recombinant urate oxidase (rasburicase) can be used to reduce uric acid levels when other treatments fail. Adequate hydration is vital, as it has a dilution effect on the extracellular fluid, improving electrolyte imbalance, and increases circulating volume, improving filtration in the kidneys. In high-risk patients, hydration should be commenced 24 hours before the start of treatment. If normal treatment methods fail to correct the problems, haemodialysis should be considered at an early stage to prevent progression to irreversibility.

Metastatic disease

Metastatic disease is the major cause of death in cancer patients and the principal cause of morbidity. For the majority, the aim of treatment is palliative but treatment of a solitary metastasis can occasionally be curative.

Brain metastases

Brain metastases occur in 10–30% of adults and 6–10% of children with cancer, and are an increasingly important cause of morbidity. Tumours that typically metastasise to the brain are shown in Box 33.14. Most involve the brain parenchyma but can also affect the cranial nerves, the blood vessels and other intracranial structures. In cases of solitary metastasis to the brain, the use of surgery and adjuvant radiotherapy has been shown to increase survival. Practices vary, however, for patients with more advanced brain metastases. In these cases, median survival without treatment is approximately 1 month. Glucocorticoids can increase survival to 2–3 months and whole-brain radiotherapy improves survival to 3–6 months, but the true efficacy of these interventions has not been proven adequately in a randomised trial setting. Patients with brain metastases as the only manifestation of an undetected primary tumour have a more favourable prognosis, with an overall median survival of 13.4 months. Tumour type also influences prognosis; breast cancer patients have a better prognosis than those with other types of cancer, and those with colorectal cancer tend to have a poorer prognosis.

33.14 Primary tumour sites that metastasise to the brain

Primary tumour	Patients (%)
Lung	48
Breast	15
Melanoma	9
Colon	5
Other known primary	13
Unknown primary	11

Clinical features

Presentation is with headaches (40–50%), focal neurological dysfunction (20–40%), cognitive dysfunction (35%), seizures (10–20%) and papilloedema (< 10%).

Investigations and management

The diagnosis can be confirmed by CT or contrast-enhanced MRI. Treatment options include high-dose glucocorticoids (dexamethasone 4 mg 4 times daily) for tumour-associated oedema, anticonvulsants for seizures, whole-brain radiotherapy and chemotherapy. Surgery may be considered for single sites of disease and can be curative; stereotactic radiotherapy may also be considered for solitary site involvement where surgery is not possible.

Lung metastases

These are common in breast cancer, colon cancer and tumours of the head and neck. The presentation is usually with a lesion on chest X-ray or CT. Solitary lesions require investigation, as single metastases can be difficult to distinguish from a primary lung tumour. Patients with two or more pulmonary nodules can be assumed to have metastases. The approach to treatment depends on the extent of disease in the lung and elsewhere. For solitary lesions, surgery should be considered, with a generous wedge resection. Radiotherapy, chemotherapy or endocrine therapy can be used as systemic treatment and is dependent on the underlying primary cancer diagnosis.

Liver metastases

Metastatic cancer in the liver can represent the sole or life-limiting component of disease for many with colorectal cancer, ocular melanoma, neuro-endocrine tumours (NETs) and, less commonly, other tumour types. The most common clinical presentations are with right upper quadrant pain due to stretching of the liver capsule, jaundice, deranged liver function tests or an abnormality detected on imaging. In selected cases, resection of the metastasis can be contemplated. In colorectal cancer, successful resection of metastases improves 5-year survival from 3% to 30–40%. Other techniques, such as chemoembolisation or radiofrequency ablation, can also be used, provided the number

and size of metastases remain small. If these are not feasible, symptoms may respond to systemic chemotherapy.

Bone metastases

Bone is the third most common organ involved by metastasis, after lung and liver. Bone metastases are a major clinical problem in patients with myeloma and breast or prostate cancers, but other tumours that commonly metastasise to bone include those of the kidney and thyroid. Bone metastases are an increasing management problem in other tumour types that do not classically target bone, due to the prolonged survival of patients generally. Accordingly, effective management of bony metastases has become a focus in the treatment of patients with many incurable cancers.

Clinical features

The main presentations are with pain, pathological fractures and spinal cord compression (see above). The pain tends to be progressive and worst at night, and may be partially relieved by activity, but subsequently becomes more constant in nature and is exacerbated by movement. Most pathological fractures occur in metastatic breast cancer (53%); other tumour types associated with fracture include the kidney (11%), lung (8%), thyroid (5%), lymphoma (5%) and prostate (3%).

Investigations and management

The most sensitive way of detecting bone metastases is by isotope bone scan. This can have false-positive results in healing bone, particularly as a flare response following treatment and false-negative results occur in multiple myeloma due to suppression of osteoblast activity. Plain X-ray films are therefore preferred for any sites of bone pain, as lytic lesions may not be detected by a bone scan. In patients with a single lesion, it is especially important to perform a biopsy to obtain a tissue diagnosis, since primary bone tumours may look very similar to metastases on X-ray.

The main goals of management are:

- pain relief
- preservation and restoration of function
- skeletal stabilisation
- local tumour control (e.g. relief of tumour impingement on normal structure).

Surgical intervention may be warranted where there is evidence of skeletal instability (e.g. anterior or posterior spinal column fracture) or an impending fracture (e.g. a large lytic lesion on a weight-bearing bone with more than 50% cortical involvement). Intravenous bisphosphonates (pamidronate, zoledronic acid or denosumab) are widely used for bone metastases and are effective at improving pain and in reducing further skeletal related events, such as fractures and hypercalcaemia. In certain types of cancer, such as breast and prostate, hormonal therapy may be effective. Radiotherapy, in the form of external beam therapy or systemic radionuclides (strontium treatment), can also be useful for these patients. In some settings (e.g. breast carcinoma), chemotherapy may be used in the management of bony metastases.

Malignant pleural effusion

This is a common complication of cancer and 40% of all pleural effusions are due to malignancy. The most common causes are lung and breast cancers, and the presence of an effusion indicates advanced and incurable disease. The presentation may be with dyspnoea, cough or chest discomfort, which can be dull or pleuritic in nature. Diagnosis and management of ascites are discussed on page 863.

33.15 How to aspirate a malignant pleural effusion

- Ask the patient to sit up and lean forwards slightly.
- Identify a suitable site for aspiration. Typically, this should be in the mid-scapular line, below the top of the fluid level and above the diaphragm.
- Confirm that the site is below the fluid level by reviewing the chest X-ray and percussing the chest.
- Infiltrate the skin and the intercostal space immediately above the rib below with 1% lidocaine.
- As you advance the needle, aspirate at each step prior to injecting the local anaesthetic.
- On reaching the pleural cavity, you should be able to aspirate pleural fluid; when you do, note the depth of the needle.
- Insert a thoracentesis needle into the pleural space by advancing it along the same track as was used for the local anaesthetic and connect it to a three-way tap and container to collect the fluid.
- Drain the pleural effusion, to a maximum of 1.5 L. If the effusion is larger than this, repeat the procedure on further occasions as necessary.
- Consider using ultrasound-guided placement of a drainage catheter if the effusion proves difficult to drain.
- Permanent drains can be useful for some patients with recurrent effusions where pleurodesis is not possible.

Investigations and management

Pleural aspirate is the key investigation and may show the presence of malignant cells. Malignant effusions are commonly blood-stained and are exudates with a raised fluid to serum LDH ratio (>0.6) and a raised fluid to serum protein ratio (>0.5). Treatment should focus on palliation of symptoms and be tailored to the patient's physical condition and prognosis. Aspiration alone may be an appropriate treatment in frail patients with a limited life expectancy (Box 33.15). Those who present with malignant pleural effusion as the initial manifestation of breast cancer, small cell lung cancer, germ cell tumours or lymphoma should have the fluid aspirated and should be given systemic chemotherapy to try to treat disease in the pleural space. Treatment options for patients with recurrent pleural effusion include pleurodesis, pleurectomy and pleuroperitoneal shunt. Ideally, pleurodesis should be attempted once effusions recur after initial drainage.

Therapeutics in oncology

Anti-cancer therapy may be either curative or palliative, and this distinction influences the approach to management of individual patients. The goal of treatment should be recorded in the medical notes.

- *Palliative chemotherapy* is the most common treatment and is primarily used to treat patients with metastatic disease. The goal is an improvement in symptoms with a focus on improving quality of life, and any survival increments are secondary. As a result, the treatment should be well tolerated and should aim to minimise adverse effects.
- *Adjuvant chemotherapy* is given after an initial intervention that is designed to cyto-reduce the tumour bulk and remove all macroscopic disease. Chemotherapy is then given with the intention of eradicating the micrometastatic disease that remains. The focus is on achieving an improvement in disease-free and overall survival.

- *Neoadjuvant chemotherapy* or primary medical therapy is where chemotherapy is administered first before a planned cyto-reductive procedure. This can result in a reduced requirement for surgery, increase the likelihood of successful debulking, reduce the duration of hospitalisation and improve the fitness of the patient prior to interval debulking. This approach has the same goals as adjuvant treatment but creates an opportunity for translational research to measure responses to treatment and correlate with subsequent specimens removed at the time of surgery.
- *Chemoprevention* is the use of pharmacological agents to prevent cancer developing in patients identified as being at particular risk. The agents used therefore aim to modify risk and, as such, should not have significant adverse effects.

Surgical treatment

Surgery has a pivotal role in the management of cancer. There are three main situations in which it is necessary.

Biopsy

In the vast majority of cases, a histological or cytological diagnosis of cancer is necessary, and tissue will also provide important information such as tumour type and differentiation, to assist subsequent management. Cytology can be obtained with fine needle aspiration but a biopsy is usually preferred. This can be a core biopsy, an image-guided biopsy or an excision biopsy.

Excision

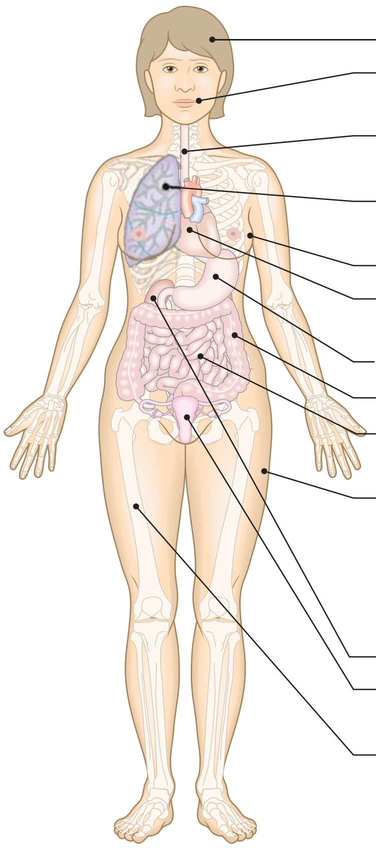
The main curative management of most solid cancers is surgical excision. In early, localised cases of colorectal, breast and lung cancer, cure rates are high with surgery. There is increasing evidence that outcome is related to surgical expertise, and most multidisciplinary teams include surgeons experienced in the management of a particular cancer. There are some cancers for which surgery is one of two or more options for primary management, and the role of the multidisciplinary team is to recommend appropriate treatment for a specific patient. Examples include prostate and transitional cell carcinoma of the bladder, in which radiotherapy and surgery may be equally effective.

Palliation

Surgical procedures are often the quickest and most effective way of palliating symptoms. Examples include the treatment of faecal incontinence with a defunctioning colostomy; fixation of pathological fractures and decompression of spinal cord compression; and the treatment of fungating skin lesions by 'toilet' surgery. A more specialist role for surgery is in resection of residual masses after chemotherapy and, in very selected cases, resection of metastases.

Systemic chemotherapy

Chemotherapeutic drugs are classified by their mode of action. They have the greatest activity in proliferating cells and this provides the rationale for their use in the treatment of cancer. Chemotherapeutic agents are not specific for cancer cells, however, and the side-effects of treatment are a result of their antiproliferative actions in normal tissues such as the bone marrow, skin and gut.



Combination therapy

The dosing schedule and interval are determined by the choice of drugs and recovery of the cancer and normal tissues. For most common chemotherapy regimens, the treatment is administered every 21 or 28 days, which defines one cycle. A course of treatment often uses up to 6 cycles of treatment. An increase in effectiveness can be achieved by changing the approach to treatment. In some cases this will increase toxicity too, but it can change the nature of the toxicity and such developments are evaluated in clinical trials.

- *Low-dose therapy* is the standard approach and most palliative chemotherapy is given in this manner. The next cycle is started once bone marrow function has recovered sufficiently to start the treatment (neutrophils $>1.0\times10^9$/L and platelets $>100\times10^9$/L).
- *High-dose therapy* uses a higher individual drug dose to achieve a higher cell kill but results in more bone marrow toxicity. This can be minimised by using G–CSF. This approach allows more drug to be delivered within the same schedule of administration, but the total received dose can be less than the intended dose due to limitations of non-haematological toxicity.
- *Dose-dense therapy* involves fractionating the intended dose of drug and administering each fraction on a more frequent basis (often weekly). Each individual dose produces less toxicity but the anti-cancer effect is related to the accumulative dose over time. Such an approach can overcome drug resistance, produce a greater cell kill and, in some cases, produce a response with weekly administration when the 3-weekly schedule demonstrates a lack of response or even disease progression.
- *Alternating therapy* involves giving different drugs in an alternating manner. This is most commonly used with haematological malignancies and is designed to treat different subpopulations of cancer cells where individual clones of cells might be resistant to one or more of the agents.

Adverse effects

Most cytotoxics have a narrow therapeutic window or index and can have significant adverse effects, as shown in Figure 33.6. Considerable supportive therapy is often required to enable patients to tolerate therapy and achieve benefit. Nausea and vomiting are common, but with modern antiemetics, regimens such as the combination of dexamethasone and highly selective 5-hydroxytryptamine (5-HT_3, serotonin) receptor antagonists like ondansetron, most patients now receive chemotherapy without any significant problems. Myelosuppression is common to almost all cytotoxics and this not only limits the dose of drug but also can cause life-threatening complications. The risk of neutropenia can be reduced with the use of specific growth factors that accelerate the repopulation of myeloid precursor cells. The most commonly employed is G–CSF, which is widely used in conjunction with chemotherapy regimens that induce a high rate of neutropenia. More recently, it has been used to 'accelerate' the administration of chemotherapy, enabling standard doses to be given at shorter intervals where the rate-limiting factor has been the time taken for the peripheral neutrophil count to recover. Accelerated chemotherapy regimens have now been demonstrated to offer therapeutic advantages in small cell lung cancer, lymphoma and possibly breast cancer.

	Chemotherapy (often drug-specific)	Radiotherapy
Hair follicles	Alopecia	Alopecia
Oral mucosa	Mucositis	Mucositis Xerostomia
Oesophagus	Mucositis	Mucositis Strictures
Lung	Fibrosis	Cough Fibrosis
Breast tissue		↑ Risk breast cancer
Heart	Arrhythmias Heart failure	↑ Risk ischaemic heart disease
Upper GI tract	Nausea and vomiting	
Bowel	Mucositis, diarrhoea	
Small bowel		Nausea, diarrhoea Fibrosis and perforation
Skin	Erythema	Erythema and desquamation Telangiectasia, thinning of the skin
Neural tissue	Sensory neuropathy Motor neuropathy Nerve deafness	
Kidneys	Renal impairment	
Fertility	Premature gonadal failure Amenorrhoea	Premature gonadal failure
Bone marrow	Neutropenia, anaemia Thrombocytopenia	Neutropenia ↓ Haemoglobin, platelet count
Any organs		Increased risk of malignancy
Children		Reduced growth

Fig. 33.6 Adverse effects of chemotherapy and radiotherapy. Acute effects are shown in pink and late effects in blue.

Radiation therapy

Radiation therapy (radiotherapy) involves treating the cancer with ionising radiation; for certain localised cancers it may be curative. Ionising radiation can be delivered by radiation emitted from the decay of radioactive isotopes or by high-energy radiation beams, usually X-rays. Three methods are usually employed:

- *Teletherapy*: application from a distance by a linear accelerator.
- *Brachytherapy*: direct application of a radioactive source on to or into a tumour. This allows the delivery of a very high, localised dose of radiation and is integral to the management of localised cancers of the head and neck, and cancer of the cervix and endometrium.
- *Intravenous injection of a radioisotope*: such as ^{131}iodine for cancer of the thyroid and ^{89}strontium for the treatment of bone metastases from prostate cancer.

The majority of treatments are delivered by linear accelerators, which produce electron or X-ray beams of high energy that are used to target tumour tissue. The biological effect of ionising radiation is to cause lethal and sublethal damage to DNA. Since normal tissues are also radiosensitive, treatment has to be designed to maximise exposure of the tumour and minimise exposure of normal tissues. This is possible with modern imaging techniques such as CT and MRI, which allow better visualisation of normal and tumour tissue. In addition, techniques such as conformal radiotherapy, in which shaped rather than conventional square or rectangular beams are used, allow much more precise targeting of therapy to the tumour, and reduce the volume of normal tissue irradiated by up to 40% compared to non-conformal techniques.

Biological differences between normal and tumour tissues are used to obtain therapeutic gain. Fundamental to this is fractionation, which entails delivering the radiation as a number of small doses on a daily basis. This allows normal cells to recover from radiation damage but recovery occurs to a lesser degree in malignant cells. Fractionation regimens vary, but radical treatments given with curative intent are usually delivered in 20–30 fractions given daily on 5 days a week, over 4–6 weeks. Radiotherapy can be extremely useful for the alleviation of symptoms, and for palliative treatments such as this a smaller number of fractions (1–5) is usually adequate.

Both normal and malignant tissues vary widely in their sensitivity to radiotherapy. Germ cell tumours and lymphomas are extremely radiosensitive and relatively low doses are adequate for cure, but most cancers require doses close to or beyond that which can be tolerated by adjacent normal structures. Normal tissue also varies in its radiosensitivity, the central nervous system, small bowel and lung being among the most sensitive. The side-effects of radiotherapy (see Fig. 33.6) depend on the normal tissues treated, their radiosensitivity and the dose delivered.

Adverse effects

An acute inflammatory reaction commonly occurs towards the end of most radical treatments and is localised to the area treated. For example, skin reactions are common with breast or chest wall radiotherapy, and proctitis and cystitis with treatment to the bladder or prostate. These acute reactions settle over a period of a few weeks after treatment, assuming normal tissue tolerance has not been exceeded. Late effects of radiotherapy develop 6 weeks or more after treatment and occur in 5–10% of patients. Examples include brachial nerve damage and subcutaneous fibrosis after breast cancer treatment, and shrinkage and fibrosis of the bladder after treatment for bladder cancer. There is a risk of inducing cancer after radiotherapy, which varies depending on the site treated and on whether the patient has had other treatment such as chemotherapy.

Hormone therapy

Hormone therapy is most commonly used in the treatment of breast cancer and prostate cancer. Breast tumours that are positive for expression of the oestrogen receptor (ER) respond well to anti-oestrogen therapy, and assessment of ER status is now standard in the diagnosis of breast cancer. Several drugs are now available that reduce oestrogen levels or block the effects of oestrogen on the receptor. When targeted appropriately, adjuvant hormone therapy reduces the risk of relapse and death at least as much as chemotherapy, and in advanced cases can induce stable disease and remissions that may last months to years, with acceptable toxicity. Hormonal manipulation may be effective in other cancers. In prostate cancer, hormonal therapy (e.g. luteinising hormone releasing hormone (LHRH) analogues such as goserelin and/or anti-androgens such as bicalutamide) aimed at reducing androgen levels can provide good long-term control of advanced disease, but there is no convincing evidence that it is an effective therapy following potentially curative surgery. Progestogens are active in the treatment of endometrial and breast cancer. In the metastatic setting, progestogen use (e.g. megestrol acetate) is associated with response rates of 20–40% in endometrial cancer. In breast cancer, progestogens are used in patients whose disease has progressed with conventional anti-oestrogen therapy. Their exact mechanism in this setting is not fully understood.

Immunotherapy

A profound stimulus to the patient's immune system can sometimes alter the natural history of a malignancy, and the discovery of interferons was the impetus for much research. Although solid tumours show little benefit, interferons are active in melanoma and lymphoma, and there is evidence that they are beneficial as adjuvants (after surgery and chemotherapy, respectively) to delay recurrence. Whether interferon-induced stimulation of the immune system is capable of eradicating microscopic disease remains unproven. More powerful immune responses can be achieved with potent agents like IL-2 but the accompanying systemic toxicity is a problem still to be overcome. The most striking example of successful immunotherapy is that with rituximab, an antibody against the common B-cell antigen CD20. It increases complete response rates and improves survival in diffuse large cell non-Hodgkin lymphoma when combined with chemotherapy, and is effective in palliating advanced follicular non-Hodgkin lymphoma (p. 965).

Biological therapies

Advances in knowledge about the molecular basis of cancer have resulted in the development of a new generation of treatments to block the signalling pathways responsible for the growth of specific tumours. This has created the potential to target cancer cells more selectively, with reduced toxicity to normal tissues. Some examples are discussed below, but in the years to come many more such agents will come into clinical use, with the potential to revolutionise our approach to some cancers.

Gefitinib/erlotinib

These agents inhibit the activity of the EGFR, which is over-expressed in many solid tumours. However, the drugs' activity does not depend on the amount of receptor over-expression but rather on factors such as gene copy number and mutation status.

Imatinib

Imatinib was developed to inhibit the *BCR-ABL* gene product, tyrosine kinase, that is responsible for chronic myeloid leukaemia (p. 958), and it does this extremely effectively. It is also active in malignant gastrointestinal stromal tumour (GIST), a type of sarcoma that has over-expression of another cell surface tyrosine kinase, c-kit. This agent has good tolerability and is particularly useful in GIST, where conventional chemotherapy is less effective.

Bevacizumab

This is a humanised monoclonal antibody that inhibits vascular endothelial growth factor A (VEGF-A), a key stimulant of angiogenesis in tumours. Bevacizumab has activity in colorectal, lung, breast, renal and ovarian cancers, although the licence was subsequently revoked for breast cancer; while bevacizumab slows the rate of progression of metastatic breast cancer, it had little impact on survival or improved quality of life.

Trastuzumab

Trastuzumab (Herceptin) targets the HER2 receptor, an oncogene that is over-expressed in around one-third of breast cancers and in a number of other solid tumours (e.g. gastric cancer). It is effective as a single-agent therapy, but also improves survival in patients with advanced breast cancer when used in conjunction with chemotherapy. Unfortunately, trastuzumab can induce cardiac failure by an unknown biological mechanism, especially in combination with doxorubicin.

Evaluation of treatment

The evaluation of treatment includes an assessment of overall survival duration, response to treatment, remission rate, disease-free survival and response duration, quality of life and treatment toxicity. Uniform criteria have been established to measure these, including the response evaluation criteria in solid tumours (RECIST, Box 33.16) and common toxicity criteria. This allows clinicians to inform patients accurately about the prognosis, effectiveness and toxicity of chemotherapy and empowers patients to take an active role in treatment decisions.

Late toxicity of therapy

The late toxicities of treatment for cancer are particularly important for patients where the multimodality therapy is given with curative

33.16 Response evaluation criteria in solid tumours (RECIST)

Response	Criteria
Complete response (CR)	Disappearance of all target lesions
Partial response (PR)	At least a 30% decrease in the sum of the longest diameter (LD) of target lesions, taking as reference the baseline sum LD
Progressive disease (PD)	At least a 20% increase in the sum of the LD of target lesions, taking as reference the smallest sum LD recorded since the treatment started and at least 5 mm increase or the appearance of one or more new lesions
Stable disease (SD)	Neither sufficient shrinkage to qualify for PR nor sufficient increase to qualify for PD, taking as reference the smallest sum LD since the treatment started

intent, the patient is young and more patients are living longer. This can cause considerable morbidity: for example, radiotherapy can retard bone and cartilage growth, impair intellect and cognitive function, and cause dysfunction of the hypothalamus, pituitary and thyroid glands. Late consequences of chemotherapy include heart failure due to cardiotoxicity, pulmonary fibrosis, nephrotoxicity and neurotoxicity.

Premature gonadal failure can result from chemotherapy or radiotherapy and leave a patient subfertile. Patients should be made aware of this before treatment is initiated, as it may be possible to store sperm for male patients before treatment starts; this should always be offered, if practical. Egg or embryo banking after in vitro fertilisation may be an option for young women. Sterility develops at higher radiotherapy doses but erectile dysfunction is seen in patients receiving high radiotherapy doses to the pelvis, as in prostate cancer. Additional social or psychological support may be required. Infertility and pubertal delay are potential late effects of therapy in children, especially boys.

Second malignancies may be induced by cancer treatment and occur at greatest frequency following chemoradiation. Secondary acute leukaemia (mostly AML) can occur 1–2 years after treatment with topoisomerase II inhibitors, or 2–5 years after treatment with alkylating agents. The most common second malignancy within a radiation field is osteosarcoma but others include soft tissue sarcoma and leukaemia.

Specific cancers

The diagnosis and management of cancers are discussed in more detail elsewhere in the book (Box 33.17). Here we discuss the pathogenesis, clinical features, investigation and management of common tumours that are not covered elsewhere.

Breast cancer

Globally, the incidence of breast cancer is second only to that of lung cancer, and the disease represents the leading cause of cancer-related deaths among women. Invasive ductal carcinoma with or without ductal carcinoma in situ (DCIS) is the most common histology, accounting for 70%, whilst invasive lobular carcinoma accounts for most of the remaining cases. DCIS constitutes 20% of breast cancers detected by mammography screening. It is multifocal in one-third of women and has a high risk of becoming invasive (10% at 5 years following excision only). Pure DCIS does not cause lymph node metastases, although these are found in 2% of cases where nodes are examined, owing to undetected invasive cancer. Lobular carcinoma in situ (LCIS) is a predisposing risk factor for developing cancer in either breast (7% at 10 years). The survival for breast cancer by stage is outlined in Box 33.18.

33.17 Specific cancers covered in other chapters

Bladder cancer	p. 435
Colorectal cancer	p. 827
Familial cancer syndromes	p. 56
Gastric cancer	p. 803
Hepatocellular carcinoma	p. 890

Prostate cancer	p. 438
Renal cancer	p. 434
Seminoma	p. 439
Skin cancer	p. 1229
Teratoma	p. 439
Thyroid cancer	p. 649

33.18 Five-year survival rates for breast cancer by stage

Tumour stage	Stage definition	5-year survival (%)
I	Tumour <2 cm, no lymph nodes	96
II	Tumour 2–5 cm and/or mobile axillary lymph nodes	81
III	Chest wall or skin fixation and/or fixed axillary lymph nodes	52
IV	Metastasis	18

Pathogenesis

Both genetic and hormonal factors play a role; about 5–10% of breast cancers are hereditary and occur in patients with mutations of *BRCA1*, *BRCA2*, *AT* or *TP53* genes. Prolonged oestrogen exposure associated with early menarche, late menopause and use of hormone replacement therapy (HRT) has been associated with an increased risk. Other risk factors include obesity, alcohol intake, nulliparity and late first pregnancy. There is no definite evidence linking use of the contraceptive pill to breast cancer.

Clinical features

Breast cancer usually presents as a result of mammographic screening or as a palpable mass with nipple discharge in 10% and pain in 7% of patients. Less common presentations include inflammatory carcinoma with diffuse induration of the skin of the

breast, and this confers an adverse prognosis. Around 40% of patients will have axillary nodal disease, with likelihood correlating with increasing size of the primary tumour. Distant metastases are infrequently present at diagnosis and the most common sites of spread are bone (70%), lung (60%), liver (55%), pleura (40%), adrenals (35%), skin (30%) and brain (10–20%).

Investigations

Following clinical examination, patients should have imaging with mammography or ultrasound evaluation, and a biopsy using fine needle aspiration for cytology or core biopsy for histology. Histological assessment should be carried out to assess tumour type and to determine oestrogen and progesterone receptor (ER/PR) status and HER2 status. If distant spread is suspected, CT of the thorax and abdomen and an isotope bone scan are required. Molecular subtyping is being used to classify tumours into four major subtypes: luminal A, luminal B, HER2 type and basal-like (often called ‘triple negative’, as these tumours are ER-, PR- and HER2-negative). This may allow more targeted selection of therapies in future.

Management

Surgery is the mainstay of treatment for most patients, and this can range from a lumpectomy, where only the tumour is removed, to mastectomy, where the whole breast is removed. Breast-conserving surgery is as effective as mastectomy if complete excision with negative margins can be achieved. Lymph node sampling is performed at the time of surgery. Adjuvant radiotherapy is given to reduce the risk of local recurrence to 4–6%. Adjuvant hormonal therapy improves disease-free and overall survival in pre- and post-menopausal patients who have tumours that express ER. Patients at low risk, with tumours that are small and ER-positive, require only adjuvant hormonal therapy with tamoxifen. Patients with tumours that are ER-positive and who are pre-menopausal should receive an LHRH analogue. Aromatase inhibitors also have benefit in this setting but are still under investigation.

Adjuvant chemotherapy is considered for patients at higher risk of recurrence. Factors that increase the risk of recurrence include a tumour of >1 cm, a tumour that is ER-negative or the presence of involved axillary lymph nodes. Such patients should be offered adjuvant chemotherapy, which improves disease-free and overall survival. The role of adjuvant treatment has been studied by meta-analyses and data support the use of adjuvant trastuzumab, a humanised monoclonal antibody to HER2, in addition to standard chemotherapy for women with early HER2-positive breast cancer.

Metastatic disease management includes radiotherapy to palliate painful bone metastases and second-line endocrine therapy with aromatase inhibitors, which inhibit peripheral oestrogen production in adrenal and adipose tissues. Advanced ER-negative disease may be treated with combination chemotherapy.

Ovarian cancer

Ovarian cancer is the most common gynaecological tumour in Western countries. Most ovarian cancers are epithelial in origin (90%), and up to 7% of women with ovarian cancer have a positive family history. Patients often present late in ovarian cancer with vague abdominal discomfort, low back pain, bloating, altered bowel habit and weight loss. Occasionally, peritoneal deposits are palpable as an omental ‘cake’ and nodules in the umbilicus (Sister Mary Joseph nodules).

Pathogenesis

Genetic and environmental factors play a role. The risk of ovarian cancer is increased in patients with *BRCA1* or *BRCA2* mutations, and Lynch type II families (a subtype of hereditary non-polyposis colon cancer, HNPCC) have ovarian, endometrial, colorectal and gastric tumours due to mutations of mismatch repair enzymes. Advanced age, nulliparity, ovarian stimulation and Caucasian descent all increase the risk of ovarian cancer, while suppressed ovulation appears to protect, so pregnancy, prolonged breastfeeding and the contraceptive pill have all been shown to reduce the risk of ovarian cancer.

Investigations

Initial workup for patients with suspected ovarian cancer includes imaging in the form of ultrasound and CT. Serum levels of the tumour marker CA-125 are often measured. Surgery plays a key role in the diagnosis, staging and treatment of ovarian cancer, and in early cases, palpation of viscera, peritoneal washings and biopsies are generally performed to define disease extent.

Management

In early disease, surgery followed by adjuvant chemotherapy with carboplatin, or carboplatin plus paclitaxel, is the treatment of choice. Surgery should include removal of the tumour along with total abdominal hysterectomy, bilateral salpingo-oophorectomy, and omentectomy. Even in advanced disease, surgery is undertaken to debulk the tumour and is followed by adjuvant chemotherapy, typically using carboplatin and paclitaxel. Bevacizumab is indicated for patients with high-grade tumours that are suboptimally debulked or those with a more aggressive biological pattern. Monitoring for relapse is achieved through a combination of serum CA-125 and clinical examination with CT imaging for those with suspected relapse. Second-line chemotherapy is aimed at improving symptoms and should not be used for CA-125 elevation only in the absence of symptoms. Treatments can include further platinum/paclitaxel in combination, liposomal doxorubicin or topotecan. These regimens are associated with a response rate of 10–40%. The best responses are observed in patients with a treatment-free interval of more than 12 months.

Endometrial cancer

Endometrial cancer accounts for 4% of all female malignancies, producing a 1 in 73 lifetime risk. The majority of patients are post-menopausal, with a peak incidence at 50–60 years of age. Mortality from endometrial cancer is currently falling. The most common presentation is with post-menopausal bleeding, which often results in detection of the disease before distant spread has occurred.

Pathogenesis

Oestrogen plays an important role in the pathogenesis of endometrial cancer, and factors that increase the duration of oestrogen exposure, such as nulliparity, early menarche, late menopause and unopposed HRT, increase the risk. Endometrial cancer is 10 times more common in obese women and this is thought to be due to elevated levels of oestrogens.

Investigations

The diagnosis is confirmed by endometrial biopsy.

Management

Surgery is the treatment of choice and is used for staging. A hysterectomy and bilateral salpingo-oophorectomy are performed with peritoneal cytology and, in some cases, lymph node dissection. Where the tumour extends beyond the inner 50% of the myometrium or involves the cervix and local lymph nodes, or there is lymphovascular space invasion, adjuvant pelvic radiotherapy is recommended. Chemotherapy is used as adjuvant therapy and hormonal therapy and chemotherapy are used to palliate symptoms in recurrent disease.

Cervical cancer

This is the second most common gynaecological tumour worldwide and the leading cause of death from gynaecological cancer. The incidence is decreasing in developed countries but continues to rise in developing nations. The most common presentation is with an abnormal smear test, but with locally advanced disease the presentation is with vaginal bleeding, discomfort, discharge or symptoms attributable to involvement of adjacent structures, such as bladder, or rectal or pelvic wall. Occasionally, patients present with distant metastases to bone and lung.

Pathogenesis

There is a strong association between cervical cancer and sexual activity that includes sex at a young age and multiple sexual partners. Infection with HPV has an important causal role, and this has underpinned the introduction of programmes to immunise teenagers against HPV in an effort to prevent the later development of cervical cancer (p. 342).

Investigations

Diagnosis is made by smear or cone biopsy. Further examination may require cystoscopy and flexible sigmoidoscopy if there are symptoms referable to the bladder, colon or rectum. In contrast to other gynaecological malignancies, cervical cancer is a clinically staged disease, although MRI is often used to characterise the primary tumour. A routine chest X-ray should be obtained to help rule out pulmonary metastasis. CT of the abdomen and pelvis is performed to look for metastasis in the liver and lymph nodes, and to exclude hydronephrosis and hydroureter.

Management

This depends on the stage of disease. Pre-malignant disease can be treated with laser ablation or diathermy, whereas in microinvasive disease a large loop excision of the transformation zone (LLETZ) or a simple hysterectomy is employed. Invasive but localised disease requires radical surgery, while chemotherapy and radiotherapy, including brachytherapy, may be given as primary treatment, especially in patients with adverse prognostic features such as bulky or locally advanced disease, or lymph node or parametrium invasion. In metastatic disease, cisplatin-based chemotherapy may be beneficial in improving symptoms but does not increase survival significantly.

Head and neck tumours

Head and neck cancers are typically squamous tumours that arise in the nasopharynx, hypopharynx and larynx. They are most common in elderly males but now occur with increasing frequency in a younger cohort, as well as in women, especially where oropharyngeal cancers are concerned. The rising incidence of oropharyngeal cancers, especially in the developed world, is thought to be secondary to HPV infection. Presentation depends on the location of the primary tumour and the extent of disease. For example, early laryngeal cancers may present with hoarseness, while more extensive local disease may present with pain due to invasion of local structures or with a lump in the neck. Patients who present late often have pulmonary symptoms, as this is the most common site of distant metastases (Box 33.19).

i 33.19 Common presenting features by location in head and neck cancer

Hypopharynx	
• Dysphagia • Odynophagia	• Referred otalgia • Enlarged lymph nodes
Mouth	
• Non-healing ulcers	• Ipsilateral otalgia
Nasal cavity and sinuses	
• Discharge (bloody) or obstruction	
Nasopharynx	
• Nasal discharge or obstruction • Conduction deafness • Atypical facial pain	• Diplopia • Hoarse voice • Horner's syndrome
Oropharynx	
• Dysphagia • Pain	• Otalgia
Salivary gland	
• Painless swelling	• Facial nerve palsy

Pathogenesis

The tumours are strongly associated with a history of smoking and excess alcohol intake, but other recognised risk factors include Epstein–Barr virus for nasopharyngeal cancer and HPV infection for oropharyngeal tumours.

Investigations

Careful inspection of the primary site is required as part of the staging process, and most patients will require endoscopic evaluation and examination under anaesthesia. Tissue biopsies should be taken from the most accessible site. CT of the primary site and the thorax is the investigation of choice for visualising the tumour, while MRI may be useful in certain cases.

Management

Generally speaking, the majority of patients with early or locally advanced disease are treated with curative intent. In localised disease where there is no involvement of the lymph nodes, long-term remission can be achieved in up to 90% of patients with surgery or radiotherapy. The choice of surgery versus radiotherapy often depends on patient preference, as surgical treatment can be mutilating with an adverse cosmetic outcome. Patients with lymph node involvement or metastasis are treated with a combination of surgery and radiotherapy (often with chemotherapy as a radiosensitising agent – proven agents include cisplatin or cetuximab), and this produces long-term remission in approximately 60–70% of patients. Recurrent or metastatic tumour may be palliated with further surgery or radiotherapy to aid local control, and systemic chemotherapy has a response rate of around 20–30%. Second malignancies are common (3%

per year) following successful treatment for primary disease, and all patients should be encouraged to give up smoking and drinking alcohol to lower their risk.

Carcinoma of unknown origin

Some patients are found to have evidence of metastatic disease at their initial presentation, prior to diagnosis of a primary site. In many cases, a subsequent biopsy reveals adenocarcinoma but the primary site is not always clear.

Investigations

In this situation, there is a temptation to investigate the patient endlessly in order to determine the original primary site. There is a compromise, however, between exhaustive investigation and obtaining sufficient information to plan appropriate management. For all patients, histological examination of an accessible site of metastasis is required. The architecture of the tissue can assist the pathologist in determining the likely primary site, and therefore it is better to perform a biopsy rather than fine needle aspiration. The greater volume of tissue permits the use of immunohistochemistry. Extensive imaging to search for the primary is rarely indicated; a careful history to identify symptoms and risk factors (including familial) will often permit a judicious choice of imaging and other diagnostic tests, reserving additional tests for specific patients (Box 33.20).

Management

Management of the patient will depend on that person's circumstances, as well as on the site(s) involved and the likely primary sites. The overriding principle is to ensure that a curable diagnosis has been excluded. For example, lung metastases from a testicular teratoma do not preclude cure; nor do one or two liver metastases from a colorectal cancer. Early discussion with an oncologist within a multidisciplinary team is essential and avoids unnecessary investigation; for example, a single hCG-based pregnancy test in a young man with lung metastases might confirm the presence of a teratoma and allow rapid administration of potentially curative chemotherapy. Treatment should not necessarily wait for a definitive diagnosis; appropriate analgesia, radiotherapy and surgical palliation can all be helpful. Some patients remain free of cancer for some years after resection of a single metastasis of an adenocarcinoma of unknown primary, justifying this approach in selected patients.

In those with no obvious primary, systemic chemotherapy may achieve some reduction in tumour burden and alleviation of symptoms, but long-term survival is rare.

i 33.20 Initial diagnostic tests in patients presenting with carcinoma of unknown primary*

- Detailed history and examination, including breast, nodal areas, skin, genital, rectal and pelvic regions
- Full blood count, urea and electrolytes, renal function, liver function tests, calcium, urinalysis, lactate dehydrogenase
- Chest X-ray
- Myeloma screen (if lytic bone lesions)
- CT scan of chest, abdomen and pelvis
- Symptom-directed upper and lower gastrointestinal endoscopy
- Tumour markers: prostate-specific antigen (PSA) in men, cancer antigen 125 (CA-125) in women with peritoneal malignancy or ascites, α-fetoprotein (AFP) and human chorionic gonadotrophin (hCG)
- Testicular ultrasound (if clinical features suggest germ cell tumour)
- Histological examination of biopsy, with immunohistochemistry if required

*Offer when clinically appropriate.

Multidisciplinary teams

The multidisciplinary team (MDT) is well established in oncology and meets on a regular basis to discuss patient progress and provide a forum for patient-centred, interdisciplinary communication to coordinate care and decision-making. It is a platform on which individual clinicians can discuss complex cases or situations and draw on the collective experience of the team membership to decide on the best approach for an individual patient. This can be particularly important when discussing patients with a rare condition or in a rare situation.

Specific roles of the MDT include:

- planning the diagnostic and staging procedures
- deciding on the appropriate primary treatment modality (most commonly surgery but the use of neoadjuvant chemotherapy before interval surgery is increasing)
- arranging review by the oncology team to plan assessment of the patient prior to systemic therapy or radiotherapy
- discussing additional support requirements for the individual patient, such as physiotherapy; psychological support; symptom control; nutritional care or rehabilitation in the post-operative period
- ensuring access to accurate information on treatment, prognosis, side-effects and other related matters, such as stoma care
- planning surveillance strategies
- ensuring the appropriate transition from treatment with curative intent to that of palliation of symptoms
- promoting recruitment into clinical trials
- agreeing on operational policies to deliver high-quality care to patients
- planning and reviewing audit data to ensure the delivery of quality care to patients by the team.

Pain and palliative care

Pain

Pain is defined as 'an unpleasant sensory and emotional experience associated with actual or potential tissue damage or described in terms of such damage'. It is one of the most common symptoms for which people seek health-care advice. Our understanding of the mechanisms of pain has evolved considerably from Hippocrates' suggestion in 450 BC that pain arose as a result of an imbalance in vital fluids. We now know that pain is a complex symptom that is influenced and modified by many social, cultural and emotional factors, as illustrated in Figure 34.1. The sensation of acute pain that occurs in response to inflammation or tissue damage plays an important role in protection from further injury. Chronic pain serves no useful function but results in significant distress and suffering for the patient affected, as well as having a wider societal impact.

Functional anatomy and physiology

The functional anatomy of the somatosensory system is shown in Figures 25.3 and 25.6 (pp. 1065 and 1068). Here, discussion will focus on the mechanisms and mediators that are involved in pain processing.

Peripheral nerves

Peripheral nerves contain several types of neuron. These can be classified into two groups, depending on whether or not they are surrounded by a myelin sheath. Myelinated neurons have a fast conduction velocity and are responsible for transmission of various sensory signals, such as proprioception, light touch, heat and cold, and the detection of localised pains, such as pin-prick. Unmyelinated fibres have a much slower conduction velocity and are responsible for transmitting diffuse and poorly localised pain, as well as other sensations (Box 34.1).

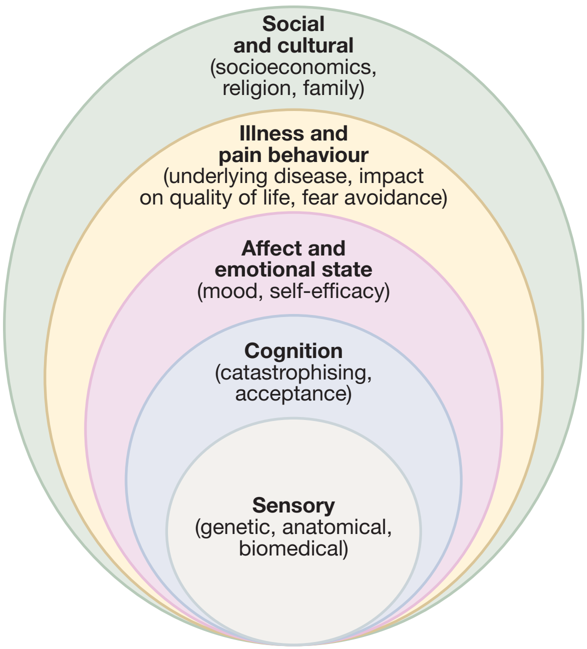

Fig. 34.1 The biopsychosocial model of pain. The perception of pain as a symptom is dependent not only on sensory inputs but also on the individual's cognitive reaction to the pain, their emotional state, their underlying disease and their social and cultural background.

i 34.1 Types of nerve fibre

Fibre type	Diameter (μm)	Conduction velocity (ms^{-1})	Function
Large myelinated			
Aα	12–20	70–120	Proprioception Motor to muscle fibres
Aβ	5–12	30–70	Light touch, pressure
A-	3–6	15–30	Motor to muscle spindles
Small myelinated			
A	2–5	12–30	Well-localised pain Thermal sensation
B	<3	3–15	Pre-ganglionic autonomic
Unmyelinated			
C	0.4–1.3	0.5–3	Diffuse pain Poorly localised thermal sensation Post-ganglionic autonomic

Sensory neurons (also known as primary afferent neurons) connect the spinal cord to the periphery and supply a defined territory or a dermatome, which can be used to identify the position of a nerve lesion (see Fig. 25.10, p. 1071). In healthy individuals dermatomes have distinct borders, but in pathological pain syndromes these may become blurred as the result of neuronal plasticity, which means that pain may be felt in an area adjacent to that supplied by a specific nerve root. Autonomic neurons also contain pain fibres and are responsible for transmitting visceral sensations, such as colic. In general, visceral pain is diffuse and less well localised than pain transmitted by sensory neurons.

Anatomical features of the afferent pain pathway are illustrated in Figure 34.2. Pain signals are transmitted from the periphery to the spinal cord by sensory neurons. These have the following components:

- *A cell body*, containing the nucleus, which is situated in the dorsal root ganglion close to the spinal cord. The cell body is essential for survival of the neuron, production of neurotransmitters and neuronal function.
- *The nerve fibre (axon) and peripheral nerve endings*, which are located in the periphery and contain a range of receptors in the neuronal membrane.
- *Specialised receptors* in the periphery, consisting of bare nerve endings known as nociceptors or pain receptors, which are activated by various mediators. They are situated mainly in the epidermis.
- *The central termination*, which travels to the dorsal horn of the spinal cord to form the first central synapse with neurons that transmit pain sensation to the brain.

When a noxious stimulus is encountered, activation of nociceptors leads to generation of an action potential, which travels upwards to the dorsal root ganglion and also stimulates the release of neurotransmitters that have secondary effects on surrounding neurons.

Spinal cord

Sensory neurons, through their central termination, synapse with second-order neurons in the dorsal horn of the spinal cord. There is considerable modulation of pain messages at

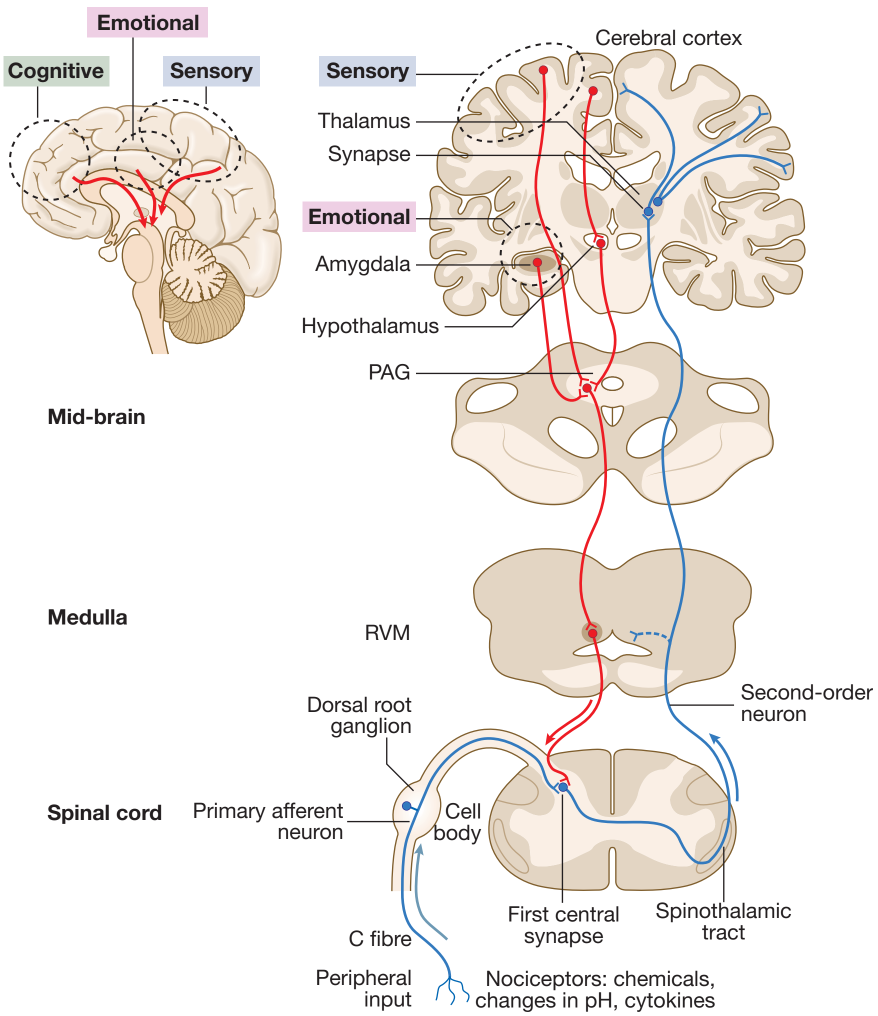

Fig. 34.2 Ascending and descending pain pathways. Ascending pathways are shown in blue and descending in red. Pain signals are detected in the periphery by nociceptors, which are activated by chemicals, changes in pH and cytokines. The signal is transmitted by the primary afferent neuron to the spinal cord, where there is a synapse with a second-order neuron, which transmits the signal onwards to the thalamus. Thereafter, the pain signal is transmitted to the cerebral cortex. The intensity of pain signals is subject to extensive modulation at several levels within the nervous system. Cognitive influences derived from the frontal lobe, coupled with sensory influences from cortex and emotional influences from the amygdyla, affect pain perception in the mid-brain around the periaqueductal gray matter (PAG) and the rostroventrolateral medulla (RVM) in the medulla. These structures form part of the descending modulatory systems, which, under normal circumstances, inhibit pain perception. In some chronic pain states, however, dysfunction of the descending pathways can occur, increasing pain.

this site, both from local neurons within the spinal cord and from neurons that descend from the brain, as depicted in Figure 25.11 (p. 1072). Several neurotransmitters are involved in pain processing at this level and these are summarised in Box 34.2. They include amino acids, such as glycine and γ-aminobutyric acid (GABA), which are inhibitory, and glutamate, which is excitatory; neuropeptides, such as substance P and calcitonin gene-related peptide (CGRP); and endorphins. Whether or not they increase or decrease pain perception depends on the connectivity of the neurons on which they act.

Central processing of pain

The signals transmitted by second-order neurons in the spinal cord are relayed to the sensory cortex by third-order neurons, which synapse with second-order neurons in the thalamus. At this site, perception of pain is influenced by interactions between a range of structures in the brain, where sensory, cognitive and emotional aspects are integrated. This is termed the pain neuromatrix (Fig. 34.2). Signals within the neuromatrix are multidirectional in nature, involving modulation of incoming messages by the cerebral cortex (top-down regulation), as well as a complex network of connections between other subcortical structures. Under normal conditions, there is a degree of descending inhibition from the brainstem that reduces input from peripheral stimuli.

It is thought that chronic widespread pain (CWP) and opioid-induced hyperalgesia may result, at least in part, from abnormalities in central processing of pain signals. It has also been suggested that variations in the levels of descending inhibition between individuals may make some people more vulnerable than others to developing chronic pain. Over recent years, there has been increasing interest in the role that glial cells (see Fig. 25.1, p. 1064) play in pain processing. Both astrocytes and microglial cells can become activated in chronic pain states and release

34.2 Neurotransmitters and receptors involved in pain processing in the spinal cord

Neurotransmitter	Receptor(s)	Receptor type	Comments*
Amino acids			
Glutamate	AMPA	Ion channel	Excitatory; permeable to cations: can be Ca^{2+}, Na^+ or K^+, depending on subunit structure
	NMDA	Ion channel	Excitatory; blocked by Mg^{2+} in the resting state; block can be altered if membrane potential changes; permeable to Ca^{2+}, Na^+ and K^+
	Kainate	Ion channel	Post synaptic – excitatory
	Gp I	GPCR	Pre-synaptic – inhibitory through GABA release; permeable to Na^+ and K^+
	Gp II	GPCR	Activates a range of signalling pathways; long-term effects on synaptic excitability
	Gp III	GPCR	Probably inhibitory; can decrease cAMP production; pre-synaptic; decreases glutamate release
Glycine	GlyR	Ion channel	Mainly inhibitory; permeable to Cl^-; blocked by caffeine
GABA	$GABA_A$	Ion channel	Mainly inhibitory in spinal cord; permeable to Cl^-; indirectly modulated by benzodiazepines (increased ion channel opening); not specifically involved in nociception, generally depressant effect on spinal cord activity
	$GABA_B$	GPCR	Predominantly inhibitory; activated by baclofen
Neuropeptides			
Substance P	Neurokinin receptors	GPCR	Mainly excitatory; increased in inflammation, decreased in neuropathic pain
Cholecystokinin	CCKRs1–8	GPCR	Excitatory; clinical trials of antagonists in progress
Calcitonin gene-related peptide	CALCRL	GPCR	Excitatory; slows degradation of substance P; implicated in migraine
Opioids			
Dynorphin	OP1 (kappa)	GPCR	Excitatory?; may be pro-nociceptive
β-endorphin	OP3 (mu)	GPCR	Inhibitory
Nociceptin	ORL-1	GPCR	Inhibitory; also expressed by immune cells

*Excitatory = increased pain; inhibitory = reduced pain.
(AMPA = α-amino 3-hydroxy, 5-methyl, 4-isoxazole propionic acid; CALCRL = calcitonin receptor-like receptor; cAMP = cyclic adenosine monophosphate; GABA = γ-aminobutyric acid; Gp = group; GPCR = G-protein-coupled receptor; NMDA = *N*-methyl-D-aspartate; OP = opioid; ORL = opioid-like receptor)

pro-inflammatory cytokines, as well as altering re-uptake of excitatory neurotransmitters such as glutamate, which can influence pain perception considerably. As our understanding of these processes improves, there is increasing potential to develop novel therapies targeted at these mediators, with some early clinical studies in neuropathic pain.

Sensitisation

Sensitisation is one of the key features of pain processing. It refers to the fact that both peripheral and central nervous systems adapt rapidly to the presence of pain, especially in response to tissue damage. This adaptive process is called neuronal plasticity. In some situations, neuronal plasticity can lead to prolonged changes in the pathways that are involved in detecting and processing nociceptive stimuli, resulting in chronic pain syndromes. The specific changes in key neurotransmitters and receptors differ between chronic pain states, with implications for the efficacy of treatments. For example, μ-opioid receptors are down-regulated in neuropathic pain, potentially leading to limited opioid responsiveness.

Peripheral sensitisation

Peripheral sensitisation can occur in association with a variety of clinical conditions, including sepsis, cancer, inflammatory disease, injury, surgery and obesity. The final common pathway by which sensitisation takes place in all of these conditions is inflammation. Inflammation is accompanied by increased capillary permeability and tissue oedema with the release of a diverse range of mediators, including bradykinin, hydrogen ions, prostaglandins and adenosine, which bind to receptors and ion channels on nociceptors of primary afferent neurons (Fig. 34.3). The signalling pathways activated by these mediators generate action potentials, which are transmitted by sensory neurons to the spinal cord. If these pain-provoking stimuli persist, the activation threshold of sensory neurons is reduced, resulting in an increased transmission of pain signals to the spinal cord.

Central sensitisation

Sensitisation may also take place at the level of the spinal cord in response to a sustained painful stimulus. It can occur acutely and rapidly, such as immediately after surgery, or may progress to chronic changes, such as chronic infection, cancer, repeated surgery or multiple traumatic episodes. Glutamate, acting via the *N*-methyl-D-aspartate (NMDA) receptor complex, plays a key role in central sensitisation (Fig. 34.4). In response to a sustained peripheral painful stimulus, increased amounts of glutamate are released in the spinal cord, overcoming the inhibitory action of magnesium ions and resulting in activation of the NMDA receptor. This initiates a cascade of intracellular signalling events that lead to prolonged modifications of somatosensory processing, with amplification of pain responses within the spinal cord and continued neuronal firing, even after the noxious stimulus has stopped. This phenomenon is termed 'after-discharge'. In neuropathic pain, prolonged activation of the NMDA pathway results in a decrease in the number of inhibitory interneurons, which further potentiates pain.

Genetic determinants of pain perception

There are marked ethnic and individual variations in how people respond to painful stimuli and studies in twins have estimated

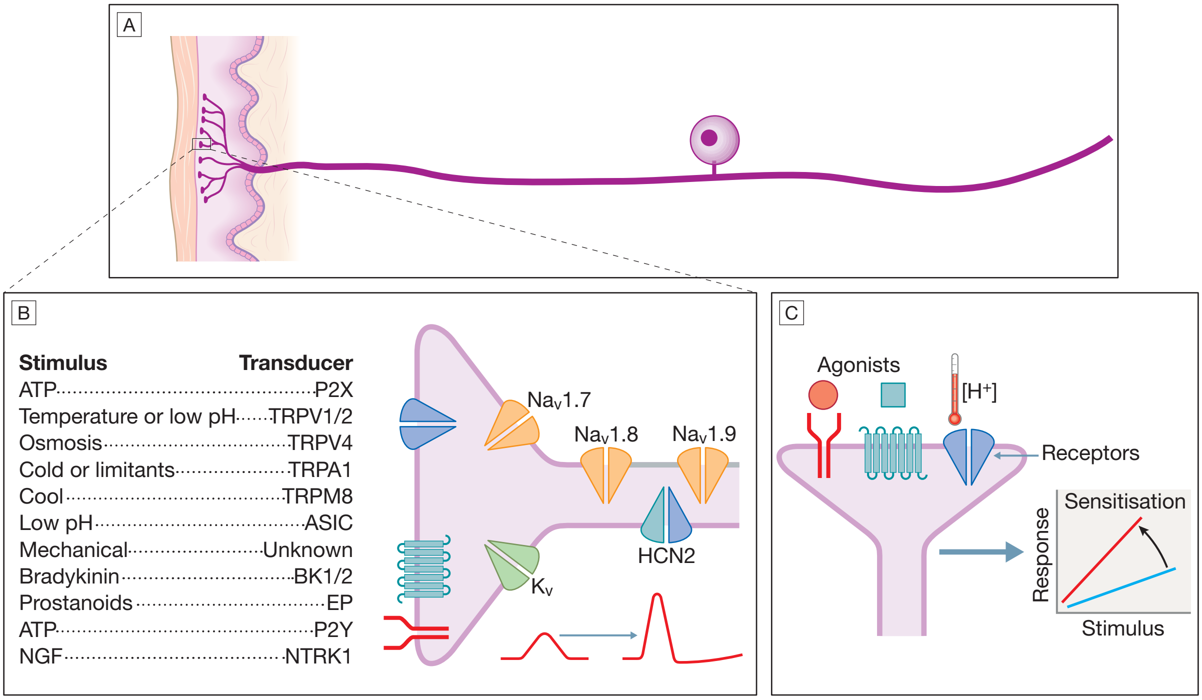

Fig. 34.3 Mechanisms of peripheral sensitisation. A Sensory nerve terminating with nociceptor in skin. B Peripheral nociceptors express various receptors and ion channels that act as mediators of pain. They include sodium channels implicated in congenital pain syndromes; the purinergic 2X (P2X) receptor for adenosine triphosphate (ATP); members of the transient receptor potential (TRP) superfamily of ion channel receptors, which detect changes in osmolality and temperature; acid-sensing ion channel (ASIC) receptors, which detect hydrogen ions; G-protein-coupled receptors, which detect bradykinin (BK), prostaglandins and ATP; and the neurotrophic tyrosine kinase 1 (NTRK1) receptor, which detects nerve growth factor (NGF). C Activation of these receptors by ligands, hydrogen ion [H^+] and high temperature (>42°C) amplifies action potentials, which increase pain signals and cause peripheral sensitisation. *Adapted from Bennett DL, Woods CG. Painful and painless channelopathies. Reprinted with permission from Elsevier (The Lancet Neurol 2014; 13:587–599).*

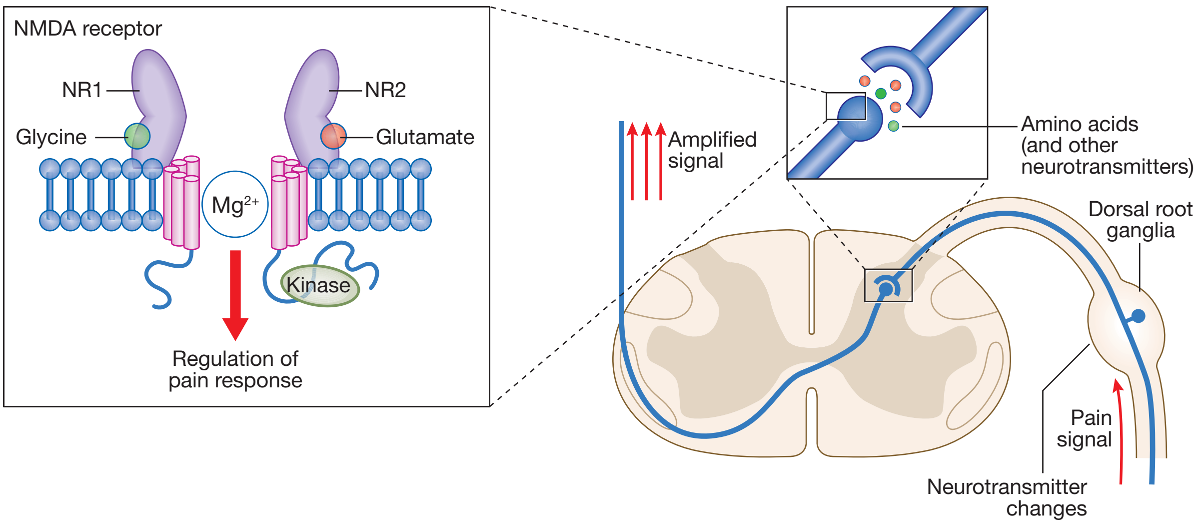

Fig. 34.4 Mechanisms of central sensitisation. Post-synaptic activation of the *N*-methyl-D-aspartate (NMDA) receptor requires the amino acids glycine and glutamate, which bind to the NR1 and NR2 subunits, respectively; these amplify pain signals at the level of the spinal cord. In contrast, magnesium ions block receptor activation.

that the heritability of CWP ranges between 30% and 50%. In the general population, the individual variants in response to pain and perception of pain are most likely due to a complex interaction between genetic and environmental influences. Few variants have been identified with robust evidence of association with CWP. Several rare syndromes have been described, however, in which insensitivity to pain or heightened pain responses occur as the result of a single gene disorder, as summarised in Box 34.3. Most are due to mutations affecting ion channels that play a key role in neurotransmission (see Fig. 34.3), but other causes include mutations in the *NTKR1* gene, which encodes the receptor for nerve growth factor, and mutations in the *PDRM12* transcription factor, which is involved in neuron development.

Investigations

Pain can be a presenting feature of a wide range of disorders and the first step in evaluation of a patient with pain should be to perform whatever investigations are required to define the underlying cause of the pain, unless this is already known. However, with most chronic pain syndromes, such as fibromyalgia, complex regional pain syndrome and CWP, investigations are negative and the diagnosis is made on the basis of clinical history and exclusion of other causes. Specific investigations that are useful in the assessment of selected patients with chronic pain are discussed below.

Magnetic resonance imaging

Magnetic resonance imaging (MRI) can be helpful in the assessment of an underlying cause in patients with focal pain that follows a nerve root or peripheral nerve distribution. Imaging is seldom helpful in individuals with CWP.

Blood tests

Blood tests are not generally helpful in the diagnosis of chronic pain, except in patients with peripheral neuropathy; in this case, a number of blood tests may be required to investigate the underlying causes of the neuropathy. Full details are provided in Box 25.86 (p. 1139). Genetic testing may be of value in patients with clinical features that point to an inherited disorder of pain processing (Box 34.3).

Quantitative sensory testing

Quantitative sensory testing can be helpful in the detailed assessment of patients with chronic pain. A simple set of tools can be used in the clinical setting (Fig. 34.5). Lightly touching the skin with a brush, swab or cotton-wool ball can be used to test for abnormalities of fine touch (allodynia). Assessing the patient's response to a pin-prick can be used to test for abnormalities in mechanical hyperalgesia. Finally, touching the patient's skin with warm and cool thermal rollers can be used to test for abnormalities of thermal sensation. An unaffected area of skin should be tested first, to establish normal sensation, before testing the affected area.

Nerve conduction studies

Nerve conduction studies can be helpful in demonstrating and quantifying a definitive nerve lesion, either peripherally or centrally. They can be used to help differentiate between central and peripheral neuropathic pain. They do not, however, effectively examine small nerve fibre function.

Nerve blocks

Performing a nerve block with infiltration of a local anaesthetic such as 1% lidocaine can be used diagnostically, in assessing whether a pain syndrome is due to involvement of a specific nerve or nerve root. Where inflammation and or swelling may be contributing to the underlying pain – for example, if there is compression of a nerve root – then a mixture of local anaesthetic

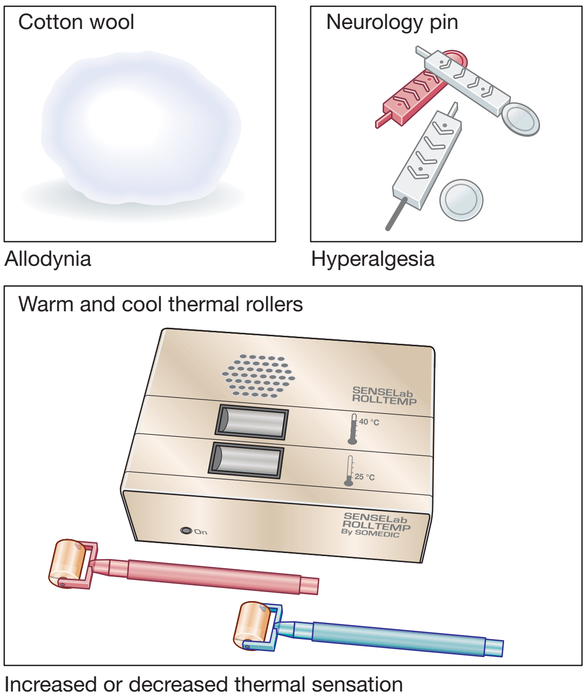

Fig. 34.5 Equipment for bedside sensory testing.

34.3 Genetic regulators of pain perception

Gene (protein)	Mutation (inheritance)	Protein function	Phenotypes
SCN9A **(Na,1.7)**	LoF (AR)	Ion channel	Absent pain, hypohydrosis, anosmia
SCN9A **(Na,1.7)**	GoF (AD)	Ion channel	Erythromelalgia, paroxysmal pain, burning pain, autonomic dysfunction
SCN11A **(Na,1.9)**	GoF (AD)	Ion channel	Absent pain, hyperhydrosis, muscular weakness, gut dysmotility
SCN10A **(Na,1.8)**	GoF (AD)	Ion channel	Burning pain, autonomic dysfunction
TRPA1 **(TRPA1)**	GoF (AD)	Ion channel	Absent pain
PDRM12 **(PDRM12)**	LoF (AR)	Transcription factor; neuron development	Absent pain
NTRK1 **(high-affinity NGF receptor)**	LoF (AR)	Tyrosine kinase; promotes neuron development	Absent pain; anhydrosis, mental retardation, increased cancer risk

(AD = autosomal dominant; AR = autosomal recessive; GoF = gain of function; LoF = loss of function; NGF = nerve growth factor)

and depot glucocorticoid may be helpful in alleviating pain. Nerve blockade can also be used to determine whether more radical therapies, such as nerve ablation, might be helpful in controlling pain, particularly that related to cancer.

Pain scoring systems

Various questionnaires and other instruments have been devised to localise pain, rate its severity and assess its impact on quality of life. Some of the most widely used are listed in Box 34.4. The distribution of pain can be documented on a diagram of the body, on which the patient can mark the sites that are painful. Similarly, other methods have been developed with which to assess the severity of pain using verbal, numerical and behavioural rating scales. Visual scoring systems employing different facial expressions may be of value in paediatric patients and those with cognitive impairment. Documenting changes in pain scores using questionnaires can be helpful in indicating to what extent drug treatments have been successful and can reduce the time taken to achieve pain control.

Principles of management

Effective management of chronic pain depends in part on the underlying cause but some general principles can be applied. In general terms, the treatment goals are to:

- educate the patient
- promote self-management
- optimise function
- enhance quality of life
- control pain.

Clinical history

Biopsychosocial assessment

A full biopsychosocial assessment should be performed in all patients with chronic pain. Although this is time-consuming, the time invested is likely to pay dividends in improving the long-term outcome for patients. A biopsychosocial assessment takes account of the underlying neurobiology of the condition in the context of wider influences, including cognition and beliefs, emotions, and social and cultural factors. For example, an individual with abdominal pain might respond differently if a close relative had recently died of gastric cancer than if a colleague had been off work with gastric upset.

An accurate clinical history is important, taking note of the duration of pain, any precipitating and relieving factors, its location and, if the pain is located at more than one site, which site is the one that impacts most on the patient's quality of life. The characteristics of the pain should be documented, by assessing whether it is described as dull, sharp, aching or burning. Associated features, such as hypersensitivity to fine touch or temperature, numbness, paraesthesia, tingling and formication (the feeling of insects crawling over the skin), should be noted. It is important to determine to what extent the pain is interfering with normal daily activities, such as work, leisure pursuits and sleep. The patient's social circumstances and cultural background should be documented, including any caring responsibilities, employment status and social and family support. The intensity of pain should also be recorded, preferably using a validated questionnaire (Box 34.4). The patient's mood should be assessed and, if evidence of low mood is detected, a suicide risk assessment should be considered (see Box 28.12, p. 1187).

The past medical and medication history should be recorded and specific enquiry made about substance misuse and any previous history of physical or mental abuse. It is also useful to enquire specifically about the patient's beliefs as to what is causing their pain, as well as what their expectation of treatment is; unless these are addressed, management may be less effective. There are some patient populations in whom particular challenges arise, often related to differences in communication ability. Strategies that can be used to overcome these difficulties are summarised in Box 34.5.

Examination

The patient's general appearance should be noted, including ability to walk and use of a walking aid. In those with focal pain, neurological examination should be performed, focusing particularly on any areas of abnormal sensation, reflexes and evidence of muscle wasting. A general examination should be carried out to determine whether there is any evidence of an underlying physical disorder that can account for the pain. In addition to the use of investigations to find the underlying cause of pain, patients with persistent or chronic pain may benefit from sensory testing or diagnostic nerve blocks to explore the underlying mechanisms and direct treatment. For example, a combined femoral and sciatic nerve block may be used in a patient with lower limb amputation to assess whether the pain is predominantly peripherally or centrally generated. If the pain is not improved by an effective nerve block, then peripherally directed therapies are unlikely to be effective.

i 34.4 Instruments used in the assessment of pain and its impact

Instrument	Comments
Brief Pain Inventory	Developed for use in cancer pain, validated and widely employed for chronic pain; based on 0–10 ratings of pain intensity and the impact of pain on a range of domains, including sleep, work and enjoyment of life
Pain Detect, s-LANSS, DN-4	A number of screening questionnaires to aid diagnosis of neuropathic pain
Pain Catastrophising Scale	Developed to assess individual levels of catastrophising, encompassing three different domains: helplessness, rumination and magnification
Tampa Scale of Kinesiophobia	Measures how much an individual is fearful of movement
Pain Self-efficacy Questionnaire	Assesses individual beliefs about self-efficacy in the context of chronic pain, and how this impacts on function
Visual analogue scale (VAS)	Patient marks pain intensity on a horizontal line
Localisation of pain	Body chart, allowing the patient to indicate where pain is situated
Beck Depression Inventory	Assesses emotional function
SF-36/EQ-5D	Assesses health-related quality of life

(DN-4 = Douleur Neuropathique questionnaire; EQ-5D = EuroQol 5-Domain questionnaire; SF-36 = Short Form 36; s-LANSS = self-completed Leeds Assessment of Neuropathic Signs and Symptoms)

34.5 Challenges in pain assessment in particular patient populations

Patient population	Challenges	Solutions
Paediatric	Assessment needs to be appropriate to developmental stage	Consider visual tools to aid pain assessment
Elderly	May have impaired cognitive function Cultural factors may reduce self-reporting of pain Risk of adverse effects of medication increased	Consider formal assessment of cognitive function Consider non-verbal assessment Consider visual tools to assess pain Employ a number of tools assessing pain behaviours
Cognitive impairment	Reporting and expression of pain may change Increased sensitivity to central nervous system effects of analgesics	Perform formal assessment of cognitive function Use non-verbal assessment: facial expressions, vocalisations, body movements, changes in social interactions
Substance misuse	Response to analgesics altered Increased tolerance Increased risk of addiction Substance misuse may affect reporting of pain	Seek specialist support early Ensure prescribing is safe

Interventions

Probably the most effective mode of treatment for pain is to identify the underlying cause. Examples include the use of immunosuppressive medication in inflammatory disease, chemotherapy, radiotherapy or hormone therapy in cancer, and antimicrobial therapy in patients with infection. There are many circumstances, however, in which the underlying cause of pain cannot be treated or the treatments available are incompletely effective. Under these circumstances, several management options are available. In all cases, a multidisciplinary approach is necessary that combines pharmacological management with supported self-management, and other specific interventions when appropriate.

Supported self-management

Self-management strategies are useful in the treatment of chronic pain. Self-management works best if the patient has some understanding of their chronic pain, and acceptance that it is unlikely to resolve completely. The aim is for patients to maximise their quality of life and function *despite* ongoing pain. Support for self-management can be delivered by health-care professionals, patients who suffer from the same condition or lay people, either on an individual basis, in a group setting or, increasingly, through web-based resources. There is a strong educational component to supported self-management, which seeks to generate an interaction between patient and tutor. The key aspects include:

- increasing activity levels, while understanding and practising pacing techniques (not overdoing things and cycling between over- and under-activity)
- using relaxation and mindfulness techniques as part of daily management
- using medication when appropriate
- having a plan to manage pain flares.

There are a number of useful online self-help resources (see 'Further reading').

Physical therapies

There is strong evidence that exercise can help in the management of chronic pain. Several types of exercise have been successfully used delivered in various ways, through physiotherapists, exercise classes or individual tuition. In choosing a form of exercise therapy, it is important to tailor the approach most likely to be acceptable to the individual patient. A successful exercise programme can help overcome 'fear avoidance', a well-recognised problem in chronic pain, where patients associate activity with an increase in pain and therefore do progressively less activity, with resultant deconditioning. Because of this it is important to pace physical activity to ensure that patients do not cycle from over-activity, with a flare in pain, to fatigue and deconditioning. This can be done by working with patients to establish their baseline level of activity and using an individually tailored, graded exercise programme (Box 34.6). This may include normal household activities, as well as targeted exercises and stretches. Manual therapy covers a variety of hands-on treatments, including manipulation, mobilisation and massage. Manual therapy can be provided by a range of therapists, including physiotherapists, osteopaths and chiropractors. There is some evidence of short-term benefit for manual therapy but limited evidence of long-term efficacy.

34.6 Physical therapies for chronic pain

Land-based

- Walking
- Gym work
- Exercise classes
- Yoga
- Pilates
- Tai-chi

Water-based

- Hydrotherapy
- Swimming
- Exercise classes

Pharmacological therapies

A range of analgesics can be used in the management of chronic pain but, for most of these, the evidence of long-term benefit is limited. In general, it is advisable to use a multimodal approach in the treatment of chronic pain, choosing different drugs to target pain processing at multiple points (Box 34.7). By employing different classes of analgesic, it is possible to use lower doses of each, thereby improving the side-effect profile. There is considerable inter-individual variability in response to analgesics, even within the same class. There are many reasons for this, including genetic variations in the enzymes that metabolise drugs. For example, the *CYP2D6* gene encodes for a liver enzyme, cytochrome P450 2D6, which metabolises a number of commonly used analgesics. Genetic variation in *CYP2D6* can influence circulating levels of many drugs, depending on whether

i 34.7 Pharmacological management of chronic pain

Drug or class of drug	Mechanism of action
Paracetamol	Central inhibition of COX-1 and COX-2 enzymes Mechanisms of action incompletely understood
Non-steroidal anti-inflammatory drugs	Inhibition of prostaglandin production
Opioids	Agonists at OP3 receptors at multiple levels in the central nervous system Blockade of ascending pain pathways
Ketamine	Antagonist of NMDA receptors Reduction of central sensitisation
Gabapentin Pregabalin	Inhibition of glutamate release by primary afferent neurons at first central synapse Decrease of excitatory neuronal activity
Tricyclic antidepressants	Inhibition of serotonin and noradrenaline (norepinephrine) re-uptake at synapses in the spinal cord, and also potential effects in the limbic system Inhibition of Na^+ channels in neurons
Serotonin (5-hydroxytryptamine, 5-HT) and noradrenaline (norepinephrine) re-uptake inhibitors	Inhibition of serotonin and noradrenaline re-uptake at synapses in the spinal cord, and also potential effects in the limbic system
Lidocaine patches	Inhibition of Na^+ in sensory neurons
Capsaicin patch	Activation of TRPV1 channels on subset of C fibres, causing selective pharmacological denervation, with a decrease in intra-epidermal nerve fibre density
Nerve blocks with lidocaine and glucocorticoids	Temporary denervation due to blockade of Na^+ channels in sensory neurons Local anti-inflammatory effect

(COX = cyclo-oxygenase; NMDA = *N*-methyl-D-aspartate; OP = opioid; TRPV1 = transient receptor potential vanilloid 1)

someone is a rapid or poor metaboliser. This is particularly important if metabolites are active, as is the case with codeine and tramadol, which are metabolised to morphine. Genetic variations have also been described in the opioid receptors and downstream pathways that they affect, with good pre-clinical evidence that variations in mu opioid receptors alter analgesic response to different opioids. Because of this there is a good rationale to try different drugs, even ones from the same class, if there is an inadequate response or there are unacceptable side-effects with one agent.

Whatever drug or combination of drugs is chosen, the key to successful pharmacological management is careful assessment and review, aiming for an acceptable balance between the benefits of treatment in providing pain relief, maximising function, and improving quality of life and adverse effects. Specific drug treatments are described below.

Non-opioid analgesics

Paracetamol

Paracetamol is widely used in the treatment of mild to moderate pain. Its mechanism of action is incompletely understood but it is known to be a weak inhibitor of the cyclo-oxygenase type 1 (COX-1) and cyclo-oxygenase type 2 (COX-2) enzymes, providing weak anti-inflammatory properties. There is also some of evidence that it activates inhibitory descending spinal pathways, via a serotonergic mechanism. Other postulated mechanisms include endocannabinoid re-uptake inhibition, and inhibition of nitric oxide and tumour necrosis factor alpha. For migraine and tension-type headache it has moderate efficacy at a dose of 1000 mg. It is used widely for musculoskeletal disorders and osteoarthritis, with very little high-quality evidence that it is much better than placebo, even at doses of up to 4000 mg per day. Acute liver failure is a well-recognised complication of paracetamol overdose but this risk may also be increased with long-term use, even within the recommended dose range. In view of this, it should be employed with caution in elderly patients and those weighing less than 50 kg.

Non-steroidal anti-inflammatory drugs

Non-steroidal anti-inflammatory drugs (NSAIDs) are widely used in the treatment of inflammatory pain and osteoarthritis. These drugs can be given systemically or locally and are discussed in more detail on page 1002. They are also useful in the management of pain in cancer patients, as discussed later in this chapter (p. 1350). Although widely prescribed, there is limited high-quality evidence of long-term efficacy in chronic pain, with a need for further studies in this area.

Topical analgesics

Topical capsaicin cream (0.025 or 0.075%) has some efficacy for osteoarthritis and may be used for neuropathic pain, although evidence of benefit is limited. A single application (done by a trained health-care professional) of a high-dose 8% capsaicin patch can give around 12 weeks of pain relief for neuropathic pain and can be repeated thereafter. Capsaicin is an agonist at the transient receptor potential vanilloid 1 (TRPV1) ion channel, found on some C fibres. Capsaicin activates the channel, causing an initial sensation of heat, but an analgesic effect subsequently results due to desensitisation of the channel.

Lidocaine 5% patches can also be helpful in focal neuropathic pain and should be applied for 12 hours out of 24 hours, with up to 4–6 weeks before maximum benefit is seen. The mode of action is blockade of sodium channels in primary afferent neurons and nociceptors, which reduces peripheral input to the spinal cord.

Adjuvant analgesics

Adjuvant analgesics is the term used to cover a range of agents that are used in the treatment of neuropathic pain, usually in combination with classical analgesics. Typically, these agents

do not produce an immediate reduction in pain, but rather exert an analgesic effect over a longer timeframe through their effects on central processing of pain. They are of particular value when used in combination in the management of pain with a neuropathic component but require careful dose titration over a number of weeks, to reach a dose that balances efficacy with side-effects. While the response to individual agents is variable, it is often possible to find an agent or combination of agents that works for most patients.

Opioid analgesics

Opioids are a class of drugs that target opioid receptors. The original receptor classification was based on pharmacological activity (mu, delta, kappa), with the more recent International Union of Basic and Clinical Pharmacology (IUPHAR) classification being generally accepted in current use (Box 34.8). Opioid receptors are G-protein-coupled receptors. Ligand binding activates several intracellular signalling pathways, increasing cyclic adenosine monophosphate (cAMP) levels, as well as altering calcium and potassium permeability of neurons. Opioids are traditionally divided into subclasses of weak opioids, such as codeine and dihydrocodeine, and strong opioids, such as morphine and oxycodone. While tramadol is a weak agonist at the mu opioid receptor, it is classified as a strong opioid in some countries. The dosages and characteristics of commonly prescribed opioids are shown in Box 34.9. There has been a large increase in the use of strong opioids for chronic pain over the last 10–20 years. A number of factors contribute to this, including a rising incidence of chronic pain with an ageing population, reluctance to use NSAIDs because of cardiovascular and gastrointestinal adverse effects, changes in patient expectation, societal attitudes and availability of new formulations of opioids. There is evidence of short- to medium-term benefit for strong opioids in low back pain and osteoarthritis but there have been very few good-quality studies of long-term use. Additionally, there is increasing concern about potential harm from long-term use. This includes addiction, dependence, opioid-induced hyperalgesia, endocrine dysfunction, fracture risk (especially in the elderly), overdose and cardiovascular

34.8 Opioids and opioid receptors

Endogenous ligand	Receptor (IUPHAR)	Alternative classification	Potential sites	Pharmacological effects
Endomorphin 1 and 2 **Met-enkephalin** **Dynorphin A** **Dynorphin B**	MOP	Mu; OP3	Brain, spinal cord, peripheral nerves, immune cells	Analgesia, reduced gastrointestinal motility, respiratory depression, pruritus
Leu-enkephalin **Met-enkephalin** **β-endorphin**	DOP	Delta; OP1	Brain, spinal cord, peripheral nerves	Analgesia, cardioprotection, thermoregulation
Dynorphin A **Dynorphin B** **β-endorphin**	KOP	Kappa; OP2	Brain (nucleus accumbens, neocortex, brainstem, cerebellum)	Analgesia, neuroendocrine (e.g. on hypothalamic–pituitary axis), diuresis, dysphoria
Orphanin FQ (nociceptin)	NOP	Orphan; ORL-1; OP4	Nucleus raphe magnus, spinal cord, afferent neurons	Opioid tolerance, anxiety, depression, increased appetite

(IUPHAR = International Union of Basic and Clinical Pharmacology; OP = opioid; ORL = opioid-like receptor)

34.9 Commonly used opioids

Opioid	Typical starting dose	Route	Oral morphine equivalent	Comments
Morphine	10 mg	Oral	10 mg	Most widely used
Codeine	100 mg	Oral	10 mg	Metabolised to morphine
Dihydrocodeine	100 mg	Oral	10 mg	Semi-synthetic
Tramadol	100 mg	Oral	10 mg	Synthetic
Oxycodone	6.6 mg	Oral	10 mg	More predictable bioavailability than morphine
Buprenorphine	5 µg/hr	Transdermal	30 mg/day	Patch change usually every 7 days (frequency of change dependent on manufacturer and dose); advantages in impaired renal function
Fentanyl	12 µg/hr	Transdermal	30 mg/day	Use with care in opioid-naïve patients; patch change usually every 72 hrs
Tapentadol	50 mg	Oral	20 mg	Use with care in opioid-naïve patients
Hydromorphone	2 mg	Oral	10 mg	Semi-synthetic; hepatic metabolism
Diamorphine	3 mg	Subcutaneous, intramuscular, intravenous	10 mg	Mainly used for acute pain or palliative care

i 34.10 Use of opioids in chronic pain

Step	Factors to take into account	Comment
1. Assess suitability for opioids	Type of pain Likelihood of dependence Co-morbidity	Neuropathic pain less likely to respond History of substance or alcohol misuse, including stimulant misuse Avoid use in conditions where adverse effects more likely: Chronic obstructive pulmonary disease Chronic liver disease Chronic kidney disease
2. Discuss with patient	Discuss potential benefits Discuss adverse effects Establish treatment goal	Improvement in pain Improvement in function Nausea Constipation Drowsiness Improvement in function
3. Plan treatment trial	Set timescale Agree on dose Agree on stopping rules	Define duration of treatment Agree frequency of review Aim for lowest effective dose Set upper dose limit Consider stopping if: Treatment goal is not met There is no dose response Tolerance develops rapidly

events, with many of these adverse effects being dose-related. There is evidence that doses of more than 120 mg morphine equivalents per day are associated with increased harm, and regular review to assess ongoing benefit is needed in this patient group. A suggested strategy for using strong opioids in chronic pain is shown in Box 34.10.

Psychological therapies

The aims of psychological therapy are to increase coping skills and improve quality of life when facing the challenges of living with chronic pain. There are a range of ways in which psychological therapies can be delivered, including individual one-to-one sessions, group sessions, multidisciplinary pain management programmes, or web-based or telephone-based programmes.

There is a good evidence for the use of a cognitive behavioural therapy (CBT)-based approach for chronic pain, delivered either individually or in a group. The overall aim is to reduce negative thoughts and beliefs, and develop positive coping strategies. The interaction between thoughts, behaviours and emotions is explored, and a problem-focused approach is used in therapy delivery.

Relaxation techniques, such as biofeedback and mindfulness meditation, require a degree of stillness and withdrawal, with regular practice required for sustained benefit (see 'Further information'). Acceptance and commitment therapy (ACT) is based on CBT principles but also uses components of mindfulness to improve psychological flexibility in the context of living with chronic pain.

Stimulation therapies

These range from minimally invasive procedures like acupuncture and transcutaneous electrical nerve stimulation (TENS) to more invasive techniques such as spinal cord stimulation.

Acupuncture (Fig. 34.6) has been used successfully in Eastern medicine for centuries. The mechanisms are incompletely understood, although endorphin release may explain, in part, the analgesic effect. Acupuncture is particularly effective in pain related to muscle spasm, with some evidence of short-term benefit for patients with low back pain. Similar mechanisms probably apply to TENS, which is worth considering in many types of chronic pain. Neuromodulation, using implanted electrodes in the epidural space (or, more recently, adjacent to peripheral nerves), has been shown to be an effective option for neuropathic pain, including failed back surgery syndrome and chronic regional pain syndrome (see below). Specialist assessment and ongoing support is necessary, as there are many potential complications, including infection, malfunction and battery failure. The likelihood of success is increased when this technique is used within the context of multidisciplinary assessment and management.

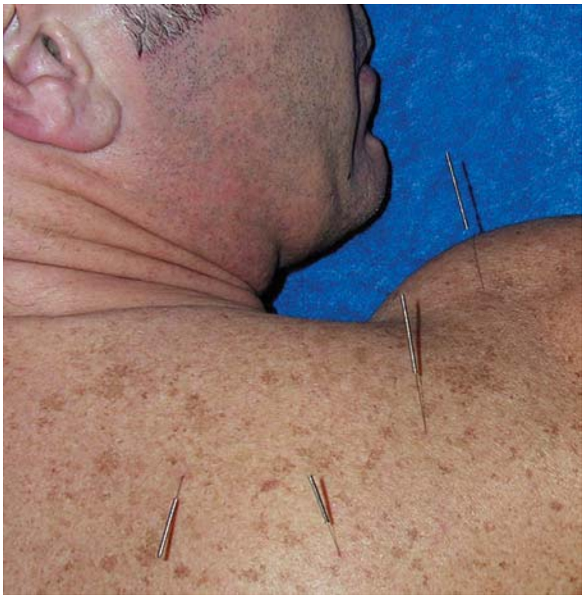

Fig. 34.6 Acupuncture.

Complementary and alternative therapies

Complementary techniques, such as herbal medicines, vitamins, homeopathy and reflexology, have been used for the treatment of chronic pain but with little evidence of efficacy. It should be noted that herbal medications may interact with conventional drugs, causing adverse effects as the result of drug–drug interactions. St John's wort (*Hypericum perforatum*) interacts with many drugs, including many antidepressants used in chronic pain, with increased serotonergic effects. Grapefruit may also increase the risk of serotonergic effects with some antidepressants. *Ginkgo biloba* may interact with paracetamol to increase bleeding time.

Nerve blocks and nerve ablation

The use of specialist nerve blocks and nerve ablation therapy can be considered for pain that is unresponsive to less invasive approaches. If these are being considered, they should form part of a multidisciplinary management plan, with the aim of restoring function and reducing pain. Local anaesthetic with or without depot glucocorticoid (non-particulate for neuraxial administration) can be effective in some circumstances. Examples include occipital nerve blocks for migraine or cervicogenic headache and trigger point injections for myofascial pain. If there is limited compression of a spinal nerve root, the nerve root injections into the epidural space may help settle symptoms and avoid the need for surgical intervention. Neurodestructive procedures can also be employed for intractable pain but are rarely used outside the palliative care setting.

Chronic pain syndromes

Chronic pain is a feature of several recognised syndromes, which are discussed in more detail below.

Neuropathic pain

Neuropathic pain is defined as 'pain associated with a lesion or disease of the somatosensory nervous system'. Neuropathic pain may be acute, such as in sciatica, which occurs as the result of a prolapsed disc, but is most problematic when it becomes chronic. Neuropathic pain causes major morbidity; in a recent study, 17% of those affected rated their quality of life as 'worse than death'. The clinical features of neuropathic pain are summarised in Box 34.11. The diagnosis is easily missed and so careful assessment is vital, in order to make the diagnosis in the first place and then to direct management appropriately. An algorithm for the management of neuropathic pain is provided in Figure 34.7. It is important to recognise the negative impact of neuropathic pain on quality of life, which has been shown to be greater than with other types of chronic pain. As a result, appropriate support and multidisciplinary management should always be considered in addition to pharmacological therapies.

Complex regional pain syndrome

Complex regional pain syndrome (CRPS) is a type of neuropathic pain that affects one or more limbs. It was previously termed reflex sympathetic dystrophy (RSD), reflecting the fact the disease is thought to be caused in part by an abnormality in the autonomic nervous system. It is a rare syndrome, occurring in about 20 per 100 000 individuals, and is more common in females, typically presenting between the ages of 35 and 50. It is classified into type I CRPS, which may be precipitated by a traumatic event

i 34.11 Clinical features of neuropathic pain

Characteristic	Symptom or clinical feature*	Descriptive term
Spontaneous pain	No stimulus required to evoke pain	
Positive sensory disturbance	Light touch painful Pressure painful Increased pain on pin-prick Cool and warm temperatures painful	Dynamic allodynia Punctate allodynia Hyperalgesia Thermal allodynia
Negative sensory disturbance	Numbness Tingling Loss of temperature sensitivity	Loss of sensation Paraesthesia
Other features	Feeling of insects crawling over skin Affected area feels abnormal	Formication Dysaesthesia

*Symptoms may cluster, with a predominance of either positive or negative symptoms, or a mixture of both, reflecting differences in underlying mechanisms.

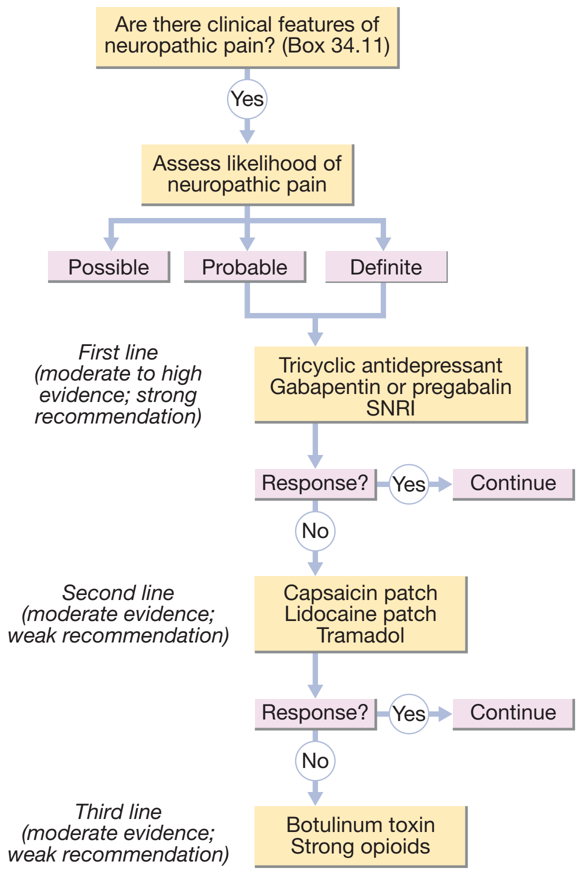

Fig. 34.7 Algorithm for pharmacological management of neuropathic pain. (SNRI = serotonin noradrenaline (norepinephrine) re-uptake inhibitor) *Adapted from SIGN 136 and NeuPSIG recommendations (Finnerup NB, Attal N, Haroutounian S, et al. Pharmacotherapy for neuropathic pain in adults: a systematic review and meta-analysis. Reprinted with permission from Elsevier (The Lancet Neurol 2015; 14:162–173)).*

34.12 Criteria for diagnosis of complex regional pain syndrome (CRPS) type 1*

Category	Symptom or sign
Sensory	Allodynia to: Temperature Light touch Deep somatic pressure Movement Hyperalgesia to pin-prick
Vasomotor	Temperature asymmetry Skin colour change and asymmetry Skin colour asymmetry
Oedema/sudomotor	Oedema Sweating change or asymmetry
Motor/trophic	Reduced range of motion Motor dysfunction: Weakness Tremor Dystonia Trophic changes: Hair Nails Skin

*The diagnosis of CRPS type 1 can be made if a patient has at least one symptom in at least three out of the four categories and at least one sign in two out of the four categories, and no other diagnosis can explain the symptoms.

such as a fracture but is not associated with peripheral nerve damage, and type II CRPS, which is associated with a peripheral nerve lesion. The diagnosis is primarily clinical, based on the features shown in Box 34.12. Imaging with MRI or radionuclide bone scan may provide support for the diagnosis of type I CRPS in showing bone marrow oedema or increased tracer uptake localised to an affected site (p. 1055).

Prompt diagnosis and early treatment with physiotherapy may prevent progression of symptoms. Management is as for neuropathic pain, additional approaches including graded motor imagery. Bisphosphonates have been used empirically for treatment but the evidence base for efficacy in controlling pain is weak. If medical management is incompletely effective, consideration should be given to the appropriateness of a spinal cord stimulator.

Phantom limb pain

Phantom limb is a common complication of amputation, occurring in up to 70% of patients. It is a form of neuropathic pain but can be particularly distressing, as the pain is felt in the area where the absent limb was previously. Although usually presenting after limb amputation, reports of phantom pain in other body parts have been reported, such as phantom breast pain following mastectomy. It is very often associated with phantom sensations, which are described as non-painful sensations in the absent body part and pain in the stump.

Diagnostic nerve blocks may be helpful in directing therapy, with use of anti-neuropathic medications as outlined in Box 34.7. If there is a definite neuroma at the stump site that is interfering with prosthesis use, surgical review may be necessary.

Chronic widespread pain

Chronic widespread pain (CWP) is often associated with other features, such as fatigue and irritable bowel syndrome. Fibromyalgia is a subtype of CWP in which there are myofascial trigger points, and is often associated with sleep disturbance. Clinical features and management of fibromyalgia are discussed in more detail on page 1018.

Joint hypermobility syndrome

Hypermobility can be associated with chronic musculoskeletal pain that often targets the joints and periarticular tissues. It is thought to be caused by abnormal stresses being placed on the joints and surrounding soft tissues due to ligament laxity, although the mechanisms are poorly understood since many people with hypermobile joints do not suffer pain. It is described in more detail on page 1059.

Palliative care

Palliative care is the term used to describe the active total care of patients with incurable disease. It can be distinguished from end-of-life care, which refers to the care of patients with far advanced, rapidly progressive disease that will soon prove fatal. The focus of palliative care is on symptom control alongside supportive care. While palliative care can and should be delivered at any stage of an incurable illness alongside optimal disease control, the focus of end-of-life care is on quality of life rather than prolongation of life or cure. Palliative care encompasses a distinct body of knowledge and skills that all good physicians must possess to allow them to care effectively for patients. Palliative care is traditionally seen as a means of managing distress and symptoms in patients with cancer, when metastatic disease has been diagnosed and death is seen as inevitable. There is, however, a growing recognition that the principles of palliative care and some of the interventions it uses are equally applicable in other conditions. Palliative may therefore be applied to any chronic disease state.

For conditions other than cancer, the challenge is recognising when patients have entered the terminal phase of their illness, as there are fewer clear markers and the course of the illness is much more variable. Different chronic disease states progress at different rates, allowing some general trajectories of illness or dying to be defined (Fig. 34.8). These trajectories are useful in decision-making for individual patients and also in planning services.

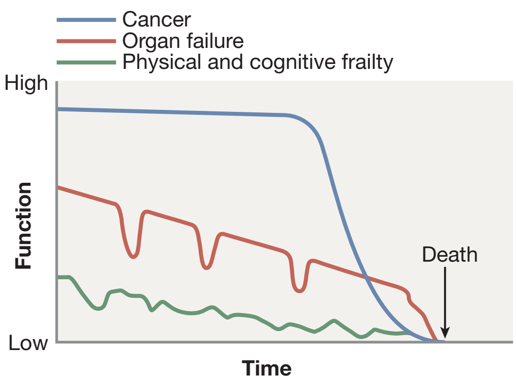

Fig. 34.8 Archetypal trajectories of dying. *Reproduced from Murray SA, Kendall M, Boyd K, et al. Illness trajectories and palliative care. BMJ 2005; 330:7498; reproduced with permission from the BMJ Publishing Group.*

The 'rapid decline' trajectory following a gradual decline, as occurs in cancer, is the best-recognised pattern of the need for palliative care, although a similar trajectory may be observed in other conditions, such as motor neuron disease can. Many traditional hospice services are designed to meet the needs of people on this trajectory. Over recent years, improvements in management of malignant disease mean that some types of cancer may follow an erratic or intermittent decline trajectory.

Many chronic diseases, such as advanced chronic obstructive pulmonary disease (COPD) and intractable congestive heart failure, carry as high a burden of symptoms as cancer, as well as psychological and family distress. The 'palliative phase' of these illnesses may be more difficult to identify because of periods of relative stability interspersed with acute episodes of severe illness. However, it is still possible to recognise those patients who may benefit from a palliative approach to their care. The challenge is that symptom management needs to be delivered at the same time as treatment for acute exacerbations. This leads to difficult decisions as to the balance between symptom relief and aggressive management of the underlying disease. The starting point of need for palliative care in these conditions is the point at which consideration of comfort and individual values becomes important in decision-making, often alongside management of the underlying disease.

The third major trajectory is categorised by years of poor function and frailty before a relatively short terminal period; it is exemplified by dementia but is also increasingly true for patients with many different chronic illnesses. As medical advances extend survival, this mode of dying is being experienced by increasing numbers of people. The main challenge lies in providing nursing care and ensuring that plans are agreed for the time when medical intervention is no longer beneficial.

In a situation where death is inevitable and foreseeable, palliative care balances the 'standard textbook' approach with the wishes and values of the patient and a realistic assessment of the benefits of medical interventions. This often results in a greater focus on comfort, symptom control and support for patient and family, and may enable withdrawal of both futile and burdensome interventions. In cases of prognostic uncertainty, open, honest and gentle communication with the patient and family is important. The most common symptoms in palliative care are discussed in the next section.

Presenting problems in palliative care

Pain

Pain is a common problem in palliative care. It has been estimated that about two-thirds of patients with cancer experience moderate or severe pain, and a quarter have three or more different sites of pain. Many of these are of a mixed aetiology and about half of patients with cancer-associated pain have a neuropathic element.

Clinical assessment

Careful evaluation to identify the likely mechanisms of pain is important so that the most appropriate treatment can be given. Clinical features and suggested management strategies for common types of pain in cancer are shown in Box 34.13. The majority of patients with cancer-associated pain can be effectively managed using a stepwise approach, as outlined below.

34.13 Common types of pain in cancer

Type of pain	Features	Management options
Bone pain	Tender area over bone Possible pain on movement	NSAIDs Bisphosphonates Radiotherapy
Increased intracranial pressure	Headache, worse in the morning, associated with vomiting and occasionally delirium	Glucocorticoids Radiotherapy Codeine
Abdominal colic	Intermittent, severe, spasmodic, associated with nausea or vomiting	Antispasmodics Hyoscine butylbromide
Liver capsule pain	Right upper quadrant abdominal pain, often associated with tender enlarged liver Responds poorly to opioids	Glucocorticoids
Neuropathic pain	Spontaneous pain Light touch, pressure and temperature changes are painful; increased pain on pin-prick Numbness, tingling or loss of temperature sensation Skin feels abnormal	Anticonvulsants: Gabapentin Pregabalin Antidepressants Amitriptyline Duloxetine Ketamine
Ischaemic pain	Diffuse, severe, aching pain associated with evidence of poor perfusion Responds poorly to opioids	NSAIDs Ketamine
Incident pain	Episodic pain usually related to movement or bowel spasm	Intermittent short-acting opioids Nerve block

(NSAIDs = non-steroidal anti-inflammatory drugs)

Management: pharmacological treatments

Pharmacological treatments are the mainstay of management in cancer-associated pain. A stepwise approach is adopted, following the principles of the World Health Organisation (WHO) analgesic ladder (Fig. 34.9), in which analgesia that is appropriate for the degree of pain is prescribed first. Patients with mild pain should be started on a non-opioid analgesic drug, such as paracetamol (1 g 4 times daily) or an NSAID (step 1). If the patient fails to respond adequately or has moderate pain, a weak opioid, such as codeine (60 mg 4 times daily), should be added (step 2). This can be prescribed separately or in the form of the compound analgesic co-codamol. If pain relief is still not achieved or if the patient has severe pain, a strong opioid should be substituted for the weak opioid (step 3). If the pain is severe at the outset, strong opioids should be prescribed and increased or titrated according to the patient's response. It is important not to move 'sideways' (change from one drug to another of equal potency), which is a common problem during step 2 of the analgesic ladder.

Opioids

Opioid analgesia plays a key role in patients with moderate to severe pain. Its successful use depends on appropriate assessment and a detailed explanation to the patient and carer about the benefits and potential side-effects of therapy. Morphine

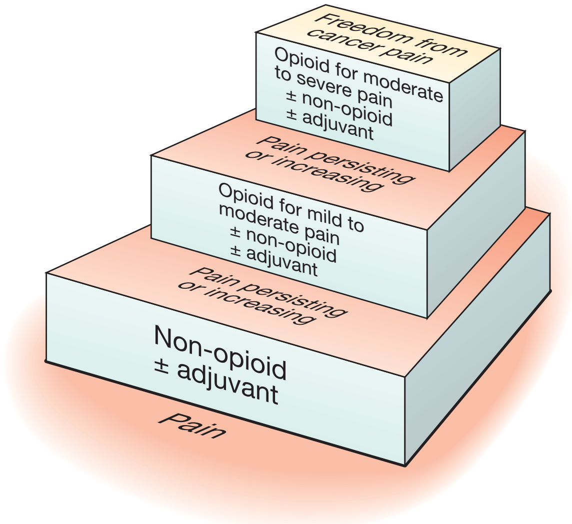

Fig. 34.9 The WHO analgesic ladder. *From WHO. Cancer pain relief, 2nd edn. Geneva: WHO; 1996.*

i 34.14 Opioid side-effects

Side-effect	Management
Constipation	Regular laxative Opioid/naloxone oral combination, in resistant constipation
Dry mouth	Frequent sips of iced water, soft white paraffin to lips, chlorhexidine mouthwashes twice daily, sugar-free gum, water or saliva sprays
Nausea/vomiting	Oral haloperidol 0.5–1 mg at night, oral metoclopramide 10 mg 3 times daily or oral domperidone 10 mg 3 times daily If constant, haloperidol or levomepromazine may be given parenterally to break the nausea cycle
Sedation	Explanation is very important Symptoms usually settle in a few days Avoid other sedating medication where possible Ensure appropriate use of adjuvant analgesics that can have an opioid-sparing effect May require an alternative opioid

is the most commonly prescribed strong opioid, although there are several alternatives, as outlined in Box 34.9.

Oral morphine takes about 20 minutes to exert an effect and usually provides pain relief for 4 hours. Most patients with continuous pain should be prescribed oral morphine every 4 hours initially, as this will provide continuous pain relief over the whole 24-hour period. Controlled-release morphine lasts for 12 or 24 hours, depending on the formulation, and if clinical circumstances dictate, a controlled-release formulation can be used to initiate and titrate morphine. The median effective morphine equivalent dose for cancer pain is about 200 mg per 24 hours.

In addition to the regular dose of morphine, an extra dose of immediate-release (IR) morphine should be prescribed 'as required' for the treatment of breakthrough pain that has not been controlled by the regular prescription. As a rule of thumb, this additional dose should be one-sixth of the total 24-hour dose of opioid. The frequency of breakthrough doses should be dictated by their efficacy and any side-effects, rather than by a fixed time interval. A patient may require breakthrough analgesia as frequently as hourly if pain is severe, but this should lead to early review of the regular prescription. The patient or carer should note the timing of any breakthrough doses and the reason for them. These should be reviewed daily and the regular 4-hourly dose increased for the next 24 hours on the basis of:

- the frequency of and reasons for breakthrough analgesia
- the degree and acceptability of side-effects.

The regular dose should be increased by adding the total of the breakthrough doses over the previous 24 hours, unless there are significant problems with unacceptable side-effects. When the correct dose has been established, a continuous release (CR) preparation can be prescribed, usually twice daily. Breakthrough analgesia used for movement-related pain is generally not included in background opioid dose titration. Attempts to control movement-related pain with background opioid dose will usually lead to over-medication and opioid-related side-effects. This can be a risk in metastatic bone pain.

Some patients may have concerns about using opioids and it is vital for these to be explored. Patients should be reassured that psychological dependence is rare when opioids are used for cancer pain, unless a pre-existing dependence problem exists. Pharmacological tolerance is not usually a clinically relevant problem; however, physical dependence, which is physiological, as manifest by a physical withdrawal syndrome, can occur if opioids are suddenly discontinued.

Nearly all types of cancer pain respond to morphine to some degree but there is a spectrum of response, such that in some patients the dose of opioid required to control neuropathic pain and all elements of metastatic bone pain may be high and associated with unacceptable side-effects. In these situations, other methods of analgesia, both pharmacological and non-pharmacological, should be explored and considered at an early stage.

The most effective and appropriate route of morphine administration is oral but transdermal preparations of strong opioids (usually fentanyl) are useful in certain situations, such as in patients with dysphagia or those who are reluctant to take tablets on a regular basis. Diamorphine is a highly soluble strong opioid used for subcutaneous infusions, particularly in the last few days of life, but is only available in certain countries.

Opioid-related adverse effects

Adverse effects are a common problem with opioids, especially on initiating treatment and on increasing the dose. The most common side-effects are nausea, drowsiness, constipation and dry mouth, as summarised in Box 34.14. Nausea and vomiting can occur initially but usually settle after a few days. Drowsiness is usually transient at opioid initiation and dose increase. If it is persistent, an alternative opioid and/or a non-opioid should be considered. In acute dosing, respiratory depression can occur but this is rare in patients on regular opioids or in those starting on small, regular doses with appropriate titration.

Tolerance usually develops to nausea, vomiting and drowsiness but not to constipation or dry mouth. All patients should therefore be prescribed a laxative, unless suffering from diarrhoea, and have access to an antiemetic and good mouth care, along with rationalisation of any concomitant medication that might exacerbate drowsiness. Newer developments include the use of preparations in which opioids are combined with opioid

antagonists, such as naloxone. The naloxone is poorly absorbed and does not antagonise the systemic analgesic effect but rather acts locally to block opioid receptors in the gut, thereby reducing opioid-related constipation. Vivid dreams, visual hallucinations (often consisting of a sense of movement at the periphery of vision), delirium and myoclonus are typical of opioid-related toxicity and, if present, require urgent reassessment of the opioid dose. Biochemistry should also be checked to exclude renal impairment, dehydration, electrolyte disturbance or hypercalcaemia.

Since opioid toxicity can occur at any dose, side-effects should be assessed regularly, but particularly after a dose increase. Pain should be reassessed to ensure that appropriate adjuvants are being used. Parenteral rehydration is often helpful to speed up excretion of active metabolites of morphine. The dose of opioid may need to be reduced or the opioid changed to a strong alternative.

Different opioids have different side-effect profiles in different people. If a patient develops side-effects, switching to an alternative strong opioid may be helpful. Options include oxycodone, transdermal fentanyl, alfentanil, hydromorphone and occasionally methadone, any of which may produce a better balance of benefit against side-effects. Fentanyl and alfentanil have no renally excreted active metabolites and may be particularly useful in patients with renal failure. It is possible to switch between opioids but great care must be taken when doing so to make sure the dose is correct and to avoid prescribing too much or too little opioid.

Adjuvant analgesics

An adjuvant analgesic is a drug that has a primary indication other than pain but which provides analgesia in some painful conditions and may enhance the effect of the primary analgesic. Commonly used adjuvant analgesics in the palliative care setting are shown in Box 34.15. Some adjuvant analgesics may enhance the side-effect profile of the primary analgesic, and dose reductions of opioids may be required when an adjuvant analgesic is added. At each step of the WHO analgesic ladder, an adjuvant analgesic should be considered, the choice depending on the type of pain.

Management: non-pharmacological treatments

Neurodestructive interventions

Neurodestructive techniques have an important role in the management of cancer pain, where life expectancy is limited. They should be used as part of an overall management plan and considered when the response to drug treatment has been inadequate. Intrathecal analgesia, delivered via either an external pump or a fully implanted device, is a good option, particularly where life expectancy is more than 3 months. Coeliac plexus blocks can be helpful for visceral pain, such as in pancreatic cancer. Lateral cordotomy to disrupt the spinothalamic tracts (either open or percutaneous) may be considered for unilateral chest wall pain, such as may occur in mesothelioma, where life expectancy is limited.

Radiotherapy

Radiotherapy is the treatment of choice for pain from bone metastases (see Box 34.13) and can also be considered for metastatic involvement at other sites. All patients with pain secondary to bone metastases should be considered for palliative radiotherapy, which can usually be given in a single dose.

Physiotherapy

Physiotherapy has a key role in the multidisciplinary approach to a wide spectrum of cancer-related symptoms, including the prevention and management of pain, muscle spasm, reduced mobility, muscle wasting and lymphoedema. Rehabilitation in palliative care has expanded and now includes pre-habilitation, which involves the use of proactive focused exercise to maintain muscle mass during cancer chemotherapy and in other chronic conditions such as COPD.

Psychological techniques

As with chronic pain, there is increasing use of psychological techniques in cancer pain management, which train the patient

34.15 Adjuvant analgesics in cancer pain

Drug	Example	Indications	Side-effects*
NSAIDs	Diclofenac	Bone metastases, soft tissue infiltration, liver pain, inflammatory pain	Gastric irritation and bleeding, fluid retention, headache Caution in renal impairment
Glucocorticoids	Dexamethasone 8–16 mg per day, titrated to lowest dose that controls pain	Raised intracranial pressure, nerve compression, soft tissue infiltration, liver pain	Gastric irritation if used together with NSAID, fluid retention, proximal muscle myopathy, delirium, Cushingoid appearance, candidiasis, hyperglycaemia
Anticonvulsants	Evidence strongest for: Gabapentin Pregabalin Duloxetine	Neuropathic pain of any aetiology	Mild sedation, tremor, delirium Exacerbation of opioid-related side-effects
Tricyclic antidepressants	Amitriptyline	Neuropathic pain of any aetiology	Sedation, dizziness, delirium, dry mouth, constipation, urinary retention Avoid in cardiac disease Exacerbation of opioid-related side-effects
NMDA receptor blockers	Ketamine	Severe neuropathic pain (only under specialist supervision)	Delirium, anxiety, agitation, hypertension

*In old age, all drugs can cause delirium.
(NMDA = *N*-methyl-D-aspartate; NSAIDs = non-steroidal anti-inflammatory drugs)

to use coping strategies and behavioural techniques. Other issues related to the specific experience of a cancer diagnosis and cancer treatment may be complex, and individual therapy in addition to group-based approaches can be helpful.

Stimulation therapies

Acupuncture and TENS are low-risk stimulation therapies that may be useful in palliative care for management of pain and nausea.

Complementary and alternative therapies

Palliative care patients often seek symptom relief from both complementary and alternative therapies. While the evidence base is poorly developed, individual patients can gain significant benefits from the complementary therapies outlined on page 1348. It is critically important that patients are encouraged to discuss any alternative medicines they are considering, given the potential interactions with other therapies.

Breathlessness

Breathlessness is one of the most common symptoms in palliative care and is distressing for both patients and carers. Patients with breathlessness should be fully assessed to determine whether there is a reversible cause, such as a pleural effusion, heart failure or bronchospasm; if so, this should be managed in the normal way. If symptoms persist, additional measures may be necessary. There are many potential causes of dyspnoea in cancer patients and in other chronic diseases; apart from direct involvement of the lungs, muscle loss secondary to cachexia, anxiety and fear can all contribute. A cycle of panic and breathlessness, often associated with fear of dying, can be dominant. Exploration of precipitating factors is important and patient education about breathlessness and effective breathing has been shown to be effective. Non-pharmacological approaches that include using a hand-held fan, pacing, and following a tailored exercise programme can help. There is no evidence to suggest that oxygen therapy reduces the sensation of breathlessness in advanced cancer any better than cool airflow, and oxygen is indicated only if there is significant hypoxia. Opioids, through both their central and their peripheral action, can palliate breathlessness. Both oral and parenteral opioids are effective. A low dose should be used initially and titrated against symptoms, unless opioids are already being prescribed for pain, in which case the existing dose can be increased further. If anxiety is considered to be playing a significant role, a quick-acting benzodiazepine, such as lorazepam (used sublingually for rapid absorption), may also be useful.

Cough

Persistent unproductive cough can be helped by opioids, which have an antitussive effect. Troublesome respiratory secretions can be treated with hyoscine hydrobromide (400–600 μg every 4–8 hours), although dry mouth is a common adverse effect. As an alternative, glycopyrronium can be useful and is given by subcutaneous infusion (0.6–1.2 mg in 24 hours).

Nausea and vomiting

The presentation of nausea and vomiting differs depending on the underlying cause, of which there are many (p. 780). Large-volume vomiting with little nausea is common in intestinal obstruction, whereas constant nausea with little or no vomiting is often due to metabolic abnormalities or adverse effects of drugs. Vomiting related to raised intracranial pressure is worse in the morning. Different receptors are activated, depending on the cause or causes of the nausea (Fig. 34.10). For example, dopamine receptors in the chemotactic trigger zone in the fourth ventricle are stimulated by metabolic and drug causes of nausea, whereas gastric irritation stimulates histamine receptors in the vomiting centre via the vagus nerve. Reversible causes, such as hypercalcaemia and constipation, should be treated appropriately. Drug-induced causes should be considered and the offending drugs stopped if possible. As different classes of antiemetic drug act at different receptors, antiemetic therapy should be based on a careful assessment of the probable causes and a rational decision to use a particular class of drug (Box 34.16).

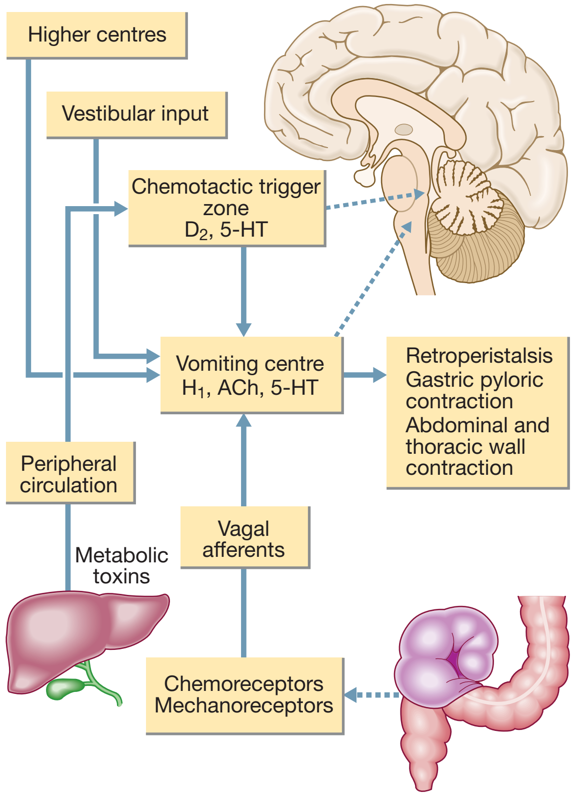

Fig. 34.10 Mechanisms of nausea. (ACh = acetylcholine; D_2 = dopamine; 5-HT = 5-hydroxytryptamine, serotonin; H_1 = histamine)

34.16 Receptor site activity of antiemetic drugs

Area	Receptors	Drugs
Chemotactic trigger zone	Dopamine$_2$ 5-HT	Haloperidol Metoclopramide
Vomiting centre	Histamine$_1$ Acetylcholine	Cyclizine Levomepromazine Hyoscine
Gut (gastric stasis)		Metoclopramide
Gut distension (vagal stimulation)	Histamine$_1$	Cyclizine
Gut (chemoreceptors)	5-HT	Levomepromazine

(5-HT = 5-hydroxytryptamine, serotonin)

The subcutaneous route is often required initially to overcome gastric stasis and poor absorption of oral medicines.

Gastrointestinal obstruction

Gastrointestinal obstruction is a frequent complication of intra-abdominal cancer. Patients may have multiple levels of obstruction and symptoms may vary greatly in nature and severity. Surgical mortality is high in patients with advanced disease and obstruction should normally be managed without surgery. The key to effective management is to address the presenting symptoms – colic, abdominal pain, nausea, vomiting, intestinal secretions – individually or in combination, using parenteral drugs that do not cause or worsen other symptoms. This can be problematic when a specific treatment worsens another symptom. Cyclizine improves nausea and colic responds well to anticholinergic agents, such as hyoscine butylbromide, but both slow gut motility. Nausea will improve with metoclopramide, although this is usually contraindicated in the presence of colic because of its prokinetic effect. There is some low-level evidence that glucocorticoids (dexamethasone 8 mg) can shorten the length of obstructive episodes. Somatostatin analogues, such as octreotide, will reduce intestinal secretions and therefore large-volume vomits. Occasionally, a nasogastric tube is required to reduce gaseous or fluid distension.

Weight loss

Patients with cancer lose weight for a variety of reasons, including reduced appetite or the effects of drug treatment, or as a consequence of low mood and anxiety. There is, however, a particularly challenging syndrome associated with weight loss, which is known as cancer cachexia. This results from an alteration of metabolism caused by a complex interaction of tumour-related factors and the body's response to these factors, resulting in muscle loss, along with anorexia. Treatment involves prescribing exercise to maintain muscle mass and strengthen muscles, ensuring that there is an adequate calorie intake and providing nutritional supplements. Anti-inflammatory medication to attenuate systemic inflammation is the subject of research and many patients self-medicate with fish oil. Glucocorticoids can temporarily boost appetite and general well-being but may cause false weight gain by promoting fluid retention. Their benefits need to be weighed against the risk of side-effects, and glucocorticoids should generally be used on a short-term basis only.

Anxiety and depression

Anxiety and depression are common in palliative care but the diagnosis may be difficult, since the physical symptoms of depression are similar to those of advanced cancer. It is therefore important to realise that these symptoms are not inevitable in advanced cancer. Patients should still expect to look forward to things and to enjoy them, within the context of the situation. Simply asking the question 'Do you think you are depressed?' can be very useful in deciding with the patient whether antidepressants or psychological interventions may be of benefit (p. 1199). In this regard, psycho-oncology has been evolving rapidly and there is now good evidence for the role of 'talk therapy' in palliative care, along with other appropriate management of anxiety and depression. If antidepressants are required, citalopram and mirtazapine are good choices since they are generally well tolerated in patients with advanced disease.

Delirium and agitation

Many patients become confused or agitated in the last days of life. It is important to identify and treat potentially reversible causes (p. 183), unless the patient is too close to death for this to be feasible. Early diagnosis and effective management of delirium are extremely important. As in other palliative situations, it may not be possible to identify and treat the underlying cause, and the focus of management should be to ensure that the patient is comfortable. It is important to distinguish between behavioural change due to pain and that due to delirium, as opioids will improve one and worsen the other. The management of delirium is detailed on page 209. It is important, even in the care of the actively dying patient, to treat delirium with antipsychotic medicines, such as haloperidol, rather than to regard it as distress or anxiety and use benzodiazepines only.

Dehydration

Deciding whether to give intravenous fluids can be difficult when a patient is very unwell and the prognosis is uncertain. A patient with a major stroke, who is unable to swallow but is expected to survive the event, will develop renal impairment and thirst if not given fluids and should be hydrated. On the other hand, when a patient has been deteriorating and is clearly dying, parenteral hydration needs very careful consideration and it is very important to manage this on an individual basis. Comfort and avoidance of distress in the family are the primary aims. Where a patient and family are happy with meticulous oral hygiene and care to reduce the sensation of dryness in the mouth, this is usually more appropriate and effective at the end of life than parenteral hydration, which by itself will not necessarily improve the sensation of dryness. In some patients, parenteral hydration will simply exacerbate pooling of secretions, causing noisy and distressing breathing. Each decision should be individual and discussed with the patient's family.

Death and dying

Planning for dying

There have been dramatic improvements in the medical treatment and care of patients with cancer and other illnesses over recent years but the inescapable fact remains that everyone will die at some time. Planning for death should be actively considered in patients with chronic diseases when the death is considered to be foreseeable or inevitable. Doctors rarely know exactly when a patient will die but are usually aware that an individual is about to die and that medical interventions are unlikely to extend life or improve its quality significantly. Most people wish their doctors to be honest about this situation to allow them time to think ahead, make plans and address practical issues. A few do not wish to discuss future deterioration or death; if this is felt to be the case, avoidance of discussion should be respected. For doctors, it is helpful to understand an individual's wishes and values about medical interventions at this time, as this can help guide decisions about interventions. It is important to distinguish between interventions that will not provide clinical benefit (a medical decision) and those that do not confer sufficient benefit to be worthwhile (a decision that can only be reached with a patient's involvement and consent). A common example of this would be decisions about not attempting cardiopulmonary resuscitation.

In general, people wish for a dignified and peaceful death and most prefer to die at home. Families also are grateful for the chance to prepare themselves for the death of a relative, by timely and gentle discussion with the doctor or other health professionals. Early discussion and effective planning improve the chances that an individual's wishes will be achieved. There are two important caveats: firstly, wishes can and do change as the terminal situation evolves, and secondly, planning in general can only be done over time as patients form a relationship with professionals and evolve an understanding of the situation in which they find themselves.

Structures for assessment and planning around end-of-life care are for guidance only and the focus should evolve with the individual patient.

Diagnosing dying

When patients with cancer or other conditions become bed-bound, semi-comatose, unable to take tablets and only able to take sips of water, with no reversible cause, they are likely to be dying and many will have died within 2 days. Doctors are sometimes poor at recognising this and should be alert to the views of other members of the multidisciplinary team. A clear decision that the patient is dying should be agreed and recorded.

Management of dying

Once the conclusion has been reached that a patient is going to die in days to a few weeks, there is a significant shift in management (Box 34.17). Symptom control, relief of distress and care for the family become the most important elements of care. Medication and investigation are justifiable only if they contribute to these ends. When patients can no longer drink because they are dying, intravenous fluids are usually not necessary and may cause worsening of bronchial secretions; however, this is a decision that can be made only on an individual basis. Management should not be changed without discussion with the patient and/or family. Medicines should always be prescribed for the relief of symptoms. For example, morphine or diamorphine may be used to control pain, levomepromazine to control nausea, haloperidol to treat delirium, diazepam or midazolam to treat distress, and hyoscine hydrobromide to reduce respiratory secretions. Side-effects, such as drowsiness, may be acceptable if the principal aim of relieving distress is achieved. It is important to discuss and agree the aims of care with the patient's family. Poor communication with families at this time is one of the most common reasons for family distress afterwards and for formal complaints.

Ethical considerations

The overwhelming force in caring for any patient must be to listen to that patient and family and take their wishes on board. Patients know when health-care professionals are just receiving the information, as opposed to receiving and understanding the information in the context of the patient, their illness and needs, their carers and the socioeconomic context. It is impossible to provide holistic care for a patient without this comprehension. Every patient is unique and it is important to avoid slipping into a tick-box mentality in addressing items that should be covered in patients with advanced, incurable disease. While the key to successful palliative care is effective interdisciplinary working, every patient needs to know who has overall responsibility for their care. Trust in the whole team will come through a solid lead working with a team who are appropriately informed and in sympathy with the patient's situation, each having a clear role.

Families and other carers are often unprepared for the challenge of caring for a dying person. It can be an exhausting experience, both emotionally and physically, and without a critical number of carers battle fatigue can ensue, resulting in urgent admissions. With much discussion about advance directives, we should not lose sight of the reality of changing circumstances and wishes. Good anticipatory care means not just providing for new physical symptoms, but also planning for any time when care at home becomes no longer possible.

34.17 How to manage a patient who is dying

Patient and family awareness

- Assess patient's and family's awareness of the situation
- Ensure family understands plan of care

Medical interventions

- Stop non-essential medications that do not contribute to symptom control
- Stop inappropriate investigations and interventions, including routine observations

Resuscitation

- Complete Do Not Attempt Cardiopulmonary Resuscitation (DNACPR) form
- Deactivate implantable defibrillator

Symptom control

- Ensure availability of parenteral medication for symptom relief

Support for family

- Make sure you have contact details for family, that you know when they want to be contacted and that they are aware of facilities available to them

Religious and spiritual needs

- Make sure any particular wishes are identified and followed

Ongoing assessment

- Family's awareness of condition
- Management of symptoms
- Need for parenteral hydration

Care after death

- Make sure family know what they have to do
- Notify other appropriate health professionals

Capacity and advance directives

The wishes of the patient are paramount in Western societies, whereas in other cultures the views of the family are equally important. If a patient is unable to express their view because of communication or cognitive impairment, that person is said to lack 'capacity'. In order to decide what the patient would have wished, as much information as possible should be gained about any previously expressed wishes, along with the views of relatives and other health professionals. An advance directive is a previously recorded, written document of a patient's wishes (p. 1307). It should carry the same weight in decision-making as a patient's expressed wishes at that time, but may

not be sufficiently specific to be used in a particular clinical situation. The legal framework for decision-making varies in different countries.

Euthanasia

In the UK and Europe, between 3% and 6% of dying patients will ask a doctor to end their life. Many of these requests are transient; some are associated with poor control of physical symptoms or a depressive illness. All expressions of a wish to die are an opportunity to help the patient discuss and address unresolved issues and problems. Reversible causes, such as pain or depression, should be treated. Sometimes, patients may choose to discontinue life-prolonging treatments, such as diuretics or anticoagulation, following discussion and the provision of adequate alternative symptom control. However, there remain a small number of patients who have a sustained, competent wish to end their lives, despite good control of physical symptoms. Euthanasia is now permitted or legal under certain circumstances in some countries but remains illegal in many others; public, ethical and legal debate over this issue is likely to continue and is often influenced by many complex non-palliative care issues. The European Association for Palliative Care does not see euthanasia or physician-assisted suicide as part of the role of palliative care physicians.

Laboratory reference ranges

Notes on the international system of units (SI units)

Système International (SI) units are a specific subset of the metre–kilogram–second system of units and were agreed on as the everyday currency for commercial and scientific work in 1960, following a series of international conferences organised by the International Bureau of Weights and Measures. SI units have been adopted widely in clinical laboratories but non-SI units are still used in many countries. For that reason, values in both units are given for common measurements throughout this textbook and commonly used non-SI units are shown in this chapter. The SI unit system is, however, recommended.

Examples of basic SI units

Length	metre (m)
Mass	kilogram (kg)
Amount of substance	mole (mol)
Energy	joule (J)
Pressure	pascal (Pa)
Volume	The basic SI unit of volume is the cubic metre (1000 litres). For convenience, however, the litre (L) is used as the unit of volume in laboratory work.

Examples of decimal multiples and submultiples of SI units

Factor	*Name*	*Prefix*
10^{6}	mega-	M
10^{3}	kilo-	k
10^{-1}	deci-	d
10^{-2}	centi-	c
10^{-3}	milli-	m
10^{-6}	micro-	μ
10^{-9}	nano-	n
10^{-12}	pico-	p
10^{-15}	femto-	f

Exceptions to the use of SI units

By convention, blood pressure is excluded from the SI unit system and is measured in mmHg (millimetres of mercury) rather than pascals.

Mass concentrations such as g/L and μg/L are used in preference to molar concentrations for all protein measurements and for substances that do not have a sufficiently well-defined composition.

Some enzymes and hormones are measured by 'bioassay', in which the activity in the sample is compared with the activity (rather than the mass) of a standard sample that is provided from a central source. For these assays, results are given in standardised 'units' (U/L), or 'international units' (IU/L), which depend on the activity in the standard sample and may not be readily converted to mass units.

Laboratory reference ranges in adults

Reference ranges are largely those used in the Departments of Clinical Biochemistry and Haematology, Lothian Health University Hospitals Division, Edinburgh, UK. Values are shown in both SI units and, where appropriate, non-SI units. Many reference ranges vary between laboratories, depending on the assay method used and on other factors; this is especially the case for enzyme assays. The origin of reference ranges and the interpretation of 'abnormal' results are discussed on page 3. No details are given here of the collection requirements, which may be critical to obtaining a meaningful result. Unless otherwise stated, reference ranges shown apply to adults; values in children may be different.

Many analytes can be measured in either serum (the supernatant of clotted blood) or plasma (the supernatant of anticoagulated blood). A specific requirement for one or the other may depend on a kit manufacturer's recommendations. In other instances, the distinction is critical. An example is fibrinogen, where plasma is required, since fibrinogen is largely absent from serum. In contrast, serum is required for electrophoresis to detect paraproteins because fibrinogen migrates as a discrete band in the zone of interest.

35.1 Urea and electrolytes in venous blood

	Reference range	
Analysis	SI units	Non-SI units
Sodium	135–145 mmol/L	135–145 mEq/L
Potassium*	3.6–5.0 mmol/L	3.6–5.0 mEq/L
Chloride	95–107 mmol/L	95–107 mEq/L
Urea	2.5–6.6 mmol/L	15–40 mg/dL
Creatinine		
Male	64–111 μmol/L	0.72–1.26 mg/dL
Female	50–98 μmol/L	0.57–1.11 mg/dL

*Serum values are, on average, 0.3 mmol/L higher than plasma values.

35.2 Analytes in arterial blood

	Reference range	
Analysis	SI units	Non-SI units
Bicarbonate	21–29 mmol/L	21–29 mEq/L
Hydrogen ion	37–45 nmol/L	pH 7.35–7.43
$Pa\mathrm{CO_2}$	4.5–6.0 kPa	34–45 mmHg
$Pa\mathrm{O_2}$	12–15 kPa	90–113 mmHg
Oxygen saturation	> 97%	

35.3 Hormones in venous blood

Hormone	Reference range: SI units	Reference range: Non-SI units
Adrenocorticotrophic hormone (ACTH) (plasma)	1.5–13.9 pmol/L (0700–1000 hrs)	63 ng/L
Aldosterone		
Supine (at least 30 mins)	30–440 pmol/L	1.09–15.9 ng/dL
Erect (at least 1 hr)	110–860 pmol/L	3.97–31.0 ng/dL
Cortisol	Dynamic tests are required – see Box 18.53, p. 680	
Follicle-stimulating hormone (FSH)		
Male	1.0–10.0 IU/L	–
Female	3.0–10.0 IU/L (early follicular)	–
	>30 IU/L (post-menopausal)	–
Gastrin (plasma, fasting)	<40 pmol/L	<83 pg/mL
Growth hormone (GH)	Dynamic tests are usually required – see Box 18.55, p. 682	
	<0.5 μg/L excludes acromegaly (if insulin-like growth factor 1 (IGF-1) in reference range)	<2 mIU/L
	>6 μg/L excludes GH deficiency	>18 mIU/L
Insulin	Highly variable and interpretable only in relation to plasma glucose and body habitus	
Luteinising hormone (LH)		
Male	1.0–9.0 IU/L	–
Female	2.0–9.0 IU/L (early follicular)	–
	>20 IU/L (post-menopausal)	–
17β-Oestradiol		
Male	<160 pmol/L	<43 pg/mL
Female: early follicular	75–140 pmol/L	20–38 pg/mL
post-menopausal	<150 pmol/L	<41 pg/mL
Parathyroid hormone (PTH)	1.6–6.9 pmol/L	16–69 pg/mL
Progesterone (in luteal phase in women)		
Consistent with ovulation	>30 nmol/L	>9.3 ng/mL
Probable ovulatory cycle	15–30 nmol/L	4.7–9.3 ng/mL
Anovulatory cycle	<10 nmol/L	<3 ng/mL
Prolactin (PRL)	60–500 mIU/L	2.8–23.5 ng/mL
Renin concentration		
Supine (at least 30 mins)	5–40 mIU/L	–
Sitting (at least 15 mins)	5–45 mIU/L	–
Erect (at least 1 hr)	16–63 mIU/L	–
Testosterone		
Male	10–38 nmol/L	290–1090 ng/dL
Female	0.3–1.9 nmol/L	10–90 ng/dL
Thyroid-stimulating hormone (TSH)	0.2–4.5 mIU/L	–
Thyroxine (free), (free T_4)	9–21 pmol/L	0.7–1.63 ng/dL
Triiodothyronine (free), (free T_3)	2.6–6.2 pmol/L	0.16–0.4 ng/dL

Notes

1. A number of hormones are unstable and collection details are critical to obtaining a meaningful result. Refer to local laboratory handbook.
2. Values in the table are only a guideline; hormone levels can often be meaningfully understood only in relation to factors such as gender, age, time of day, pubertal status, stage of the menstrual cycle, pregnancy and menopausal status.
3. Reference ranges are usually dependent on the method used for analysis and frequently differ between laboratories. Non-SI units also differ; those shown here are amongst those most widely used. Readers are encouraged to consult their local laboratory for non-SI units for individual analytes and their respective reference ranges.

35.4 Other common analytes in venous blood

Analyte	Reference range: SI units	Reference range: Non-SI units
α_1-antitrypsin	1.1–2.1 g/L	110–210 mg/dL
Alanine aminotransferase (ALT)	10–50 U/L	–
Albumin	35–50 g/L	3.5–5.0 g/dL
Alkaline phosphatase (ALP)	40–125 U/L	–
Amylase	< 100 U/L	–
Aspartate aminotransferase (AST)	10–45 U/L	–
Bile acids (fasting)	< 14 µmol/L	–
Bilirubin (total)	3–16 µmol/L	0.18–0.94 mg/dL
Calcium (total)	2.1–2.6 mmol/L	4.2–5.2 mEq/L or 8.5–10.5 mg/dL
Carboxyhaemoglobin	0.1–3.0% Levels of up to 8% may be found in heavy smokers	–
Caeruloplasmin	0.16–0.47 g/L	16–47 mg/dL
Cholesterol (total)	Ideal level varies according to cardiovascular risk (see cardiovascular risk chart, p. 511)	
HDL-cholesterol	Ideal level varies according to cardiovascular risk, so reference ranges can be misleading. According to the National Cholesterol Education Programme Adult Treatment Panel III (ATPIII), a low HDL-cholesterol is < 1.0 mmol/L (< 40 mg/dL)	
Complement		
C3	0.81–1.57 g/L	–
C4	0.13–1.39 g/L	–
Total haemolytic complement	0.086–0.410 g/L	–
Copper	10–22 µmol/L	64–140 µg/dL
C-reactive protein (CRP)	< 5 mg/L Highly sensitive CRP assays also exist that measure lower values and may be useful in estimating cardiovascular risk	
Creatine kinase (CK; total)		
Male	55–170 U/L	–
Female	30–135 U/L	–
Creatine kinase MB isoenzyme	< 6% of total CK	–
Ethanol	Not normally detectable	
Marked intoxication	65–87 mmol/L	300–400 mg/dL
Stupor	87–109 mmol/L	400–500 mg/dL
Coma	> 109 mmol/L	> 500 mg/dL

Analyte	Reference range: SI units	Reference range: Non-SI units
γ-glutamyl transferase (GGT)	Male 10–55 U/L Female 5–35 U/L	–
Glucose (fasting)	3.6–5.8 mmol/L	65–104 mg/dL
	See page 722 for definitions of impaired glucose tolerance and diabetes mellitus, and page 738 for definition of hypoglycaemia	
Glycated haemoglobin (HbA_{1c})	4.0–6.0% 20–42 mmol/mol Hb See page 722 for diagnosis of diabetes mellitus	–
Immunoglobulins (Ig)		
IgA	0.8–4.5 g/L	–
IgE	0–250 kU/L	–
IgG	6.0–15.0 g/L	–
IgM	0.35–2.90 g/L	–
Lactate	0.6–2.4 mmol/L	5.4–21.6 mg/dL
Lactate dehydrogenase (LDH; total)	125–220 U/L	–
Lead	< 0.5 µmol/L	< 10 µg/dL
Magnesium	0.75–1.0 mmol/L	1.5–2.0 mEq/L or 1.82–2.43 mg/dL
Osmolality	280–296 mOsmol/kg	–
Osmolarity	280–296 mOsmol/L	–
Phosphate (fasting)	0.8–1.4 mmol/L	2.48–4.34 mg/dL
Protein (total)	60–80 g/L	6–8 g/dL
Triglycerides (fasting)	0.6–1.7 mmol/L	53–150 mg/dL
Troponins	Values consistent with myocardial infarction are crucially dependent on which troponin is measured (I or T) and on the method employed. Interpret in context of clinical presentation. See page 450	
Tryptase	0–135 mg/L	–
Urate		
Male	0.12–0.42 mmol/L	2.0–7.0 mg/dL
Female	0.12–0.36 mmol/L	2.0–6.0 mg/dL
Vitamin D (25(OH)D)		
Normal	> 50 nmol/L	> 20 ng/mL
Insufficiency	25–50 nmol/L	10–20 ng/ml
Deficiency	< 25 nmol/L	< 10 ng/mL
Zinc	10–18 µmol/L	65–118 µg/dL

35.5 Common analytes in urine

	Reference range	
Analyte	**SI units**	**Non-SI units**
Albumin	Definitions of microalbuminuria are given on page 394 Proteinuria is defined below	
Calcium (normal diet)	Up to 7.5 mmol/24 hrs	Up to 15 mEq/24 hrs or 300 mg/24 hrs
Copper	< 0.6 µmol/24 hrs	< 38 µg/24 hrs
Cortisol	20–180 nmol/24 hrs	7.2–65 µg/24 hrs
Creatinine		
Male	6.3–23 mmol/24 hrs	712–2600 mg/24 hrs
Female	4.1–15 mmol/24 hrs	463–1695 mg/24 hrs
5-Hydroxyindole-3-acetic acid (5-HIAA)	10–42 µmol/24 hrs	1.9–8.1 mg/24 hrs
Metadrenalines		
Normetadrenaline	0.4–3.4 µmol/24 hrs	73–620 µg/24 hrs
Metadrenaline	0.3–1.7 µmol/24 hrs	59–335 µg/24 hrs
Oxalate	0.04–0.49 mmol/24 hrs	3.6–44 mg/24 hrs
Phosphate	15–50 mmol/24 hrs	465–1548 mg/24 hrs
Potassium*	25–100 mmol/24 hrs	25–100 mEq/24 hrs
Protein	< 0.3 g/L	< 0.03 g/dL
Sodium*	100–200 mmol/24 hrs	100–200 mEq/24 hrs
Urate	1.2–3.0 mmol/24 hrs	202–504 mg/24 hrs
Urea	170–600 mmol/24 hrs	10.2–36.0 g/24 hrs
Zinc	3–21 µmol/24 hrs	195–1365 µg/24 hrs

*The urinary output of electrolytes such as sodium and potassium is normally a reflection of dietary intake. This can vary widely. The values quoted are appropriate to a 'Western' diet.

35.6 Analytes in cerebrospinal fluid

	Reference range	
Analysis	**SI units**	**Non–SI units**
Cells	$<5\times10^6$ cells/L (all mononuclear)	<5 cells/mm^3
Glucose[1]	2.3–4.5 mmol/L	41–81 mg/dL
IgG index[2]	< 0.65	–
Total protein	0.14–0.45 g/L	0.014–0.045 g/dL

[1]Interpret in relation to plasma glucose. Values in CSF are typically approximately two-thirds of plasma levels. [2]A crude index of increase in IgG attributable to intrathecal synthesis.

35.7 Analytes in faeces

	Reference range	
Analyte	**SI units**	**Non-SI units**
Calprotectin	< 50 µg/g	–
Elastase	> 200 µg/g	–

35.8 Haematological values

	Reference range	
Analysis	**SI units**	**Non-SI units**
Bleeding time (Ivy)	< 8 mins	–
Blood volume		
Male	65–85 mL/kg	–
Female	60–80 mL/kg	–
Coagulation screen		
Prothrombin time (PT)	10.5–13.5 secs	–
Activated partial thromboplastin time (APTT)	26–36 secs	–
D-dimers		
Interpret in relation to clinical presentation	< 200 ng/mL	–
Erythrocyte sedimentation rate (ESR)	Higher values in older patients are not necessarily abnormal	
Adult male	0–10 mm/hr	–
Adult female	3–15 mm/hr	–
Ferritin		
Male (and post-menopausal female)	20–300 µg/L	20–300 ng/mL
Female (pre-menopausal)	15–200 µg/L	15–200 ng/mL
Fibrinogen	1.5–4.0 g/L	0.15–0.4 g/dL
Folate		
Serum	2.8–20 µg/L	2.8–20 ng/mL
Red cell	120–500 µg/L	120–500 ng/mL
Haemoglobin		
Male	130–180 g/L	13–18 g/dL
Female	115–165 g/L	11.5–16.5 g/dL
Haptoglobin	0.4–2.4 g/L	0.04–0.24 g/dL
Iron		
Male	14–32 µmol/L	78–178 µg/dL
Female	10–28 µmol/L	56–157 µg/dL
Leucocytes (adults)	$4.0–11.0 \times 10^9/L$	$4.0–11.0 \times 10^3/mm^3$
Differential white cell count		
Neutrophil granulocytes	$2.0–7.5 \times 10^9/L$	$2.0–7.5 \times 10^3/mm^3$
Lymphocytes	$1.5–4.0 \times 10^9/L$	$1.5–4.0 \times 10^3/mm^3$
Monocytes	$0.2–0.8 \times 10^9/L$	$0.2–0.8 \times 10^3/mm^3$
Eosinophil granulocytes	$0.04–0.4 \times 10^9/L$	$0.04–0.4 \times 10^3/mm^3$
Basophil granulocytes	$0.01–0.1 \times 10^9/L$	$0.01–0.1 \times 10^3/mm^3$
Mean cell haemoglobin (MCH)	27–32 pg	–
Mean cell volume (MCV)	78–98 fl	–
Packed cell volume (PCV) or haematocrit		
Male	0.40–0.54	–
Female	0.37–0.47	–
Platelets	$150–350 \times 10^9/L$	$150–350 \times 10^3/mm^3$
Red cell count		
Male	$4.5–6.5 \times 10^{12}/L$	$4.5–6.5 \times 10^6/mm^3$
Female	$3.8–5.8 \times 10^{12}/L$	$3.8–5.8 \times 10^6/mm^3$
Red cell lifespan		
Mean	120 days	–
Half-life (^{51}Cr)	25–35 days	–
Reticulocytes (adults)	$25–85 \times 10^9/L$	$25–85 \times 10^3/mm^3$
Transferrin	2.0–4.0 g/L	0.2–0.4 g/dL
Transferrin saturation		
Male	25–50%	–
Female	14–50%	–
Vitamin B_{12}		
Normal	> 210 ng/L	–
Intermediate	180–200 ng/L	–
Low	< 180 ng/L	–

Laboratory reference ranges in childhood and adolescence

The levels of many analytes in blood vary due to the physiological changes that occur during growth and adolescence. Hospital laboratories may provide reference ranges that are age-adjusted or based on pubertal stage but this is not always the case. It is therefore important for the doctor requesting these tests to understand the impact of age and puberty on interpretation of the results. For example, a creatinine of 70 μmol/L (0.79 mg/dL) is perfectly normal for the majority of adults but may indicate significant renal impairment in a child. Reference ranges for hormone results are described according to the Tanner stages of puberty (p. 1290).

35.9 Analytes that may be significantly affected by growth and puberty*

Analyte	Age/Pubertal stage	Gender	Reference range
Alkaline phosphatase (ALP)	<1 year	M, F	80–580 U/L
	1–16 years	M, F	100–400 U/L
	16–20 years	M	50–250 U/L
		F	40–200 U/L
Creatinine	<1 year	M, F	12–39 μmol/L (0.14–0.44 mg/dL)
	1–4 years	M, F	13–42 μmol/L (0.15–0.48 mg/dL)
	4–12 years	M, F	20–57 μmol/L (0.23–0.64 mg/dL)
	12–15 years	M, F	31–67 μmol/L (0.35–0.76 mg/dL)
	15–18 years	M	39–92 μmol/L (0.44–1.04 mg/dL)
		F	34–72 μmol/L (0.38–0.81 mg/dL)
Follicle-stimulating hormone (FSH)	Prepubertal	M	<3.0 IU/L (<0.6 μg/L)
		F	<3.2 IU/L (<0.64 μg/L)
	Pubertal stage 2	M	<6.6 IU/L (<1.32 μg/L)
		F	<4.1 IU/L (<0.82 μg/L)
	Pubertal stage 3	M	0.7–5.0 IU/L (0.14–1 μg/L)
	Pubertal stages 4–5	M	1.5–6.0 IU/L (0.3–1.2 μg/L)
	Pubertal stages 3–5	F	2.5–13.5 IU/L (0.5–2.7 μg/L)
Insulin-like growth factor 1	<7 years	M	15–349 μg/L
		F	17–272 μg/L
	8–16 years	M	67–510 μg/L
		F	59–502 μg/L

Analyte	Age/Pubertal stage	Gender	Reference range
Luteinising hormone (LH)	Prepubertal	M	<1.0 IU/L (<0.1 μg/L)
	Pubertal stage 2	M	<3.0 IU/L (<0.3 μg/L)
	Prepubertal and pubertal stage 2	F	<1.0 IU/L (<0.1 μg/L)
	Pubertal stage 3	M	1.0–4.0 IU/L (0.1–0.4 μg/L)
	Pubertal stages 4–5	M	1.0–5.0 IU/L (0.1–0.6 μg/L)
	Pubertal stages 3–5	F	1.0–8.0 IU/L (0.1–0.9 μg/L)
17β-Oestradiol	Prepubertal and pubertal stages 2–3	M	<75 pmol/L (<20 pg/mL)
	Prepubertal and pubertal stage 2	F	<100 pmol/L (<27 pg/mL)
	Pubertal stages 4–5	M	<130 pmol/L (<35 pg/mL)
	Pubertal stages 3–5	F	<150 pmol/L (<41 pg/mL)
Testosterone	Prepubertal	M	<0.5 nmol/L (<10 ng/dL)
		F	<0.6 nmol/L (<20 ng/dL)
	Pubertal stage 2	M	<10.6 nmol/L (<310 ng/dL)
		F	<1.4 nmol/L (<40 ng/dL)
	Pubertal stage 3	M	0.4–30 nmol/L (10–870 ng/dL)
	Pubertal stage 4	M	5.6–30 nmol/L (160–870 ng/dL)
	Pubertal stage 5	M	10–30 nmol/L (290–870 ng/dL)
	Pubertal stages 3–5	F	0.4–1.9 nmol/L (10–50 ng/dL)

*Non-SI equivalents are given in brackets where appropriate.

Laboratory reference ranges in pregnancy

The levels of many analytes in blood vary during pregnancy, when many hormonal and metabolic changes occur. The standard adult reference ranges may therefore not be appropriate and it is important for the clinician reviewing the results to be aware of this to enable appropriate interpretation and patient management.

35.10 Analytes that may be significantly affected by pregnancy*

Analyte	Reference range		
	First trimester	Second trimester	Third trimester
Alkaline phosphatase (ALP)	17–88 U/L	25–126 U/L	38–229 U/L
Packed cell volume (PCV) or haematocrit	0.31–0.41	0.30–0.39	0.28–0.40
Haemoglobin	116–139 g/L	97–148 g/L	95–150 g/L
Human chorionic gonadotrophin	4 weeks: 16–156 IU/L 4–9 weeks: 101–233 000 IU/L 9–13 weeks: 20 900–291 000 IU/L	4270–103 000 IU/L	2700–78 300 IU/L
17β-Oestradiol	690–9166 pmol/L (188–2497 pg/mL)	4691–26 401 pmol/L (1278–7192 pg/mL)	12 701–22 528 pmol/L (3460–6137 pg/mL)
Progesterone	25–153 nmol/L (8–48 ng/mL)	Not available	314–1088 nmol/L (99–342 ng/mL)
Prolactin	765–4532 mIU/L (36–213 ng/mL)	2340–7021 mIU/L (110–330 ng/mL)	2914–7914 mIU/L (137–372 ng/mL)
Thyroid-stimulating hormone (TSH)	0.60–3.40 mIU/L	0.37–3.60 mIU/L	0.38–4.04 mIU/L
Thyroxine (free), (free T_4)	10–18 pmol/L 0.77–1.40 ng/dL	9–16 pmol/L 0.70–1.24 ng/dL	8–14 pmol/L 0.62–1.09 ng/dL

*Non-SI equivalents are given in brackets where appropriate.
